Preface

Microfluidics and nanofluidics are among the most rapidly growing fields of scientific research and technology development. Over the past 15 years, the research activities in these fields have been increasing exponentially as evidenced by the number of published papers in the literature. Microfluidics and nanofluidics not only bring exciting opportunities to study the new phenomena unique to these small scales, but also enable the development of many new and high-impact technologies from handheld biomedical laboratory (Lab-on-a-Chip) to detection and manipulation of single molecules. While these exciting and inter-disciplinary research fields attract more and more researchers, one major challenge is the lack of a single reference resource providing up-to-date reviews and overviews of various directions in the field of microfluidics and nanofluidics. This is the motivation behind the development of the Encyclopedia of Microfluidics and Nanofluidics. As a comprehensive resource, no single review paper or several books focused on specific topics can replace the role of an Encyclopedia.

This is the first Encyclopedia of Microfluidics and Nanofluidics for the scientific community. It covers the fundamentals, latest developments and cutting-edge experimental techniques, including electrical double-layers; optofluidics; DNA lab-on-a-chip; nanosensors; and much more. The high technical quality of the Encyclopedia has been ensured by our International Editorial Board consisting of leading scientists in these fields, and the over 250 experts in microfluidics and nanofluidics. The carefully selected entries deliver relevant and comprehensive information, and are fully illustrated with thousands of diagrams, photos, line art, many in full color.

The Encyclopedia provides basic information on all fundamental and applied aspects of microfluidics and nanofluidics by covering two decades of research. It is the only scientific work of its kind in the field of microfluidics and nanofluidics bringing together core knowledge and the very latest advances. Written for a wide audience with different levels of experience, it provides valuable information to graduate students and scientists who may be new to these fields of microfluidics and nanofluidics while providing up-to-date information to active scientists and experts in the field. This outstanding encyclopedia is an indispensable source for research professionals, technology investors and developers seeking the most up-to-date information on microfluidics and nanofluidics among a wide range of disciplines from science to engineering to medicine.

It takes two years of hard work of many people for this Encyclopedia to come to live. I would like to give my sincere thanks the Editorial Board members and many specially invited experts for helping me to review so many manuscripts to ensure the highest quality. I would like to thank and congratulate all contributing authors. This is your Encyclopedia and you made the great contribution to these fields. Finally, my heartfelt appreciation goes to the colleagues at Springer, Steven Elliot, Oona Schmid, Sylvia Blago, and Simone Giesler-Güllich; without their persistent efforts and hard work everyday, it is not possible to complete this Encyclopedia.

AC Dielectrophoresis Lab-on-Chip Devices

Stuart Williams
Mechanical Engineering, Purdue University,
West Lafayette, IN, USA
swilliams@purdue.edu

Synonyms

Dielectrophoretic force; DEP

Definition

Dielectrophoresis is the translational motion of a neutral particle by induced polarization in a nonuniform electric field. The magnitude and direction of the induced dielectrophoretic force are dependent on the characteristics of the applied electric field as well as the dielectric properties of the surrounding medium and of the particle itself.

Overview

Herbert Pohl was one of the first to study particle electrokinetics in the 1950s, particularly the manipulation of polarizable particles with nonuniform fields. He coined the term ►dielectrophoresis, and details of his investigations can be found in his classic text [1]. The advancement of microfabrication techniques and the demand of Lab-on-a-Chip technologies have led to the development of dielectrophoresis techniques for particulate, biological and pharmaceutical applications. Dielectrophoresis was initially used to manipulate particles and cells in the micrometer range (1 μm to 1 mm). Since the early 1990s, nanotechnology has incorporated dielectrophoresis for the manipulation of viruses, DNA, protein molecules and other nanoparticles (diameters of 1 nm to 1 μm). This article provides a brief background of dielectrophoresis followed by its basic manipulation of particles using translation, rotation (electrorotation), orientation (electro-orientation) and traveling wave dielectrophoresis. This article approaches design considerations and modeling techniques for the micrometer length scale; it does not specifically address all dielectrophoresis complexities at the nanometer scale. The majority of this article deals with popular applications of dielectrophoresis including novel techniques to induce these forces; by no means does it cover all of the existing applications. For a more extensive explanation of dielectrophoresis the reader is referred to texts by Jones [2], Morgan and Green [3], and Hughes [4], the latter of which addresses techniques for nanometer-sized particles.

For most dielectrophoresis cases, the applied electric field is an alternating current (AC) signal, created with a common frequency generator. In typical experimentation, frequencies are generally greater than 100 kHz with magnitudes below 20 V peak-to-peak. The shape of the signal is typically sinusoidal, but pulse signals have also been used in dielectrophoresis applications. This signal is applied to electrode geometries, the micrometer-sized features of which can be created using simple microfabrication techniques. Electrodes are typically fabricated on the surface of silicon wafers or glass substrates, including microscope slides. For most biological applications it is recommended that the species of interest be visually observed by optical means, which leaves glass or other transparent materials as favorable substrates. In the case where the electrodes themselves hinder visual observation they are patterned out of indium tin oxide (ITO), a transparent conducting material. Microfluidic channels and other fabricated features can easily be incorporated into the system. It is pos-

sible to manipulate, separate or group targeted cells with novel electrode geometry design and fabrication. Due to its simplicity in fabrication and its susceptibility to visual observation and analysis, dielectrophoresis is a favorable technique for biological experimentation.

Dielectrophoretic forces, though, can be induced by means other than an applied electric signal through electrodes. Optical tools can be implemented to modify an applied electric field, making these methods more susceptible for dynamic as opposed to static manipulation of electric fields with surface electrodes. Dielectrophoresis applications are not limited to particulate manipulation either. With properly configured surface-electrode geometry, it is possible to induce fluid motion and create nanoliter-sized droplets. Additionally, dielectrophoretic forces can be utilized to manipulate particles to build micro- and nano-structures such as wires.

Basic Methodology

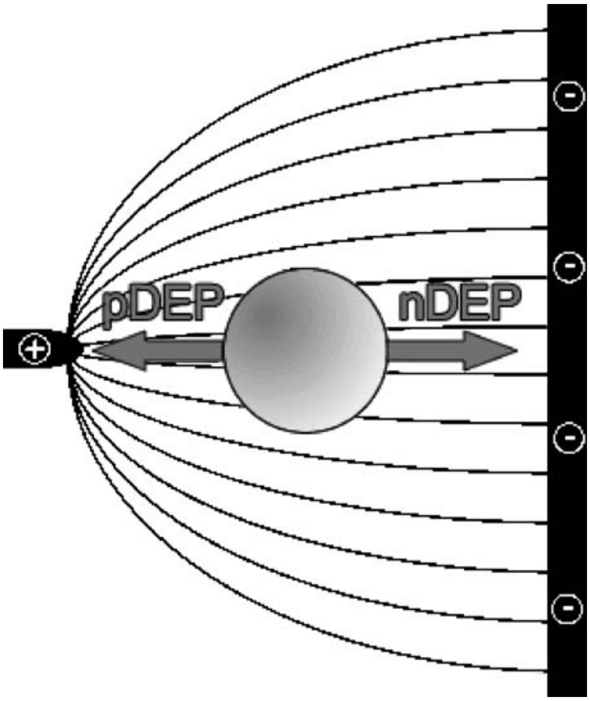
Before we can incorporate dielectrophoresis into Lab-on-a-Chip systems it is important to have a grasp of the theory behind dielectrophoresis. Basic theory, common experimental parameters, typical dielectrophoretic manipulation techniques, particle modeling considerations and dielectrophoresis-induced effects are discussed below.

Dielectrophoresis

Dielectrophoresis is the translational motion of a particle by induced polarization in a nonuniform electric field. When conductive, uncharged particles are exposed to an electric field they will polarize, inducing a dipole on the particle. The magnitude and charge orientation of the induced dipole are dependent on the permittivities and conductivities of the medium and of the particle. If the electric field is uniform the induced charges on both sides of the particle are equal, creating no net force on the particle. However, if the electric field is nonuniform (Fig. 1) there will be a net force greater than zero. The general expression for the dielectrophoretic force of a homogeneous sphere is expressed as

$$F_{\mathrm{DEP}} = 2\pi \varepsilon_0 \varepsilon_{\mathrm{m}} r^3 \mathrm{Re}\big[K(\omega)\big] \nabla E^2 \quad (1)$$

where ε_0 is the permittivity of free space, ε_{m} is the relative permittivity of the medium, r is the radius of the particle, $\mathrm{Re}\,[K(\omega)]$ is the real part of the Clausius–Mossotti factor and ∇E^2 is the gradient of the magnitude of the electric field squared. This equation assumes that the there is no applied phase gradients to the electric field. The Clausius–



AC Dielectrophoresis Lab-on-Chip Devices, Figure 1 A polarizable particle in a nonuniform electric field

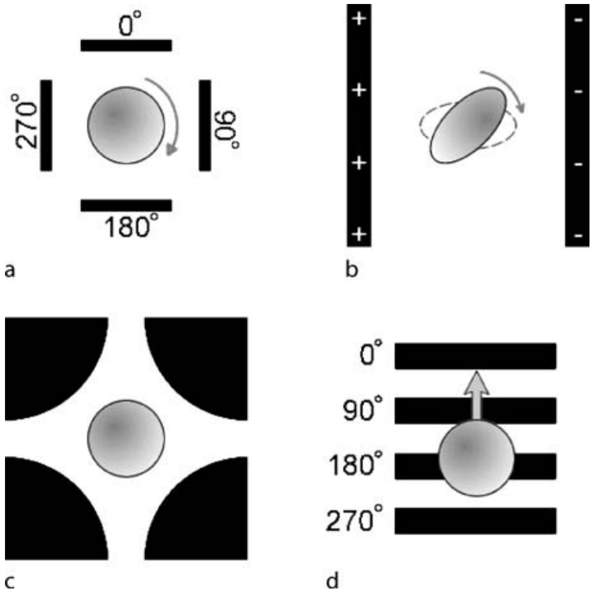
Mossotti factor is defined as

$$K(\omega) = \frac{\varepsilon_{\mathrm{p}}^* - \varepsilon_{\mathrm{m}}^*}{\varepsilon_{\mathrm{p}}^* + 2\varepsilon_{\mathrm{m}}^*} \quad (2)$$

where subscripts p and m are assigned to the particle and medium, respectively, and ε^* is called the complex permittivity. The complex permittivity is

$$\varepsilon^* = \varepsilon_0 \varepsilon_{\mathrm{r}} - j\frac{\sigma}{\omega} \quad (3)$$

where j is $\sqrt{-1}$, ε_{r} is the material's relative permittivity, σ is the material's conductivity and $\omega = 2\pi f$ (where f is the applied frequency). The Clausius–Mossotti factor is a function of frequency and, depending on the dielectric properties of the medium and particle, this factor can be either positive or negative with a possible range of $+1.0$ to -0.5. If $\mathrm{Re}\,[K(\omega)]$ is negative, the particle experiences negative dielectrophoresis (nDEP) and is repelled from gradients in the nonuniform electric field (Fig. 1). For a positive value of $\mathrm{Re}\,[K(\omega)]$, the particle is attracted to high electric field gradients with positive dielectrophoresis (pDEP). With dielectrophoresis it is possible to manipulate particles using a variety of techniques and applications.



AC Dielectrophoresis Lab-on-Chip Devices, Figure 2 Dielectrophoretic manipulation techniques: (**a**) electrorotation, (**b**) electro-orientation, (**c**) particle trapping and (**d**) traveling wave dielectrophoresis

Particle Manipulation

The majority of dielectrophoretic manipulation of particles includes translating (dielectrophoresis), rotating (electrorotation), orienting (electro-orientation), trapping and using traveling wave dielectrophoresis. Figure 2 provides an illustrative representation of each technique. In electrorotation a torque is applied to a particle that is subjected to a rotating electric field (Fig. 2a). The induced dipole takes a finite amount of time to polarize in a neutral dielectric particle, which attempts to orient itself with the direction of the electric field. This dipole, though, lags behind the applied rotating electric field. The reorientation of the dipole with the electric field induces a torque on the particle, rotating it. Next, electro-orientation involves the alignment of a nonspherical particle in a uniform electric field (Fig. 2b). When an ellipsoidal particle polarizes, the dipole moment will align the particle with its longest nondispersed dipole parallel to the field lines. Its orientation is a function of the electric field frequency and the dielectric properties of the medium and particle.

Dielectrophoretic forces, though, can be used to not only rotate a particle, but trap it as well. There are two types of particle trapping, those that utilize pDEP or nDEP forces. For example, four electrodes can be positioned in a quadrupole arrangement and, when the appropriate electric field is applied, a particle or particles are trapped in the electric field null at its center (Fig. 2c). Particle trapping will be revisited later in this article. Traveling wave dielectrophoresis is the linear application of electrorotation (Fig. 2d). An AC electric wave is produced by applying an electric field that travels linearly along a series of electrodes. The particle will translate in the same or opposite direction as the traveling wave depending on the properties of the applied signal frequency and the dielectrics of the particle and medium.

Modeling and Dielectrophoretic Effects

When incorporating dielectrophoresis in Lab-on-a-Chip systems, additional modeling parameters and electrophysiological interactions need to be considered. Obviously, biological cells and some particulates are not all completely spherical nor are they homogeneous. Typically cells are modeled as multi-shelled particles with each shell having its own respective conductivity and permittivity. Additionally, nonspherical particles are modeled as ellipsoids. For each of these situations the Clausius–Mossotti factor is extended to include these geometrical and layered effects by applying polarization factors. These modifications are described in detail elsewhere [2–4]. The dielectric properties of some particles and cells are unknown; however, dielectric techniques can be applied to determine these characteristics. For example, when an induced particle changes from pDEP to nDEP, or vice versa, this is called its crossover frequency. Similarly, a particle in electrorotation that changes in rotational velocity or direction under different conditions will give insight into its dielectric properties. Many of the previously mentioned dielectrophoretic manipulation techniques can be applied to determine particle dielectric characteristics. By varying both the medium conductivity and the applied frequency, the changes in a particle's induced dielectrophoretic behavior can be visually observed.

The electric field can induce higher order poles, called multipoles, instead of the assumed dipole. This occurs when the electric field is highly nonuniform; for example, when the electrode geometry is on the same length scale as the particle or when a particle is in a field null. For most applications, though, the dipole assumption accurately depicts the behavior of the particle. However, multipoles can effect the particle's interaction with the electric field and will react differently from an induced dipole. The electric field can also induce some negative physiological effects to the cell by inducing cell heating and influencing transmembrane voltage. Transmembrane voltage can affect ion movement and damage voltage-sensitive proteins. The electric field itself can heat the surrounding medium in what is called *Joule heating*. Joule heating creates temperature gradients that can directly heat the cell or create localized convection currents. By working at the

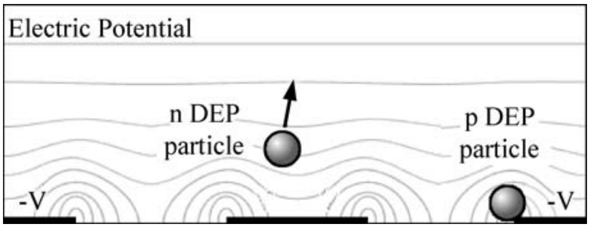
micrometer length scale some of these negative effects are minimized; however, they may still influence the system and cannot be ignored.

Key Research Findings

This dielectrophoresis background only serves as a brief overview; these technologies need to be explored in more detail before incorporating them into a Lab-on-a-Chip system. Lab-on-a-Chip systems integrate techniques of small fluid and sample handling with detection or process capabilities. Dielectrophoresis can be incorporated into these systems to manipulate, separate or trap cells as well as control small amounts of fluid. This technology can be used to trap cells for additional analysis, separate cell types based on dielectric properties, dispense picoliter droplets or used for similar manipulative applications. However, dielectrophoresis itself cannot be used as a sensor, except to determine dielectric properties of cells or detect such changes in response to stimuli. The integration of sensory technologies with dielectrophoresis is not discussed. Instead, specific novel dielectrophoresis applications are addressed in detail.

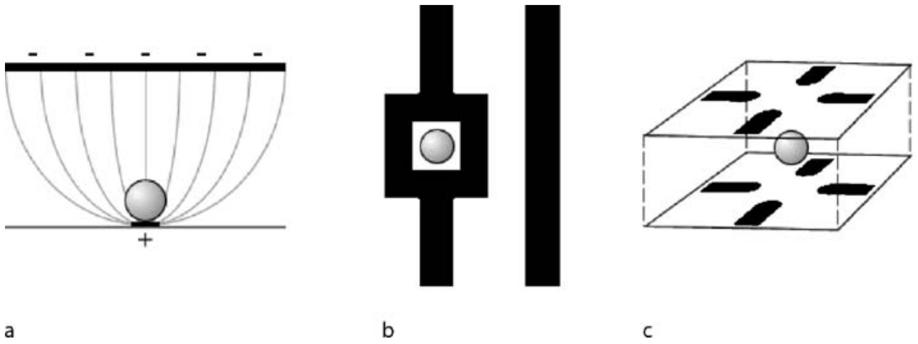
Trapping Particles

One of the more popular dielectrophoretic manipulation techniques involves the trapping of individual or groups of cells. Dielectrophoresis can be thought of as *electrical tweezers* that will grab onto and position cells. Trapping can be accomplished by means of novel electrode geometries that utilize pDEP or nDEP forces to selectively capture a particle or cell. Some electrode geometries induce both types of forces simultaneously; an example of such an arrangement involves interdigitated electrodes (Fig. 3). Planar electrode fingers, whose width and gap separation are a few times larger than the diameter of the particles of interest, have alternating applied voltages (either 180° out of phase or alternating $+V/\text{ground}$). This geometry creates a strong pDEP force at the edges of the electrodes and a field null above the center of each electrode strip. This arrangement provides both trapping capabilities and the ability to determine unknown particle dielectric properties from visual observation. For example, at a particular frequency and medium conductivity a particle will experience a pDEP force. However, for a different applied frequency and/or a change in medium conductivity the same particle could undergo nDEP. The strength of the dielectrophoretic trapping force can be estimated with the hydrodynamic drag necessary to release the particle. Similarly, interdigitated electrodes can be used to separate two cells that experience opposite pDEP/nDEP forces due to their different dielectric characteristics. Interdigitated electrodes are one of the simpler electrode geometries, compared to other trapping arrangements.



AC Dielectrophoresis Lab-on-Chip Devices, Figure 3 Dielectrophoresis of particles with interdigitated electrodes (side view). Particles experiencing pDEP are attracted to the edges of the electrode while nDEP forces repel the particle to the middle of the electrode

Other electrode geometries have been designed to capture individual cells using either pDEP or nDEP forces. A number of these geometries have been explored by Voldman and his research group [5] and will be discussed here. For pDEP, geometries are created that generate extreme electric field gradients in the trapping region. A geometry that creates such a field gradient is illustrated in Fig. 4a. An electrode smaller than the diameter of the particle has the signal applied through it to a larger, receiving electrode. The generated electric field would be similar to that illustrated in Fig. 1, with a high gradient in proximity to the smaller electrode. Electric field nulls have also been generated with electrode geometries for nDEP traps. Recall the quadrupole geometry in Fig. 2c. When an appropriate electric field is applied a field null is created in the center of the trap. The trapped particle is repelled from the surrounding regions of field gradients. Another nDEP trap is illustrated in Fig. 4b. The electric field is applied from the trapping electrode to the receiving electrode strip. A particle is trapped within the generated null inside the "boxed" electrode geometry. These previous geometries will trap a particle near the surface of the substrate. Electrodes, though, can be arranged three-dimensionally to create traps that capture particles and cells in suspension. One example is a nDEP trap using two stacked quadrupole geometries, resulting in an octopole trap (Fig. 4c). The electric field null is generated in the midplane between these two electrode substrates and thus a particle experiencing nDEP is captured in suspension. These are just a few examples of established trapping geometries, as others could be designed to suit a particular trapping application.
There are numerous trap geometries that exist for both pDEP and nDEP. These electrode arrangements and cell concentration can be varied to trap both single cells and groups of cells alike. However, there are dielectrophoretic interactions that cannot be ignored for trapping applications. Multipoles may need to be considered for single-

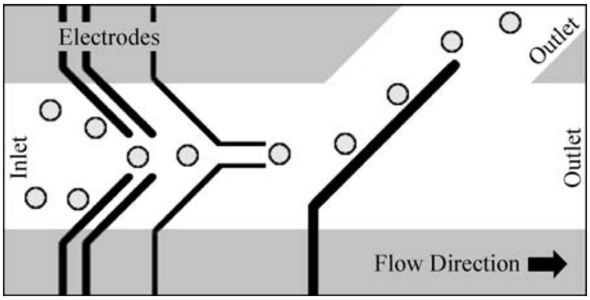


AC Dielectrophoresis Lab-on-Chip Devices, Figure 4 Various electrode geometries for dielectrophoretic traps: (**a**) pDEN trap (side view), (**b**) nDEP planar trap (top view), and (**c**) nDEP octopolar trap

particle traps since the generated field will have inhomogeneities on the scale of the particle itself. Also, particle–particle dielectrophoretic interactions will influence the capabilities of multi-particulate traps. Dielectrophoresis, therefore, needs to be accurately modeled and thoroughly investigated prior to use in a specific application.

Electrode-Based Systems

Microsystems have incorporated dielectrophoretic forces into microchannels to manipulate particles and cells with various electrode geometries. Electrodes can be used to align target cells or separate particulate cells from the rest of the sample, an example of which is illustrated in Fig. 5. These systems use a three-dimensional arrangement of electrodes, with mirrored electrode geometries aligned and separated by microfluidic structures. Thus the electrodes in Fig. 5 are on the top and bottom surfaces of the microchannel and do not significantly impede or manipulate the fluid flow. This system is optimized for a particular set of cells such that the applied signals generate the strongest dielectrophoretic forces; this system will operate with the maximum possible applied flow rate for more effective processing. The system, though, will be selective to a set of cells with the same or similar dielectric properties. This process is obviously advantageous for an application that selectively separates cells based on their dielectric properties. Additionally, this system can simultaneously separate and trap targeted cells for selective biological investigations. An example of a dielectrophoresis system and a description of its potential for biological analysis is explained in [6]. These dielectrophoresis techniques can be coupled with a variety of existing biological tools for innovative applications including fluorescence evaluation of cells in small populations, cell sorting, long-term investigations of single cells, cellular kinetics and other similar Lab-on-a-Chip analyses.



AC Dielectrophoresis Lab-on-Chip Devices, Figure 5 An illustration of a dielectrophoretic microsystem that can selectively sort particles (top view). Recall that the electrodes are on the top and bottom surfaces of the microchannel and to not mechanically manipulate the particles

Insulating Dielectrophoresis

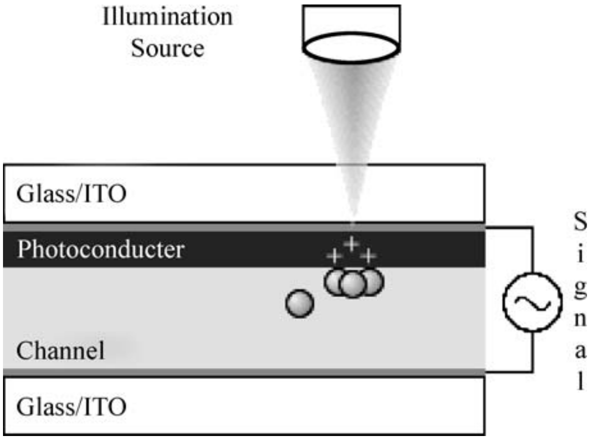
Conventionally, the nonuniform electric fields for dielectrophoresis applications are produced directly with an arrangement of conductive electrodes. However, a nonuniform electric field can be generated in microchannels without direct interaction with electrodes. For example, Cummings generated nonuniform electric fields using remote electrodes placed at the inlet and outlet of the microchannel [7]. The electric field is applied across the channel and is deformed by the variations in the channel geometry or by insulating structures or posts within the microchannel. These mechanical structures within the channel will affect the generated electric field as well as dynamically change the flow field; these can be successfully coupled to produce an efficient particle concentrator within the channel. By using remote electrodes, electrochemical reactions and other unwanted dielectrophoretic effects will not occur within the section of particle collection or concentration. However, this technique relies on the application of higher voltages to produce the necessary electric field gradient, with magnitudes in the hundreds to thousands of volts

(outside the range of conventional waveform generators). The driving mechanism for fluid flow for these systems is electrokinetic in that it combines features of electroosmotic and electrophoretic flows. Insulating dielectrophoresis Lab-on-a-Chip systems use a coupled arrangement of electrokinetic and dielectrophoretic phenomena to separate or capture targeted particles. Consider such a dielectrophoresis system that has an array of insulating posts within a microchannel. At a low applied electric field there will be induced electrokinetic motion but minimal particle manipulation effects from dielectrophoresis. However, at higher magnitudes the influence of insulating posts becomes apparent, inducing dielectrophoretic forces on the particles. At a certain threshold in the applied electric field dielectrophoresis forces on the particles are greater than the electrokinetic forces, resulting in captured targeted particles at the insulating posts. Releasing these particles is just a simple decrease in signal magnitude. Structures other than posts have been successfully used to similarly manipulate and separate particles of different dielectric properties.

Optical Dielectrophoresis

An electrode-less approach to induce localized dielectrophoretic forces can be created by light illumination in optically induced dielectrophoresis. This technique utilizes low-power optical beams to manipulate particles and cells. Consider an AC electric signal applied across two parallel electrodes with a film of photoconductive layer in between. This generates a uniform electric field across the film; however, the photoconductive layers have higher conductivities under illumination, thus distorting the otherwise uniform electric field. An illustration of a simplified optically induced dielectrophoresis system is shown in Fig. 6. The illumination of the photoconductive layer produces a virtual electrode and locally induced dielectrophoretic forces. These forces can be used in pDEP or nDEP applications and have the distinct advantage of being temporary, as opposed to permanent microfabricated electrode features. For example, trapped particles can be moved with the translation of the illumination pattern and released by simply turning off the light.

These optical methods, though, have been developed to include image projectors to manipulate cells using larger, patterned illumination areas. For example, virtual structures can be used to direct cells or can be alternatively used to pattern trapped cells. An investigation of optically induced dielectrophoresis for cellular manipulation is found in detail elsewhere [8]. This investigation characterizes the controllability of these optical techniques. This technique, though, should not be confused with optical tweezers (also called optical traps), which manipulate cells with forces generated by a highly focused laser beam. Optical tweezers use high optical intensity that may cause damage to the cell or induce localized heating. In contrast, optically induced dielectrophoretic techniques have about 1000 times less optical intensity.

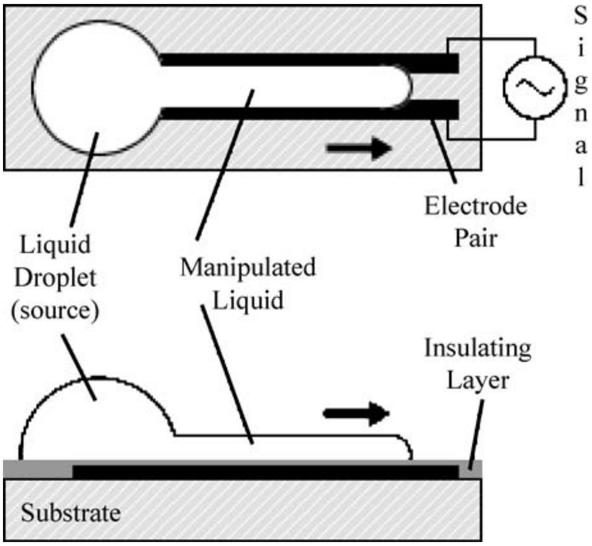


AC Dielectrophoresis Lab-on-Chip Devices, Figure 6 An example for a simple setup for optically induced dielectrophoresis. The optical source is illuminated through the ITO/glass substrate onto the photoconductive layer, creating an electric field gradient in which particles experiencing pDEP are attracted

Liquid Manipulation

Outside of particle manipulation, dielectrophoresis has also been used to control small volumes of liquid [9]. Liquids themselves also polarize and will, therefore, respond to nonuniform electric fields by being attracted to high-field-intensity regions. Liquid dielectrophoresis influences hydrostatic equilibrium and does not directly manipulate the fluid using dynamic mechanisms typically associated with electro-osmotic flow, electroconvection or other electrohydrodynamic methods. As with all dielectrophoresis techniques, liquid dielectrophoretic forces become stronger at smaller length scales, typically the micrometer length scale. Simple applications of this technique require a fluid running between two closely spaced planar electrodes (Fig. 7). A signal is applied between these two electrodes inducing the collection of individual molecules to the area of highest field intensity, along the edges of the electrodes. The liquid will translate and fill the area along these electrode “fingers” until equilibrium is achieved.

When the signal is removed the liquid will retract and return to its original hydrostatic equilibrium form. This retraction can be coupled together with surface structures to generate nanoliter droplets. However, typical voltage magnitudes are in the hundreds of volts, resulting in Joule



AC Dielectrophoresis Lab-on-Chip Devices, Figure 7 Liquid dielectrophoresis with a set of planar electrode fingers with an insulating layer (top view and side view). A signal is applied to manipulate the liquid to travel along the gap between the electrodes

heating and electrolysis. Electrolysis can be easily avoided by coating the electrode surface with an insulating layer. Heating is typically insignificant when liquids are nonconductive; however, water and other highly conductive liquids will undergo Joule heating. To cope with these issues in present liquid dielectrophoresis systems, very short applications of voltage (< 0.1 s) are applied to avoid heating. Liquid dielectrophoresis involves a complex relationship between electrohydrodynamics, fluid dynamics, surface effects, Joule heating and dielectrophoresis but this technique provides a rapid actuation of liquid that can be utilized in Lab-on-a-Chip systems.

Molecular Dielectrophoresis

Dielectrophoresis has also been used to manipulate macromolecules such as DNA, viruses, proteins and carbon nanotubes. The term *colloids* will be used here to generally describe a particle between 1 nm and 1000 nm. At this scale we need to take into consideration additional parameters that will affect the efficiency and application of dielectrophoresis. The first is Brownian motion, or the random chaotic movement of molecules, which will introduce another destabilizing variable if we were to trap colloids. Second, electrostatic effects at the surface of colloids, created by the electrical double layer, will influence particle–particle interactions. Factors such as hydrodynamic drag, buoyancy, electrothermal effects and a particle's double layer interactions need to be considered when applying dielectrophoresis to colloids.

The importance of mechanically controlling these structures in Lab-on-a-Chip systems with dielectrophoretic techniques will aid in the understanding of their biological interactions with other subcellular entities. For example, miniature quadrupole traps can be used to determine the crossover frequency of specific proteins and viruses. Capturing viruses at a particular set of experimental parameters will give insight into their identification as well as provide a means to concentrate or separate these particles. The crossover frequency of a protein is not only a function of medium conductivity, but it is dependent on the pH as well. Thus, dielectrophoresis can be coupled with chemistry-oriented techniques in order to approach the experimentation of single molecules. DNA has also been manipulated using dielectrophoresis. In one study [10], DNA was uncoiled from its natural bundled condition and stretched between two electrodes, aligning itself along the field lines. It was shown that it took about one-third of one second to uncoil a 48,500 base-pair DNA to a length of 17 μm. The applications of DNA manipulation include electrical measurements between electrodes and positioning of DNA for structural purposes or modification. Carbon nanotubes have also been manipulated similarly. These manipulative techniques have contributed to the assembly of nanometer-sized structures.

Dielectrophoretic Assembly

Dielectrophoresis can be utilized in assembly procedures to induce particle–particle interactions or to use attractive forces between electrodes to position a component and complete a circuit. When two polarized particles come into close proximity to each other they will undergo an attractive force due to their dipole interactions. This is referred to as dipole–dipole interaction, mutual dielectrophoresis or pearl chaining because this phenomenon creates strings of particles. Recall that a particle's induced dipole aligns itself to the electric field and that like particles will always have the same dipole orientation. These particles will have an attractive force since their opposite charges are aligned facing each other. Additionally, these particle chain formations can also be attributed to the distorted electric field caused by the particle's induced dipole. These field disturbances can cause a localized dielectrophoretic force, increasing the strength of these particle–particle interactions. Pearl chains are typically observed near electrode edges where the strength of the electric field is the greatest.

Pearl chains of nanoparticles can be arranged and fused together to create a nanowire or other similar struc-

tures. However, other dielectrophoresis techniques can be utilized to assemble a variety of geometries. Dielectrophoretic traps and optical dielectrophoresis can assemble groups of like particles. Electro-orientation techniques have been used to align and connect nanowires between electrodes. Functionalized particles can be implemented with dielectrophoresis Lab-on-a-Chip systems to create biological sensory or assembly systems. Dielectrophoresis, therefore, is a very versatile engineering tool.

Future Directions for Research

As a nonmechanical and minimally invasive process, dielectrophoresis presents as a tool to be used in Lab-on-a-Chip systems to manipulate particles and cells. These techniques will continue to evolve as the size of microfabricated features continue to decrease past the nanometer scale. This miniaturization will give rise into more comprehensive, subcellular microsystems which need novel methods to manipulate specific entities to suit a biological, chemical or sensory purpose. Dielectrophoresis phenomena at these decreasing length scales will continue to be characterized, leading to newly developed dielectrophoresis phenomena and subsequent innovative manipulation techniques. The future of dielectrophoresis is with the continued investigation and development of novel applications of dielectrophoresis techniques. With the integration of these technologies, a complete dielectrophoresis-driven Lab-on-a-Chip diagnostics system is possible.

Definition

AC electro-osmosis (ACEO) is a ►nonlinear electrokinetic phenomenon of induced-charge electro-osmotic flow around electrodes applying an alternating voltage.

Overview

Classical electrokinetic phenomena, such as ►electro-osmotic flow and ►electrophoresis, are linear in the applied voltage and thus cannot produce any net flow under alternating current (AC) conditions. A variety of

► nonlinear electrokinetic phenomena, which persist in AC fields, have been known for decades in colloid science, but the focus has been on electrophoretic mobility and particle interactions. The advent of microfluidics has stimulated interest in the use of electric fields to drive fluid flows, without any moving parts. In this context, nonlinear electrokinetics offers some unique advantages, such as the reduction of unwanted electrochemical reactions (using AC voltages) and the ability to drive fast, programmable flows at low voltages (using closely spaced micro-electrodes).

In the late 1990s, Ramos et al. discovered steady electro-osmotic flow over a pair of micro-electrodes applying an AC voltage and dubbed the effect *AC electro-osmosis* [1]. Around the same time, Ajdari predicted ACEO flow over periodic electrode arrays and showed how the effect could be used for long-range pumping [2]. As the performance of ACEO pumps has advanced [3, 4], ACEO has also been exploited, in conjunction with ► dielectrophoresis (DEP), in different geometries to manipulate particles and cells in microfluidic devices [5–7].

Basic Methodology

Local Flow Generation

ACEO is a phenomenon of ► induced-charge electro-osmosis (ICEO), where flow is generated by the action of an electric field on its own induced diffuse charge near a polarizable surface. The main difference with other examples of ICEO, such as flows around metal colloids, is that ACEO involves electrode surfaces, which supply both the electric field and the induced screening charge, in different regions at different times. For this reason, ACEO is inherently time-dependent (as the name implies) and tied to the dynamics of diffuse charge, as ions move to screen the electrodes.

Perhaps the easiest way to understand ACEO is to consider a pair of planar electrodes applying a sudden DC voltage (which is analogous to ICEO flow around a polarizable particle in an sudden electric field). As shown in Fig. 1, charge relaxation can initially be described by an equivalent RC circuit, where the diffuse layers act as capacitors, connected to "current-tube" resistors of varying length through the bulk solution. Since the resistance is smaller (and the field larger) near the gap, the inner portions of double layers on the electrodes charge more quickly than the outer portions. As shown in Fig. 2, this causes ICEO flow to occur, directed outward from the gap, only when the electrodes are partially screened, as the tangential field from the unscreened outer portions acts on induced charge on the inner portions. Note that the flow is independent of the sign of the applied voltage: If the polarity were reversed, then the field and induced charges would both change sign, resulting in the same ICEO flow.

Under AC forcing, the flow peaks when the oscillation period is comparable to the charging time (Fig. 2b). ACEO flow decays at higher frequencies, since there is not enough time for charge relaxation (Fig. 2a). It also decays at lower frequencies, since there is enough time to completely screen the bulk electric field (Fig. 2c).

Mathematical models of ACEO follow other examples of ICEO, as described in the article on ► nonlinear electrokinetic phenomena. A major simplification in the case of small voltages is to assume sinusoidal response to sinusoidal AC forcing and solve only for the complex amplitudes of the potential and velocity components at a single frequency ω (Fourier mode) [2]. In this regime, the basic scaling of time-averaged ACEO flow is

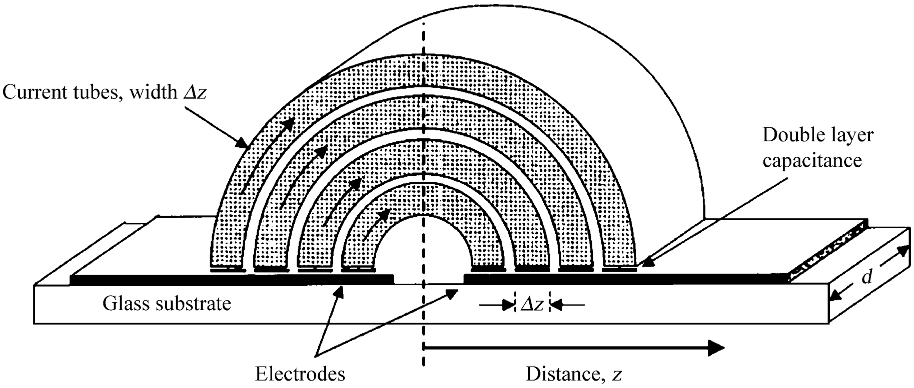
$$\langle u \rangle \propto \frac{\varepsilon V^2}{\eta(1+\delta)L\left[\frac{\omega}{\omega_c}+\frac{\omega_c}{\omega}\right]^2} \tag{1}$$

where V is the applied voltage, ε and η are the permittivity and viscosity of the liquid (both assumed constant), L is electrode spacing (roughly center to center), δ is the ratio of the diffuse-layer to compact-layer capacitances (both assumed constant). The peak frequency is at the scale of the RC charging time

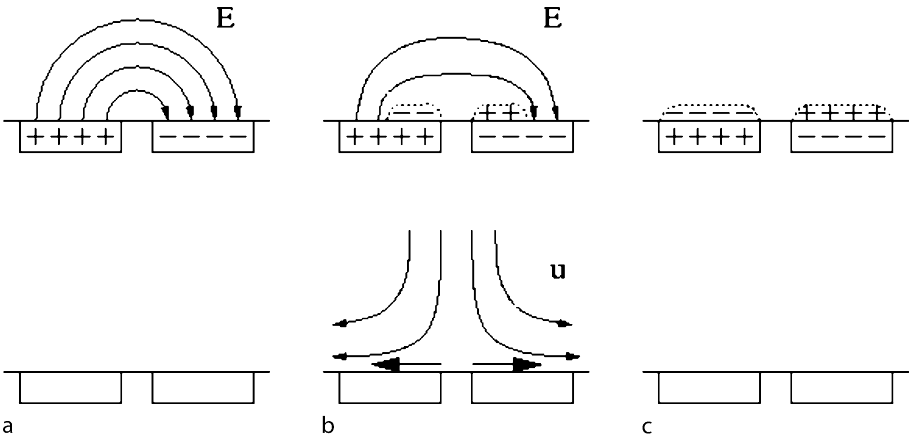
$$\omega_c \propto \frac{D\,(1+\delta)}{\lambda L} \tag{2}$$

where λ is the Debye screening length and D is a characteristic ionic diffusivity.

The relevant case of a large applied voltage, $V \gg kT/e = 25\,\mathrm{mV}$, is not yet fully understood. A variety of new effects could become important, such as steric effects of finite molecular sizes, viscoelectric effects, discrete electrostatic correlations, dissociation and de-solvation kinetics, and/or Faradaic electrochemical reactions passing current through the surface. In particular, *Faradaic charging* (as opposed to *capacitive charging*, described above) has been proposed to explain experimentally observed flow reversal at high voltage [7], although this has not yet been borne out in a complete mathematical model of ACEO. Standard models of Faradaic reactions mainly predict suppression of the flow (by short-circuiting of the double layer charging process) and flow reversal only in certain cases, at lower frequencies than in the experiments [2, 8]. Although reactions surely play a role in ACEO, high-frequency flow reversal may be attributable to other effects, such as ion crowding in the diffuse layer [9].



AC Electro-Osmotic Flow, Figure 1 Equivalent RC circuit model for double-layer charging over a pair of electrodes. The inner edges of the electrodes encounter less bulk resistance (due to shorter "current tubes") and thus charge more quickly than the outer edges (reproduced from [1]



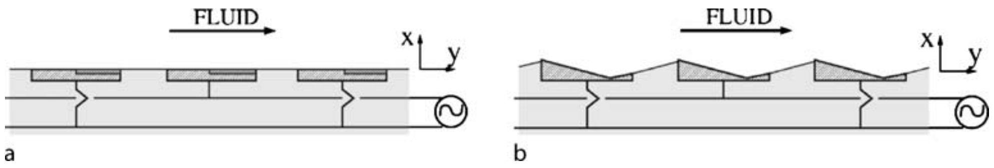
AC Electro-Osmotic Flow, Figure 2 The basic mechanism of AC electro-osmosis: Electrochemical relaxation (top) and induced -charge electro-osmotic flow (bottom) in response to a suddenly applied voltage across an electrode pair. (**a**) At first the electric field has no tangential component on the electrodes, since they are equipotential surfaces, and thus there is no electro-osmotic flow. (**b**) Capacitive double-layer charging begins near the gap where the initial normal current is strongest and causes the unscreened field lines dip down and provide tangential components over the induced charge; the result is ICEO flow directed away from the electrode gap. (**c**) After the charging time passes, the electrodes are fully screened, leaving no electric field and thus no flow. An AC voltage can drive a steady time-averaged flow, similar to (**b**), if its period is comparable to the charging time

Fluid Pumping

Regardless of the details of flow generation, there are some useful general principles to guide the development of microfluidic pumps. ACEO flow over a small set of electrodes can be used for local fluid mixing or particle trapping at stagnation points, but the flow decays quickly away from the electrode surfaces. A symmetric, periodic array of many inter-digitated electrodes (of alternating polarity at each moment in time) similarly produces an array of counter-rotating convection rolls, but no net pumping of the fluid in one direction. Instead, long-range pumping over an electrode array requires broken symmetry within each spatial period to rectify the AC forcing.

There are several ways to design ACEO pumps by breaking symmetry in a periodic electrode array. Ajdari originally suggested modulating either the electrode capacitance via a dielectric coating (Fig. 3a) or the surface height (Fig. 3b) with half the spatial period of the array, so that the one side of each electrode drives stronger ACEO flow compared to the other side and thus "wins" to produce net pumping over the array [2]. In the first implementation of an ACEO pump, Brown, Smith and Rennie opted instead to break symmetry by using planar electrodes of different widths and gaps [10], and, until recently, this design was the only one studied experimentally [3] or theoretically [8].

The performance of ACEO pumps can be greatly enhanced by designing appropriate non-planar electrode geometries.



AC Electro-Osmotic Flow, Figure 3 Sketches of local broken symmetries in a periodic electrode array which lead to global time-averaged ACEO pumping: (**a**) non-uniform surface coatings; (**b**) non-uniform surface height (reproduced from [2])

As recently predicted by Bazant and Ben [11], various *3D ACEO* designs exhibit dramatically increased flow rate without flow reversal, due to a special geometry in which the non-uniform slip profile on the electrodes all contributes to flow in the same direction. The basic idea is to create a *fluid conveyor belt* with electrodes each having steps of two different heights: On each electrode, the region of desired forward flow is raised up, while the region of reverse flow is recessed below, so as to recirculate in a vortex aiding the forward flow (rather than fighting it, as in planar designs). This can be accomplished with electrodes having electroplated metal steps, as shown in Fig. 4, although other designs are possible, such as flat electrode steps deposited on a grooved surface (without the vertical metal surfaces). Simulations predict that 3D ACEO pumps are faster than planar pumps by more than an order of magnitude, at the same voltage and minimum feature size, and thus can achieve mm/s velocities with only a few volts. This suggests using 3D ACEO pumps to drive flows in battery-powered, portable or implantable microfluidic devices.

Fluid pumping over electrode arrays can also be achieved by applying a traveling wave of voltage. At low frequency, a similar induced-charge electro-osmotic mechanism, which peaks at the RC frequency (2), is responsible for the flow [12]. At high frequency (or with a thick dielectric coating on the electrodes), the classical Erlich–Melcher effect used to pump dielectric liquids, which peaks at the Debye frequency, $\sigma/\varepsilon = D/\lambda^2$, can also be observed [13]. Although traveling-wave ACEO seems to produce slower flow than standing-wave ACEO with planar electrodes, the possibility of designing suitable non-planar electrodes has not yet been considered.

Key Research Findings

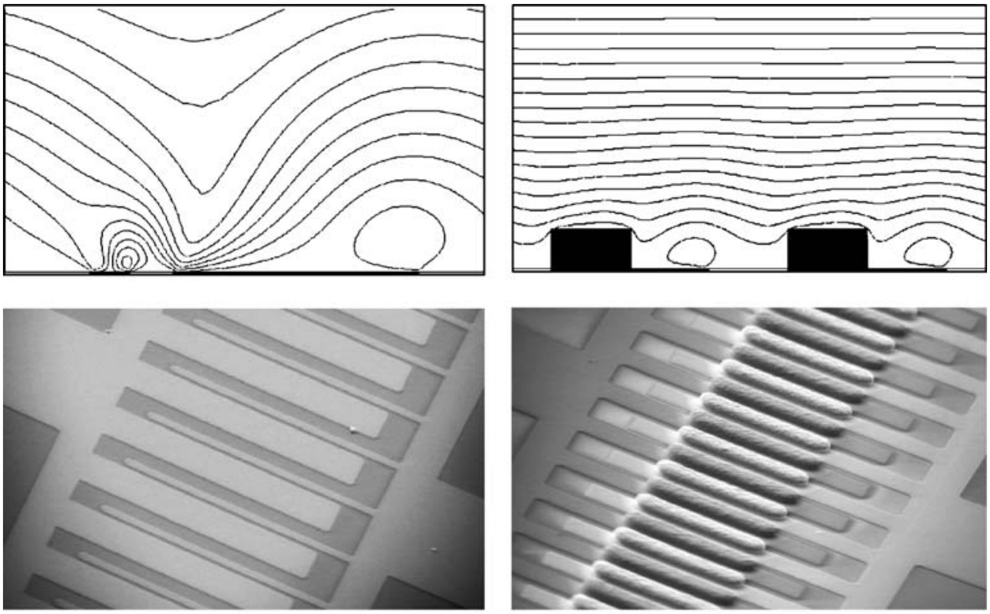
The groups of Ramos [1] and Green [15] have pioneered the study of ACEO by developing theoretical models and measuring flows around pairs of micro-electrodes in dilute KCl. Their work has ruled out ▶electrothermal effects (below 5 V in dilute electrolytes) and clarified the capacitive charging mechanism described above. The basic model successfully predicts the scaling of ACEO flow at low voltage and low salt concentration, although it tends to over-estimate velocities.

Following Ajdari [2], there has been extensive experimental [3, 4, 10, 12, 13] and theoretical [8, 9, 11] work on ACEO flows driven by periodic inter-digitated electrode arrays. Velocities exceeding 100 μm/s have been demonstrated in water [4, 10] and dilute KCl [3] by applying several volts at 1 – 100 kHz frequencies using asymmetric arrays of planar electrodes with unequal widths and gaps, at the scale of several microns. Somewhat slower flows have also been achieved by applying traveling-wave voltages with inter-digitated planar electrodes [12, 13], although the electrical connections are more complicated.

A puzzling feature of ACEO in many situations with planar electrodes is that the flow direction can reverse (compared to the theory) with increasing voltage, typically above 2 V. For example, high-voltage flow reversal has been observed in dilute KCl for AC forcing [3] and traveling-wave forcing [13] and in tap water for AC forcing with a DC offset [7]. As shown in Fig. 5a, the reverse flow is eventually faster than the forward flow and seems to grow more quickly with voltage than the expected scaling $u \propto V^2$.

Another puzzling feature of ACEO is the strong decay of the flow with increasing salt concentration. For this reason, all experiments in the literature have used either very dilute solutions (mostly KCl) or water (de-ionized or from the tap). A few groups have studied the concentration dependence of ACEO in aqueous KCl solutions [3, 15, 16]. These experiments and recent work on ▶electrokinetic motion of heterogeneous particles suggest that flows due to ▶induced-charge electro-osmosis exhibit a universal decay with concentration like $u \propto \log(c_{\max}/c)$ at large voltage [9]. As shown in Fig. 5b, the flow effectively vanishes above a bulk salt concentration of only $c_{\max} \approx 10$ mM, which is an order of magnitude smaller than most biological solutions.

Nevertheless, advances have been made in applying ACEO flows to pumping, mixing, and trapping particles in microfluidic devices. Experiments on 3D ACEO pumps with non-planar stepped electrode arrays have demonstrated an order of magnitude increase in flow rate versus the fastest planar design, due to the robust fluid-conveyor-



a b

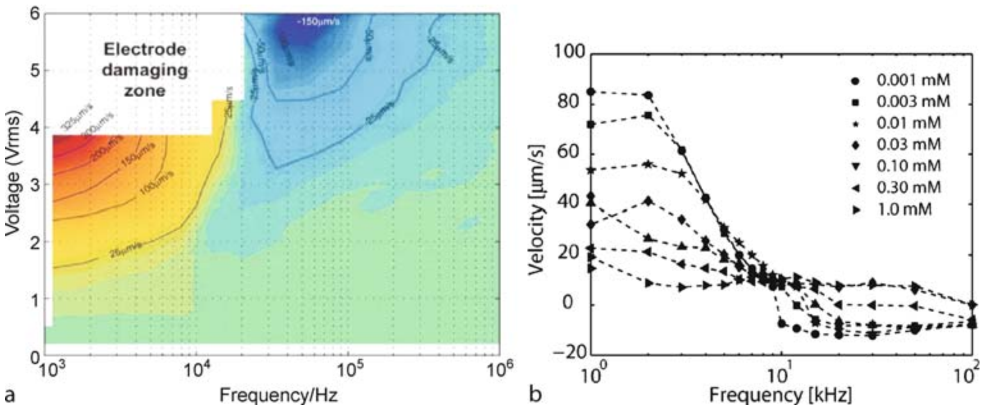
AC Electro-Osmotic Flow, Figure 4 Top: Simulations of ACEO microfluidic pumps, showing the time-averaged flow over a pair of micro-electrodes (dark regions) in one spatial period of an interdigitated-electrode array. (**a**) A nearly optimal planar design with different electrode sizes and gaps; the smaller electrode has the largest local slip velocity, but the larger electrode "wins" in overall pumping from left to right. (**b**) A much faster 3D ACEO design with stepped electrodes having a symmetric footprint and the same minimum feature size; the reverse slip now recirculates in a vortex to create a *fluid conveyor belt* for the raised pumping flow from left to right (reproduced from [11]). Bottom: Scanning electron microscopy images of each design fabricated in gold on glass with minimum feature size (gap) of 5 μm (unpublished, courtesy of J. P. Urbanski using the methods of [4, 14])

belt mechanism [4]. For a wide range of near-optimal step heights, there is also no observed flow reversal [14]. Therefore, it is now possible to drive fast, reliable mm/s flows in water or dilute electrolytes with less than 3 V, which can be provided by a small lithium battery.

Progress has also been made in exploiting ACEO flows to manipulate colloidal particles and biological cells in microfluidic devices [5–7]. The basic strategy is to use ACEO flow to draw particles to stagnation points on the electrodes, where they are trapped, presumably by DEP (although the classical theory does not seem to predict this effect). By increasing the voltage, the ACEO flow can be reversed, and particles are observed to move away from the stagnation lines, overcoming any remaining trapping force. In this way, it is possible to "write" and "erase" suspended particles, bacteria, or micro-algae on microelectrodes, as shown in Fig. 7a. This effect can be enhanced by added a DC bias voltage to the low-frequency AC voltage (50 – 100 Hz) between adjacent electrodes [7]. Particles are observed to collect only on the positively biased electrode, as shown in Fig. 7b. It has been suggested that opposing ACEO flows are produced by the competition between Faradaic charging on one electrode (positive bias) and capacitive charging on the other (negative bias), but a quantitative theory remains to be developed and confirmed systematically by experiments.

Future Directions for Research

ACEO is attractive to exploit in microfluidics since it offers precise local flow control without moving parts, using standard fabrication methods from the electronics industry. Device operation requires only the voltage (few Volts), power (mW), and current (mA) of a small battery, and Faradaic reactions are reduced or eliminated. These features make ACEO a promising route to portable or implantable microfluidic systems. In contrast, DC electro-osmotic pumps, such as those exploiting electroosmotic flow in porous media, typically require several 100 V and produce bubbling at the electrodes due to electrolysis, which can require a catalytic gas management system. On the other hand, ACEO pumps have so far only produced very small pressures (< 10 Pa) far below those of porous-plug DC pumps (> 100 kPa), but new designs could close this gap. In any case, the ability to tune flows and particle motion by ACEO at the micron scale by modulating relatively small AC voltages could have many uses, e. g. for



AC Electro-Osmotic Flow, Figure 5 Experimental data for ACEO pumping of KCl around a microfluidic loop, one-fifth covered by the asymmetric planar electrode array of Fig. 4a. (**a**) Contour plot of mean velocity versus AC frequency and RMS voltage at a bulk salt concentration of 0.1 mM (reproduced from [3]), where *electrode damaging* refers to bubble formation and inability to observe consistent flows. (**b**) Velocity versus AC frequency at 2 V peak-to-peak for different concentrations (reproduced from [16]). Both show high-voltage, high-frequency flow reversal, and the latter shows the strong decay with salt concentration

mixing, flow fragmentation, or manipulation of colloids and cells.

Understanding flow reversal in ACEO is an important open question, from both fundamental and practical points of view. As noted above, it has been attributed to Faradaic reactions, using theoretical arguments suggesting a scaling $u \propto e^V$ [7]. Simulations of ACEO pumps using standard Butler–Volmer reaction kinetics have failed to predict any flow reversal, except at low frequencies below 100 Hz [2, 8], although this may be consistent with experiments showing low-frequency flow reversal with a DC bias [7]. In contrast, high-voltage flow reversal with unbiased AC forcing in electrode-array pumps tends to occur at high frequency (> 10 kHz), as shown in Fig. 5. An alternative hypothesis, which predicts high-frequency, high-voltage flow reversal due to capacitive charging alone, is based on the reduction of double-layer capacitance due to ion crowding effects [9]. The question is far from settled, however, and more theoretical and experimental work is needed.

Another important open question concerns the dependence of ACEO flow on the solution chemistry (concentration, ionic species, solvent characteristics, etc.). The suppression of ACEO above 10 mM bulk salt concentration limits its use in biological applications and points to possible new physics of the double layer at large voltages, such as a dramatic increase in the diffuse-layer viscosity upon ion crowding [9]. Very few electrolytes have been studied experimentally, but current work suggests that varying the ionic species can also substantially alter the flow. An interesting direction for future research would be to develop surface coatings, electrode materials, and buffer solutions to mitigate or manipulate these complex interfacial phenomena.

Definitions

A biosensor is defined as an analytical device that uses a biological recognition system to target molecules or macromolecules. Biosensors use a physio-chemical transducer to convert the signal from the bio-recognition system into a detectable signal [1]. Biosensors consist of three components: 1) the detector, which identifies the stimulus; 2) the transducer, which converts this stimulus to an output; and 3) the output system, which involves amplification and display of the output in an appropriate format [1].
Piezoelectricity is a phenomenon displayed in certain crystals, such as quartz and Rochelle salt, where mechanical stress induces voltage generation and vice versa.

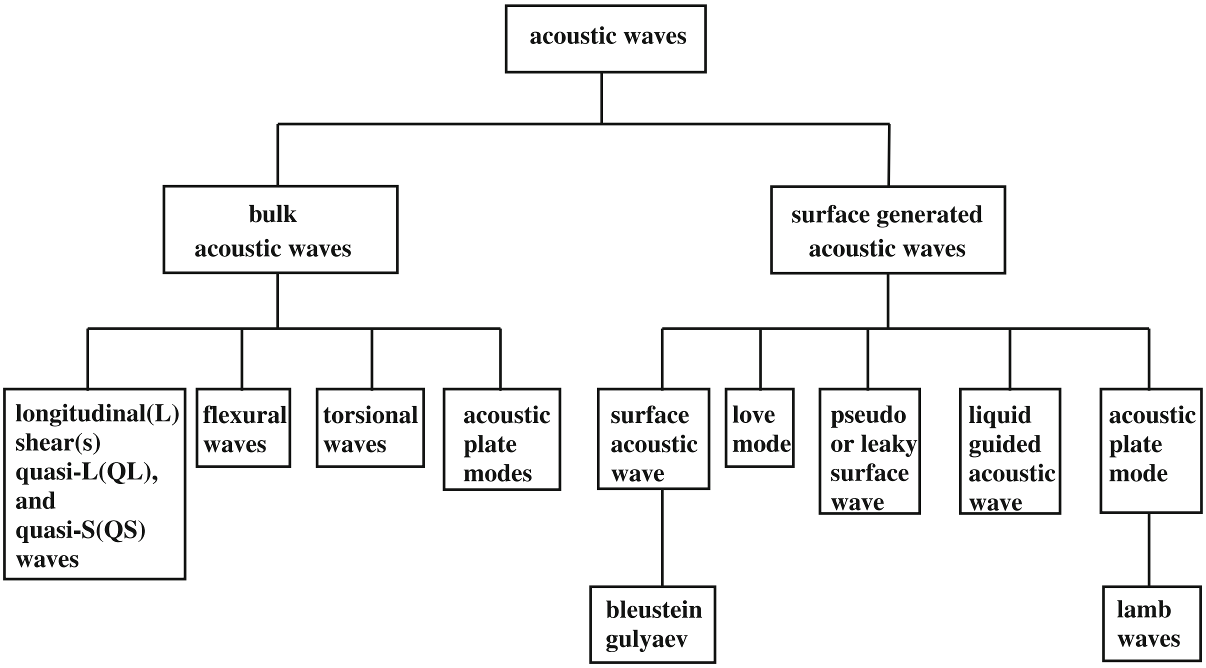
Overview

There is an increasing demand for small, reliable, disposable, and inexpensive sensors in industrial, medical, and a variety of other science and engineering fields. Sensors are one of the fastest growing markets, with annual growth of about 18%. In particular, the market for biosensors is increasingly promising due to their application in progressing areas of healthcare, biotechnology, and medicine. For instance, the use of biosensors in personal glucose testing, HIV, and early cancer detection are areas with great medical relevance [1]. In addition, the ability to detect pathogenic and physiologically relevant molecules in the body with high sensitivity and selectivity offers a powerful tool in early diagnosis and treatment of diseases [1].
An acoustic wave biosensor utilizes acoustic or mechanical waves as a detection mechanism to obtain medical, biochemical, biophysical information about the analyte of interest [1, 2]. It detects changes in mass, elasticity, conductivity and dielectric properties from mechanical or electrical variations. These devices also employ the piezoelectric effect to excite acoustic waves electrically at an input transducer and to receive the waves at the output transducer [2].
The first scientific experiment of piezoelectricity was conducted in 1880 by Pierre and Paul Jacques Curie, who found that compression of various crystals leads to voltage production on their surface. They showed the converse effect the following year by demonstrating the elongation of certain crystals when injected with electric current. Although these observations intrigued the scientific community, piezoelectricity remained much of a laboratory technology until Paul Langevin used piezoelectric transducers to construct sonar for submarine detection in 1915 [3]. Acoustic biosensors can be made with piezoelectric crystals such as quartz, lithium niobiate or lithium tantalate since they are robust and environmentally stable. In addition, such sensors are versatile and can detect, in principle, various biomolecules [1]. Acoustic wave sensors can be categorized according to the waves they generate, such as bulk or surface acoustic waves (Fig. 1). Each of these wave mechanisms have various advantages and disadvantages depending on their specific applications [1].
The goal of this review is to categorize and describe the mainstream acoustic wave biosensors. We will begin by discussing biosensors that utilize bulk acoustic waves and subsequently analyze devices that employ surface acoustic waves. We will also examine sensors that employ capacitive micromachined ultrasound transducers, a novel technology that does not require piezoelectric substrates. For each type of these sensors, we will present an overview of their scientific mechanisms and fabrication techniques in the Basic Methodology section. We will then go on to discuss the advantages and applications in biology and medicine in the Key Research Findings and Future Direction for Research sections.

Basic Methodology

Bulk Acoustic Wave (BAW) Devices

Bulk acoustic wave (BAW) biosensors employ either longitudinal or shear waves, although the latter is often preferred to reduce acoustic radiation in the medium of



Acoustics Based Biosensors, Figure 1 Classification of acoustic waves [1]

interest. They are the oldest and the simplest acoustic wave devices. BAW devices consist of a parallel electrode placed on both sides of the thin piece of crystal. A BAW sensor can technically employ any piezoelectric element and typically quartz is used, as it is an inexpensive material readily available in nature and easily synthesizable in abundant quantities. In addition, thin disks of quartz are more stable at high temperatures than other piezoelectric elements. When an alternating electric field is applied, it results in a potential difference between the two electrodes and the shear deformation of the crystal. As a result, there is mechanical oscillation of a standing wave across the bulk of the quartz. The frequency of the vibrations is dependent on quartz properties such as density, size, and phase in contact with the crystal surface [4]. Currently, thickness shear mode (TSM) resonator and shear-horizontal acoustic plate mode (SH-APM) sensors remain the most widespread BAW sensors. The other two common BAW sensors that lie beyond the scope of this article are the thin rod acoustic wave sensors and the flexural plate wave devices [4].

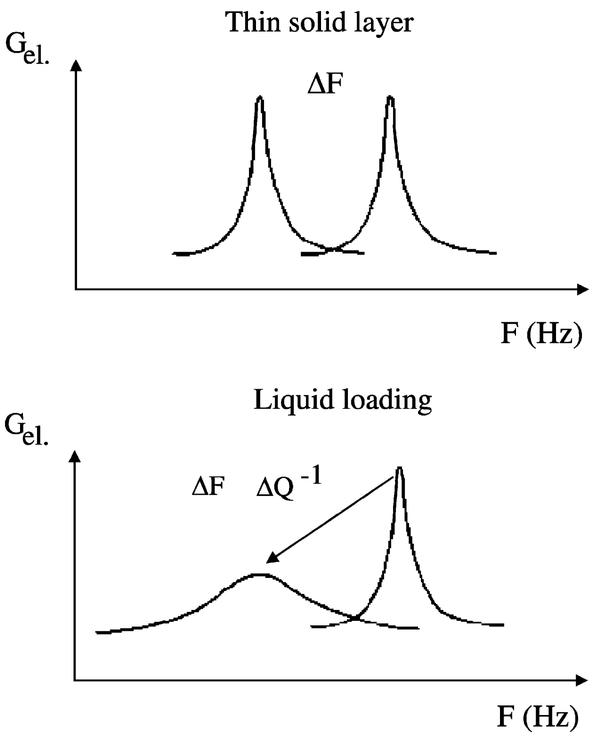
BAW Device – Thickness Shear Mode (TSM) Resonator

TSM resonator, also known as quartz crystal microbalance (QCM), is the simplest and most widespread acoustic wave device today. TSM typically composes of a quartz plate sandwiched by electrodes on opposite faces. Electric field crosses through this plate when voltage is applied to the electrodes, resulting in a shear mechanical strain or displacement in the quartz. By oscillating the voltage frequency, a mechanical resonance can be generated, where the maximum displacement of crystal occurs at the surfaces. The resonant frequency, F_r, and the quality factor, Q, are the two resonance parameters. While F_r is the mechanical thickness shear resonance as mentioned before, it is also defined as the frequency of the maximum value of the electrical conductance, G_{el}. Q is approximated mathematically from the electrical conductance resonance spectrum as $Q = F_r/\Delta F_{BW}$, or the ratio of resonant frequency to the half bandwidth [5] (1).

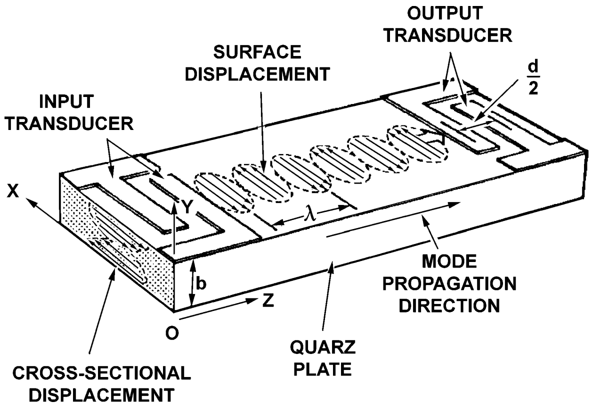
Coupling of molecules in solid, liquid, or gas phase to the TSM resonator changes the resonance parameters. When mass attaches onto the crystal face, it raises the quartz's overall weight and reduces F_r. Saurbrey first derived the mathematical relationship between loading mass and F_r to be:

$$\Delta f = -\frac{2f_0^2 \Delta m}{A_{piezo}(u_q p_q)^{1/2}}$$

(1) The variables $\Delta f, f_0$, Δm, A_{piezo}, u_q, and p_q represent, respectively, the crystal's measured frequency shift, initial resonant frequency, mass change, surface area, shear mod-



Acoustics Based Biosensors, Figure 2 Changes to the resonance peaks due to a thin solid layer (top) and liquid (bottom). Note the decrease in Q for TSM resonator in liquid [22]



Acoustics Based Biosensors, Figure 3 SH-APM can sense on either side of the device because waves travel between the upper and lower surfaces of the plate [2]

ulus, and density [6]. TSM resonators immersed in liquid present a special case because acoustic energy dissipation through the fluid lowers Q as well. Additional formulas need to be applied to account for the liquid's viscosity and loading [6]. Figure 2 shows a comparison between shifts induced by solid and liquid loading on resonators.

TSM resonators possess lower mass sensitivity than most acoustic wave sensors that employ other mechanisms since they typically operate between only 5 and 30 MHz. Thinner devices can be used to increase frequencies that result in increased mass sensitivity, they are more fragile and harder to manufacture and handle [5]. Recent research on this topic has been on creating high-frequency TSM resonators with piezoelectric films and bulk silicon micromachining techniques.

TSM Fabrication

TSM resonator fabrication usually utilizes photolithography [2]. The resonance frequency of the quartz crystal depends on the shear modulus, density, and material thickness [1]. After polishing the quartz, photoresist is deposited and the device is exposed to UV light through a mask, which determines the active areas that have to be metalized on the devices. On a TSM resonator, they represent the location of the electrode plates. A chemical interface is then added to the remaining crystal surface, where molecules in the liquid can bond to and be detected [2].

BAW Device – Shear-Horizontal Acoustic Plate Mode (SH-APM) Sensor

First introduced in the 1980s, SH-APM sensors use a thin piezoelectric substrate, or a plate, to guide the acoustic wave and to confine its energy within the plate's top and bottom surfaces. Most of the production and analysis principles employed in SH-APM sensors are used in a TSM resonator. Their most striking difference is that SH-APM sensors employ interdigital transducers (IDT) rather than electrode plates. IDTs are deposited on opposite ends of a surface, where one IDT generates displacement waves through application of an oscillating voltage and the other receives it (Fig. 3) [2]. The surface without IDT is immersed in the targeted liquid and acts as the sensor, so the device will not suffer from corrosion problems as electrode plates do in biological solutions [7].

Like TSM resonators, SH-APM sensors prevent the acoustic waves from gaining a shear vertical component and thus lessening energy radiation in the form of compression waves into the liquid. They achieve this by restraining particle displacement within the plate plane. However, given a SH-APM and a TSM device of similar plate thickness, the former usually attains higher mass sensitivity than the latter because IDT is much smaller and precise than the electrode plates on TSM. In general, SH-APM devices generate waves with a frequency ranging from 100 to 150 MHz, but they are also more complex and expensive than their TSM relatives [2].

SH-APM Fabrication

Although the crystals and substrates may be different, SH-APM sensors are fabricated in a similar fashion as TSM resonators. One difference that must be noted is the use of IDTs in SH-APM fabrication, which is not present in TSM resonators. Depending on the application, the optimization of sensor performance can be achieved through adjustments of the length, width, position, and thickness of the IDTs. These parameters can be altered by varying the design of the masks, amount of photoresist and other chemicals used in the fabrication process [2, 7].

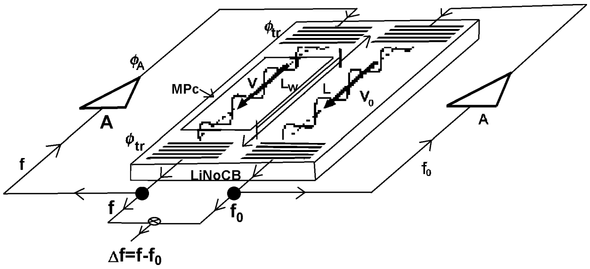
Moreover, SH-APM devices require additional processing during their fabrication of the thin plates with respect to the IDT periodicity. Thin slices of piezoelectric materials such as quartz are often used. The whole procedure permits researchers to choose the correct crystallographic orientation for generating the desired shear waves. Despite this improvement, SH-APM devices remain less sensitive than SAW devices for two reasons. First, energy of the wave does not reach a maximum at the surface. Second, similar to TSM, SH-APM is restrained by a minimum thickness of piezoelectric plate [2, 7].

Surface Acoustic Wave Sensors (SAW)

Surface acoustic wave (SAW) sensors have been used for years in measuring temperature, pressure, viscosity, acceleration, concentration and chemical/biological entities [3]. They are also used to perform signal-processing operations and are sensitive to their environment [8]. This type of acoustic wave sensors consists of basic components such as piezoelectric substrate (crystals such as quartz, GaAs, or $LiNbO_3$), micrometallization patterns (electrodes), interdigital transducers (IDT) and active thin films. Unlike BAW, which only interacts with the environment at the opposite surface of the material by traversing through it, SAW travels along or near the surface of the piezoelectric material [3]. The piezoelectric device detects small mass changes at the surface of the sensor as a frequency response, as the electrodes on the surface of the piezoelectric substrate transmit and receive acoustic waves [8]. The acoustic wave is confined to the surface of the piezoelectric substrate and the excited wave is propagated along the crystal surface. The surface wave velocity changes due to the mass or the viscosity changes due to the binding reactions on the sensor surface. The range that SAW device operates depends on the acoustic velocity of the crystal substrate and IDT wavelength, and it usually lies between lower MHz range to the GHz range [8]. These devices are commonly used because of their ability to directly sense the changes in mechanical and mass properties and they have a broad range of applications such as pressure, temperature, viscosity, mass, chemical and biological sensing [8]. SAW sensors coated with organic and/or inorganic materials can be used to analyze absorption on the surface of a device [9]. For chemical sensing, the chemoselective material must be tailored to the analyte of interest. During its operation, SAW sensor responds to a gas or vapor exposure in air by a shift in resonant signal frequency, and then recovers to the original signal frequency, when the sensor is exposed to ambient air free of the responding analyte [8]. The SAW velocity changes according to the absorbed chemical substance and it results in the alternation of the mass load, the elastic stress and the conductivity of the polymer coating on the SAW device.

SAW devices are also considered as "electronic noses." An electronic nose is a device that is composed of a chemical-sensing system and a pattern-recognition system. Electronic noses mostly have the ability to detect very low vapor concentrations [8]. If there is vapor on the piezoelectric surface of the SAW device, the chemical substances in the vapor and in the acoustic wave interact and the properties of the wave changes. Sensitivity of the SAW detector is dependent on the temperature of the piezoelectric crystal and the vapor-pressure of the analyte. Chemical concentration of analyte of interest can be tested by monitoring the frequency. The SAW chemical sensor requires no special support gases and no consumables other than electrical power. Many of the SAW devices have been produced for military and defense applications. They are used for on-the-spot vapor detection of plastic explosives containing nitro groups such as trinitrotoluene (TNT) and cyclotrimethylenetrinitramine (RDX) [8]. As a result, SAW sensors are attractive for real-time detection and monitoring of toxic or hazardous gases, vapors and they are used in biology as a sensitive method for detection of biochemicals and biomolecular interactions [9].

SAW devices operate at high frequencies, which lead to smaller, more sensitive devices that have limits in the picogram range [8]. SAW devices can be miniaturized by using photolithographic techniques and complex circuits can be present on the substrate surface. Miniaturization makes them advantageous since the smaller dimensions increases the sensing surface area and binding properties [6]. Moreover, there is a dual-delay system with SAW sensors (Fig. 4). It is a layered structure and has three fundamental advantages. First, it compensates the influence of temperature on the differential frequency and the air pressure. Second, it reduces the measured frequency of the system from MHz range to kHz range [6]. Third, SAW devices have the ability to directly sense mass and mechanical changes in an environment, which makes them more sensitive than other electrical and thermal biosensors. Furthermore, they have numerous advantages in bio-



Acoustics Based Biosensors, Figure 4 SAW device dual delay line structure and its principal of operation [21]

logical applications [6]. These devices are also more cost-efficient than the optical biosensors and easier to handle. They are employed to study biomolecular interactions and allow easy and direct detection of analyte of interest [8]. In summary, SAW technology is a cost-effective method of label-free detection of biomolecular interactions and allows direct monitoring on the surface of a transducer in real time [10].

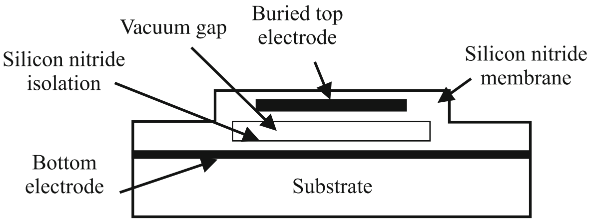
SAW Device Fabrication

Various lithographic techniques are used in the fabrication of interdigital transducers (IDT's) for surface acoustic wave sensors. The most widely used and least costly photolithographic technique to fabricate SAW devices is conventional contact printing. It uses rigid or conformable glass plates bearing the photographic image, which can be negative or positive depending on the fabrication steps of the IDT pattern [11]. Mass production of acoustic devices is done by optical lithography. Excitation of the SAW harmonics depends on the metallization ratio between the gaps and the electrodes of the SAW device. A lithography method especially suited for the fabrication of small gaps is the near-field phase shift technique. In this technique, a transparent mask with a pattern on its surface is brought into contact with the substrate. The phase of the exposing light is modulated at the edges of the patterned relief. High frequency, low-loss SAW devices can be fabricated by depositing thin piezoelectric films on substrates. These include ZnO, GaN, AlN, and $Al_xGa_{1-x}N$ thin films on sapphire, SiC and diamond substrates. The SiO_2/ZnO/diamond structure can provide a high acoustic velocity and a zero temperature coefficient of frequency. Extremely high velocity SAW modes with moderate coupling coefficient in AlN and GaN thin films are deposited on SiC, diamond, or sapphire substrates [12]. In addition, imprint lithography is a commercial method to fabricate SAW devices, especially for simple pattern, one-mask-level applications, where large areas can be patterned with nanometer-scale critical dimensions and high fidelity. Moreover, nanoimprint lithography is becoming a popular lithographic method. SAW filters and SAW correlators, present ideal structures to be fabricated using this method.

Capacitive Micromachined Ultrasonic Transducers (CMUTs)

Electrostatic transducers have been used for sound wave excitation and detection as an alternative to piezoelectric devices that are used widely for nondestructive evolution and medical-related applications. The vibration of a thin plate under electrostatic forces is the main acoustic actuation and sensing mechanism of these devices. These devices are based on the electrostatic attraction force between the backplate and the metallized membrane. The simplest forms of this device consists of a thin metal membrane that is stretched above a back electrode forming a small gap [13]. Upon exposure to sound waves, the gap height is modulated at the frequency of the incoming pressure field that induces a change in the device capacitance, which generates an output voltage proportional to the amplitude of the field. The capacitor is also used to generate sound waves. The advantage of the electrostatic devices compared to the other types of transducers is the impedance matching between the transducer and the surrounding medium. Advances in the silicon micromachining techniques enabled the fabrication of micro electro-mechanical systems (MEMS) based electrostatic transducers. These devices use the ultrasonic waves due to the miniaturization capacity of the silicon machining techniques and are called, capacitive micromachined ultrasonic transducers (CMUTs) [13].

CMUT are made of small and thin transducer membranes that are suspended over a conductive silicon substrate (Fig. 5). The two plates of the capacitor, substrate and the membrane are separated by a vacuum-sealed cavity. Two-dimensional (2D) arrays of miniaturized electrostatic cells are micro-scale cells that operate in parallel and driven in phase. Surface silicon micromachining is used for their microfabrication [13]. The operation principle of these devices is based on the capacitance modulation of a micro-condenser. Between the metalized membrane and the substrate, a direct current voltage is applied. The membrane is attracted toward the bulk by the electrostatic force, and induced stress within the membrane resists the attraction. If the membrane is exposed to ultrasound, a current output is generated as the capacitance changes under constant bias voltage. The amplitude of the current output is a function of the frequency of the incident wave, the bias voltage, and the capacitance of the device. CMUTs perform operation in the megahertz range. The lateral dimensions of each cell are in the order of tens of microns [13]. The gap



Acoustics Based Biosensors, Figure 5 Schematic cross section of a CMUT transducer membrane [23]

between the membrane and the substrate vacuum-sealed or unsealed can be as small as 500 Å. The membranes may be conductive or coated with a conductive electrode. This structure results in very efficient transducers that can compete with their piezoelectric counterparts in terms of efficiency and bandwidth. The small and thin membranes that constitute the CMUT transducer are micromachined onto a silicon substrate [13].

CMUT Fabrication

There are two conventional methods to fabricate CMUT; sacrificial release process and wafer-bonding method. The first CMUT was created by using a sacrificial release process and this method has become the standard CMUT fabrication for many years. In the sacrificial release process, a cavity underneath the membrane is created by depositing or growing a sacrificial layer on the carrier substrate. The sacrificial layer is removed with an etchant after the membrane deposition. However, there are some problems associated with this technology. The surface micromachining process causes limitation on the cavity and membrane size of a CMUT device. In addition, it is hard to batch produce surface micromachined CMUTs to tight quality specifications [14]. On the other hand, wafer-bonding method is a new fabrication technique that combines bulk and surface micromachining techniques. The transducer membrane and cavity are defined on a SOI wafer and on a prime wafer, respectively. Two wafers are then bonded by using silicon direct bonding in a vacuum environment, together forming the transducer (Fig. 6) [14]. This new method improves CMUT performance since it decreases the number of process steps, device turn-around time, and increases the overall uniformity, reliability, repeatability.

Key Research Findings

Advantages of BAW Devices over SAW Devices

Acoustic biosensors generally employ BAW rather than SAW because BAW devices generate waves that mainly propagate in the shear horizontal motion. Since shear horizontal wave does not radiate significant amount of energy into liquids, it minimizes damping in the liquid operation. Besides few exceptions, the SAW sensor induces considerable surface-normal displacement that radiates compression waves into the liquid and causes excessive damping. Since biosensors detect chemicals in liquid solutions, BAW is often preferred over SAW for many biosensing applications [2].

Biological Applications of SH-APM Sensors

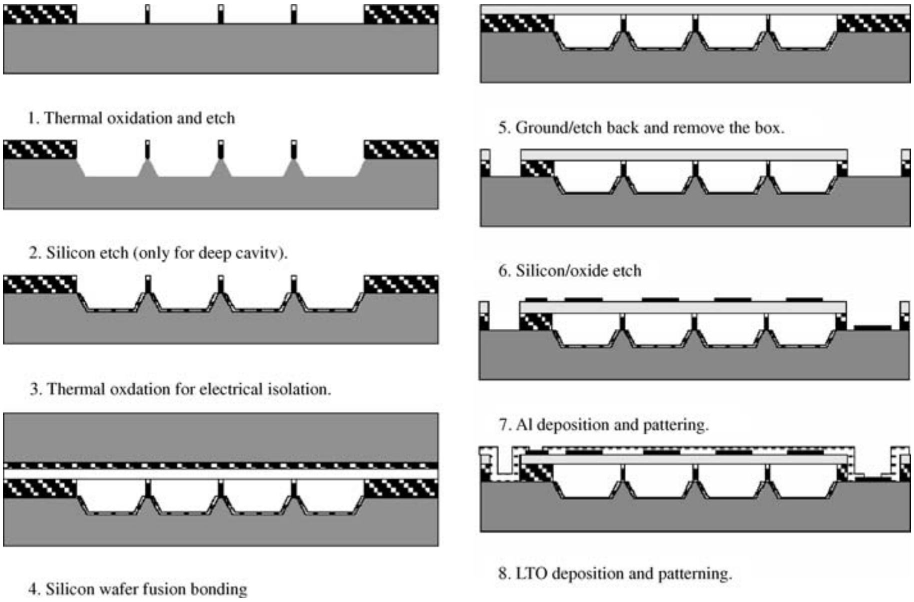
SH-APM sensors have been utilized in various biological applications. For example, Liren et al. [15] presented a urease biosensor in which a 0.5 mm thick ZX-$LiNbO_3$ substrate was used and a resonant frequency approximately centered at 50 MHz. APM was generated and detected by IDTs, with a period of 88 um and a center distance of 10 mm, on the same PZ crystal. The group also fabricated two pairs of IDTs on the substrate so that one would conduct biochemical reactions while the other acted as a reference. Using this device, they successfully measured urea concentrations by detecting variations in the resonant frequency [15].

SH-APM sensors have also been applied in immunochemical reactions. In order to observe antigen-antibody reactions through mass loading on the crystal surface, Dahint et al. [7] constructed an immunosensor using a 150 MHz APM device on a ZX-$LiNbO_3$ plate with a thickness of 0.5 mm. These sensors, which could detect mass as small as to 200 pg/mm^2 of crystal surface, marked a shift in resonant frequency of around 1 kHz upon antigen adsorption [7].

Biological Applications of TSM Resonators

Many biosensors that employ TSM resonators are available on the market today. Depending on their design, they can detect biological entities such as nucleic acids, viruses, bacteria, and cells. An example of TSM-based biosensor was presented by Davis et al. [16]. They used a coating of human IgG and subsequently used a TSM resonator to detect the presence of sheep antihuman IgG as marked by the decrease in the resonant frequency, signifying an increase in the mass loading from the attachment of the antibodies [16].

TSM sensors can also be used as DNA-based sensors. Okahata et al. [28] studied the use of oscillatory driven 9 or 27 MHz quartz to quantify DNA–DNA and DNA–protein interactions. They used quartz with one side specifically coated and the other side rubber cased, which was dipped into a stirred and thermostated solution of the target. Binding amounts were evaluated quantitatively as mass per unit area. Effects of probe immobilization tech-



Acoustics Based Biosensors, Figure 6 Major steps of CMUT fabrication with wafer bonding method. (Reprinted with permission from Ergun et al.[24])

niques, chain lengths, ionic strengths, temperatures and mismatches on hybridization, regulatory protein binding, and electrostatic effects in DNA-binding properties of lysine containing oligopeptides were evaluated quantitatively. In addition, Tessier et al. [22] used a TSM sensor, or specifically an antibody functionalized quartz sensor, to detect human erythrocytes. Adsorption and desorption studies of antibody conjugated phages at antigen immobilized TSM resonator-surfaces in a high-throughput set-up were also performed [4].

Biological Applications of SAW

SAW devices are useful in industrial and commercial applications of chemical and biological sensing. In biological applications, these devices can be used to detect molecules by mass. A potential application of SAW devices in biology is in building immunosensors. In a study, immunosensor SAW devices were first coated with a parylene thin film to create a chemically homogeneous layer. Then, photoactive and functional groups containing dextran were immobilized and antibodies were bonded. This sensor consisted of lithium tantalate substrate with gold transducers and used to monitor urease binding [10]. This sensor was applied to monitor the amount of the urea in human urine to diagnose the onset of liver and kidney diseases [10]. In addition, another study immobilized polysaccharides to a silicon oxide surface intended for SAW. The pneumococcal polysaccharide (PPS) vaccine can immobilize via Protein A after pre-treatment of the surface with hydrochloric acid. The results show that the immobilization of PPS via Protein A increased the sensitivity of Streptococcus pneumoniae antibodies detection in human serum when compared with ELISA [17]. This study shows that SAW sensors can be used in detection of microbial contaminants in the environment.

Advantages of CMUT Devices

Piezoelectric ultrasonic transducers are used to generate and detect ultrasound over the last 30 years. This technology gives a bandwidth as high as 60–80% and a high sensitivity [18]. Nevertheless, the piezoelectric transducers have disadvantages in air or fluid-coupled applications due to the impedance mismatch between the medium and the piezoceramic material. Moreover, it is an expensive technique and shows some restrictions for the 2D arrays. On the other hand, CMUT devices became an attractive alternative to piezoelectric transducers as they have inherently low mechanical impedance associated with a thin vibrating membrane. Thin membranes that are fully supported with insulating posts on all sides and these devices have the advantage of the good mechanical properties of silicone and silicone nitride [19]. As the mechanical impedance of such thin membranes is much closer to those of fluids in a wide frequency range, CMUTs are better in immersion applications than piezoelectric devices. Moreover, CMUTs are fabricated using standard micromachining processes and provide ease of fabrication, batch production, very high level of integration and repeatability. Tak-

ing advantage of the microfabrication techniques, these devices can provide the broad bandwidth and coupling efficiency required for high performance. Furthermore, this kind of ultrasonic transducers have the ability to make complex array designs using standard photolithographic techniques that makes them usable for imaging applications [19]. A transducer with a wider band increases the resolution as well as enabling the design of the image processed. In addition, CMUTs are an alternative for intravascular imaging systems as they can be microfabricated as small 2D imaging arrays and maintain electroacoustic performance [19].

Biological Applications of CMUTS

Today's ultrasound technology has a wide range of applications in industrial and medical field, from distance measurement to medical diagnostic imaging. The fields such as dermatology, ophthalmology, and cardiovascular medicine require ultrasonic imaging systems. CMUTs enable in vivo medical imaging at high frequencies. They are also used in the microfluidics and acoustic sensing, which have applications in the biomedical engineering.

Intravascular ultrasound (IVUS) is a medical imaging technique that uses ultrasound equipment with long, thin catheters and enables visualization of blood vessels through the blood column and inner wall of blood vessels. This gives information about cardiovascular diseases. In addition, a pulse-echo phased array B-scan sector, 1D linear CMUT array was produced by Demirci et al. [19] to demonstrate the viability of CMUTs for ultrasound imaging for medical applications. 64- and 128-element 1D CMUT arrays with 100% yield and uniform element response were fabricated. For imaging experiments, resolution test phantom was used to mimic the attenuation properties of soft tissue. The image quality was found in order to show the practicality of using CMUT devices for ultrasound medical imaging due to its wide bandwidth and high sensitivity. Current l-dimensional (1D) side looking ultrasound imaging probes do not have the forward viewing capability. Demirci et al. [19] showed forward-viewing annular CMUT arrays can be used for medical imaging applications. 64-element, forward-viewing annular arrays were fabricated and designed for imaging applications in the 20 MHz range. The devices operate in the 5–26 MHz range with a fractional bandwidth of 135%. These forward-viewing annular CMUT arrays are promising tools for measuring blood flow and imaging upon being mounted on the front surface of a cylindrical catheter probe [19]. Forward-viewing IVUS enables new procedures in cardiac medicine such as viewing blood vessels, guiding stent placement, and monitoring operations in the heart [20]. In addition, researchers focused on developing a forward-looking 2D imaging arrays that can be microfabricated and integrated with electronics. CMUTs are alternative tools for 2D medical imaging arrays. In a study, ring annular CMUT was used for forward-looking IVUS imaging at 16 MHz. This 1 mm diamater arrayed CMUT device was used for volumetric imaging and they were found to have potential use in IVUS imaging catheters [20]. Another study by Knight et al. [29] modeled and designed the CMUT membranes for performance in forward looking IVUS. They used finite element analysis to calculate the electromechanical coupling coefficient, k^2 and showed that the CMUT geometry can be optimized for maximum coupling coefficient, allowing CMUT IVUS array elements to be designed with more than 60 dB/V dynamic range with 10 MHz bandwidth around 20 MHz by fabricating a 1.02 mm diameter 64-element array [20]. A recent improvent in CMUT technology produces a three dimensional ultrasound imaging system using a forward-looking ring array with a diameter of 2 mm and 64 elements each 100 μm × 100 μm in size. 3D images of several wire targets and Palmaz–Schatz stents indicate the potential of imaging with such a device. In addition, further improvements point to a promising future for forward-viewing CMUT ring arrays in intravascular imaging [21]. CMUT devices are used in the real time in vivo imaging applications with an improved performance over the existing medical ultrasound transducers. A wafer bonded CMUT probe showed a bandwidth of 130 % (3–13 MHz), which covers nearly the entire frequency range for medical ultrasound applications. Carotid artery and thyroid gland were imaged with surface and bulk-micromachined CMUT arrays and real time in vivo images were compared with a PZT array. The bandwidth and resolution performance of the surface micromachined arrays were slightly better than PZT. However, depth of penetration was not as good as in PZT. Bulk micromachined CMUT arrays showed the first real-time in-vivo images and had improved resolution and bandwidth but less depth of penetration. As a result, improved axial resolution and extremely broad bandwidth are achieved by CMUTs. Improved axial resolution will allow smaller targets to be resolved in tissue for such applications as imaging micro-calcifications in the breast, small abnormalities in the thyroid, or better delineation of the intimal linings of blood vessels to search for plaque build-up [22].

Future Directions for Research

Advancements made over the past decades have culminated in the initiation and development of acoustic wave biosensors. The ability to detect biological molecules by

these sensors may contribute to treatment of many diseases such as HIV and cancer. In addition, these devices are promising in medical imaging given their ability to generate high-resolution pictures in real time. However, there are still limitations to some of these devices that can be surmounted through future research and though the potential of the application of these devices to biological situations has been recognized, more work is left to be done in order to employ them on a wider scale. Below are some limitations and potentials of the devices.

SAW Devices

There are a number of potential limitations with the SAW sensors as they are today. One limitation is that SAW sensors are sensitive to a variety of parameters [8]. In addition, the intensity of an acoustic wave can decrease in biological solution such that the sensing system may not work efficiently. Furthermore, many SAW devices that are used in the gas-sensing applications may not be used to detect molecules in the liquid phase. When a fluid contacts the SAW surface, the longitudinal wave component pumps a compression wave into the fluid [2]. In air, the energy losses are not too effective. However, in many liquids, all the energy is pumped out of the acoustic wave before it reaches the device's receiving transducer. SAW devices can perform well in liquids when they rely on surface waves with no longitudinal components like horizontally polarized shear waves, surface transverse waves, and the guided acoustic waves called "Love waves" [2]. Recent advances in liquid sensors and immunoassays improved the detection limits. In addition, surface technologies like functionalization with fluorescent probes, DNA, and enzymes increased the use of SAW devices in liquid samples [7]. There are also radar-type SAW sensors for high-voltage applications that detect at long distances. These sensors cannot be used scans of wider areas due to two main limitations. According to the radar equation, the radiofrequency signal changes with the fourth power of the distance between the radar unit and SAW sensor. As a result, high signal attenuation is governed by this equation. Second, only a few echo sounds can be distinguished because all sensors in the detection range respond immediately. Attaining this requires differentiated sensors that responds within different time slots, and multiple sensors can be used with a limited number of reflectors and limited identity-code capacity [25].

In addition, generation of acoustic waves in microstructures requires various processes and technologies, with compatibility as one of the main limitations in the development of smart sensors. Restrictions of manual handling and fabrication process limit minimum thickness of the devices to be about 100 microns. Adoption of silicon fabrication opens the possibility for the integration of the acoustic devices and electronic driving circuitry, leading to the development of smart sensors. This technique involves localization of specific fabrication steps to common areas to minimize the total number of process steps in the fabrication process as well as to maintain SAW and Lamb wave device integrity and quality [26].

Most of today's acoustic wave generation and focusing apparatus suffer from these further limitations: The piezoelectric arrays are expensive, and it is hard to get high-level, well-distributed intensities. In addition, shocks are generated at a rate of one or two shocks per second, whereas extracorporeal shockwave treatment (ESWT) typically requires thousands of shocks per treatment. Acoustic lenses are mostly fragile and non-effective for larger apertures. Moreover, electrohydraulic approach has disadvantages of non-uniform discharges, pain and high noise level.

BAW Devices – TSM Resonator

The limitations of TSM resonators are mostly related with the experimental setup, accuracy in modeling the sensor and physical behavior of a viscoelastic polymer. Researchers should be careful in model approximations, parameter estimations, and measurement errors. For acoustically thin polymers, the thickness can be calculated with a small error, but the shear moduli can hardly be extracted from measurements due to negligible influence on the sensor behavior. On the other hand, the coating thickness should be known because of the existence of multipleidentical solutions for acoustically thick polymers [27]. In addition, for detailed interpretation of sensor response in liquid requires more sophisticated experimental setup [4]. In addition, mechanical, optical, and electrochemical properties are helpful to characterize interactions at biological surfaces and interfaces. However, the needed equipment are expensive. While miniaturized quarts arrays seem to present a solution for low cost sensor setups, miniaturization has its limitations because small electrode areas can load enough molecules to achieve measurable frequency shifts. As a solution, combination of automatized pipetting systems, microfluidics, integrated sensor arrays and multicomponent data analysis may open the way towards high throughput screening with acoustic wave sensors [4].

Two major challenges are present in the application of TSM resonator as a biosensor. First, cross reactions such as unspecific protein adsorption affects the accuracy of the results. This limits the resonator's use to binding sites that specifically bond to the targeted biological molecules

and poses a significant disadvantage in environments containing various compounds. Second, since the resonator only responds to mass loadings, the analysis cannot differentiate this signal from other factors that can affect the resonant frequency such as viscoelasticity and acoustic coupling effect. This leads to a disagreement between the experimental and theoretical values of mass uptake, an error that needs to be accounted for by researchers [4]. Immunochemical analyzes or nucleic acid hybridization results of TSM resonators should always be coupled with a reference analysis method. In addition, dry- and wet-coated TSM resonators may not give the same results due to changes in viscoelasticity, so calibration should be done in the sensing medium during nucleic acid analyzes. Complexation of DNA may limit the flexibility of the molecule strands and ionic strength changes or interaction with the surface might vary extension and shape of the molecule. These may change viscoelastic behavior and produce erroneous results from TSM resonators [4].

CMUTs

CMUTs have the potential to make ultrasound a far more versatile and important imaging modality. This technology has made advances in acoustic matching and the micro-miniaturization of electronics. It enables higher frequency imaging, allows clinicians to view small features in the body, and is useful for ultrasound imaging especially in the area of volumetric in vivo imaging, intravascular, and intracardiac research.

Synonyms

Steady streaming; Eulerian streaming

Definition

Acoustic streaming is a secondary steady flow generated from the primary oscillatory flow. It includes not only the Eulerian streaming flow caused by the fluid dynamical interaction but also the Stokes drift flow which arises from a purely kinematic viewpoint.

Overview

Acoustic streaming originates from the acoustics. When the compressible fluid experiences a high-frequency oscillation driven by a certain source of sound, the nonlinear interaction causes a steady current in the field. This phenomenon is usually referred to as acoustic streaming. However, it was found that even an incompressible fluid can produce such steady streaming when the fluid oscillates adjacent to a certain obstacle or an interface. So, as pointed out by Riley [1], the term *acoustic streaming* is misleading. Instead of acoustic streaming he insisted on using *steady streaming* to encompass the case of incompressible fluid. *Acoustic streaming* in this article means both of these effects.

Another important issue that must be addressed is, whether or not the Stokes drift flow should be included in the streaming flow category. The Stokes drift flow is purely kinematic and so it is basically different from the Eulerian streaming flow, which is driven by the time average of the Reynolds stress term. However, the mass-transport effect given by the Stokes drift flow is not weaker than the Eulerian streaming. On the contrary, in the case of a progressive wave, the Stokes drift flow plays a dominant role (e. g., application of flexural plate waves to pumping and mixing in microfluidics [2]). Therefore, the Stokes drift flow must be understood as a kind of streaming flow.

Unfortunately, little is known about the historical background to the study of acoustic streaming. Therefore, instead of trying to give the historical background of the general concept, we will briefly survey the modeling and applications of acoustic streaming in microfluidics. A survey of steady streaming flow has been given by Riley [1].

In the early period, study mainly focused on the acoustic streaming of compressible fluids. The simplest and seminal phenomenon associated with acoustic streaming is the *quartz wind*. When the air experiences a high-frequency oscillation given by an ultrasound source, a progressive wave is established in the air. Due to the attenuation of the wave, a nonzero time averaged Reynolds stress is built in the region close to the sound source, and this stress pushes the air in the direction of wave propagation. The resultant wind is called a quartz wind. Lighthill [3] has provided a physical and simple analytical treatment of this steady streaming flow. Another important phenomenon is the so-called Kundt's dust pattern. When the air within a duct receives a standing wave, a nonzero time average of the Reynolds stress is built inside the duct. Due to the interaction between the air and the duct wall, a steady recirculating flow takes place within the duct. The net effect is that dust or particles accumulate at nodes.

On the other hand, researchers interested in mass transport in water waves have shown that a similar phenomenon occurs for incompressible flow (see [4] for an example). The salient feature is when an obstacle oscillates with high frequency in the quiescent viscous fluid. In this case the steady streaming emerges from both sides of the obstacle along the oscillating direction at small viscosity [5].

In this article, we will describe in some detail the fundamentals of three types of streaming flows associated with the microfluidic applications. First, the quartz wind which corresponds to the one-dimensional compressible flow will be introduced. Second, the Eulerian streaming flow

in two-dimensional space will be considered. Kundt's dust phenomenon will also be explained. Finally, we address the flexural plate wave and its net effect, i.e., the Stokes drift flow.

Basic Methodology

One-Dimensional Compressible Flow Model – Quartz Wind

In this and next subsections we closely follow the review by Riley [1] to describe the physical mechanism of acoustic streaming. We first consider the case when the sound is generated from a source and travels along a certain direction, say the x^*-direction, in a space. The governing equation for the motion of the compressible fluid is

$$\frac{\partial \rho^*}{\partial t^*} + \frac{\partial \rho^* u^*}{\partial x^*} = 0 \tag{1a}$$

$$\frac{\partial u^*}{\partial t^*} + u^* \frac{\partial u^*}{\partial x^*} = -\frac{1}{\rho^*}\frac{\partial p^*}{\partial x^*} + \frac{4}{3}\nu \frac{\partial^2 u^*}{\partial x^{*2}} \tag{1b}$$

where u^* is the flow velocity, p^* the pressure, t^* the time, ρ^* the density of the fluid and ν the kinematic viscosity of the fluid. The fluid particle is assumed to oscillate back and forth with amplitude A_0, frequency ω, and wavelength λ. We then take $1/\omega$, $\lambda/2\pi$, $A_0\omega$, and $\rho_0^* A_0 \omega^2(\lambda/2\pi)$ as the reference quantities for the time, length, velocity, and pressure, respectively. Further, we expand the density as

$$\rho^* = \rho_0^* (1 + \varepsilon\rho_0 + \varepsilon^2 \rho_1 + \ldots) \tag{2}$$

where ρ_0^* corresponds to the undisturbed fluid density. We also expand the dimensionless velocity and pressure, respectively, as

$$u = u_0 + \varepsilon u_1 + \varepsilon^2 u_2 + \ldots \tag{3a}$$

$$p = p_0 + \varepsilon p_1 + \varepsilon^2 p_2 + \ldots \tag{3b}$$

Then the leading-order equations of Eqs. (1a) and (1b) for the small value of the parameter ε become

$$\frac{\partial \rho_0}{\partial t} + \frac{\partial u_0}{\partial x} = 0 \tag{4a}$$

$$\frac{\partial u_0}{\partial t} = -\frac{\partial p_0}{\partial x} + \frac{4}{3}\delta \frac{\partial^2 u_0}{\partial x^2} \tag{4b}$$

where the variables without an asterisk are dimensionless. Here, the two dimensionless parameters are

$$\varepsilon = \frac{A_0}{\lambda/2\pi}, \quad \delta = \frac{\nu}{\omega(\lambda/2\pi)^2} \tag{5}$$

which can be considered as the dimensionless amplitude of the flow motion and the inverse of the Reynolds number, respectively. As usual, these parameters are assumed to be small. To solve this system of equations we eliminate the perturbed density in Eq. (4a) and the pressure in Eq. (4b) by using the definition of sound

$$\frac{\partial p^*}{\partial \rho^*} = c^{*2} = \omega^2 (\lambda/2\pi)^2 \tag{6}$$

We then have

$$\frac{\partial^2 u_0}{\partial t^2} - \frac{\partial^2 u_0}{\partial x^2} - \frac{4}{3}\delta \frac{\partial^3 u_0}{\partial t \partial x^2} = 0 \tag{7}$$

The solution of this equation is

$$u_0 = \exp(-2\delta x/3)\cos(x - t) \tag{8}$$

Notice that the basic mode is progressive. We need the next higher-order equation of Eq. (1b), which is

$$\frac{\partial u_1}{\partial t} + \frac{\partial p_1}{\partial x} - \frac{4}{3}\delta \frac{\partial^2 u_1}{\partial x^2} = -u_0 \frac{\partial u_0}{\partial x} \tag{9}$$

The right-hand side term can be understood as a dimensionless force per unit mass. Substituting Eq. (8) into the right-hand side gives

$$-u_0 \frac{\partial u_0}{\partial x} = \exp(-4\delta x/3) \left[\frac{\delta}{3} + \frac{\delta}{3}\cos 2(x-t) + \frac{1}{2}\sin 2(x-t)\right]$$

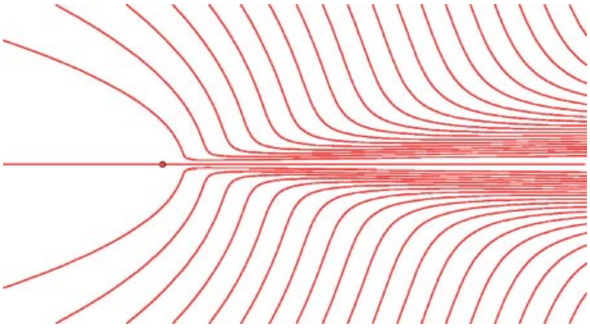
Taking the time average over one period (the operation to be denoted as $\langle\rangle$) of this provides

$$-\left\langle u_0 \frac{\partial u_0}{\partial x}\right\rangle = \frac{\delta}{3}\exp(-4\delta x/3) \tag{10}$$

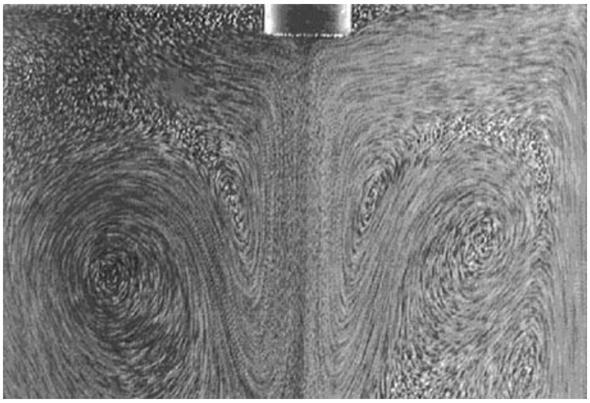
which plays a role as the driving force for the generation of the steady flow $\overline{u}_1$. Taking the time average of Eq. (9) results in

$$\frac{\partial \overline{p}_1}{\partial x} - \frac{4}{3}\delta \frac{\partial^2 \overline{u}_1}{\partial x^2} = -\left\langle u_0 \frac{\partial u_0}{\partial x}\right\rangle \tag{11}$$

It should be noted that the term (10) can be understood as a kind of body force. Lighthill [3] has presented solutions of this system of equations for the case in which the force (10) acts as a point source in an infinite space. It is seen that when the viscosity is low enough (at high streaming Reynolds numbers) the flow from the source is like a jet as shown in Fig. 1. This flow is sometimes called the *quartz wind*. The term *acoustic streaming* refers



Acoustic Streaming, Figure 1 Acoustic streaming *quartz wind* generated from a point source of ultrasound



Acoustic Streaming, Figure 2 Acoustic streaming generated from an actual ultrasonic transducer

to this flow in the case of ultrasound. As can be seen from Eq. (10), the driving force for this current vanishes when there is no attenuation, i. e., when $\delta = 0$. Therefore we can say that the acoustic streaming in for the case of ultrasound in a compressible fluid is attributed to the attenuation of sound. The photograph in Fig. 2 clearly shows the streaming flow ejected by the transducer that creates the ultrasound.

On the other hand, we can also calculate the Stokes drift velocity from the solution of Eq. (8). We can follow a certain fluid particle's path $x(x_0, t)$, where x_0 is a reference point independent of the time. From the definition of the flow velocity we can write

$$\frac{dx}{dt} = \varepsilon u \tag{12}$$

We substitute Eq. (8) into the right-hand side of this and let $x = x_0 + \varepsilon x_1(t)$. We then have

$$x_1 = -\exp(-2\delta x_0/3)\sin(x_0 - t) \tag{13}$$

and

$$u_0 = -\exp(-2\delta x_0/3)\cos(x_0 - t) + \left(\frac{\partial u_0}{\partial x}\right)_{x=x_0} \varepsilon x_1 \tag{14}$$

Here again the last term contains the steady component and it becomes

$$\varepsilon u_{\mathrm{d}} = \frac{1}{2}\varepsilon \exp(-4\delta x_0/3) \tag{15}$$

which is known as the Stokes drift velocity. The steady streaming flow $\varepsilon \overline{u}_1$ given by the solution of Eq. (11) is called the Eulerian streaming flow. Compared with the Eulerian streaming flow, the Stokes drift flow is confined in a region close to the sound source, i. e., within the region $x = O(1/\delta)$. Actually this region corresponds to the one that the force (10) acts upon. That is, within this region the steady flow velocity is composed of the Eulerian streaming velocity and the Stokes drift velocity

$$u_{\mathrm{L}} = \varepsilon \overline{u}_1 + \varepsilon u_{\mathrm{d}} \tag{16}$$

which is known as the Lagrangian velocity. Beyond this region the Stokes drift flow vanishes and only the Eulerian streaming exists. In many cases the Stokes drift velocity is ignored, but when the location of interest is not far from the sound source it should be considered. In general, the Stokes flow is expected to occur only when the primary wave is progressive, not when it is standing.

Eulerian Streaming

Even the incompressible fluid can also give rise to Eulerian streaming flow when a solid obstacle is in contact with the oscillating fluid. Consider a two-dimensional incompressible flow around a solid body governed by the following dimensionless equations:

$$\nabla \cdot \mathbf{u} = 0 \tag{17a}$$

$$\frac{\partial \mathbf{u}}{\partial t} + \varepsilon \mathbf{u} \cdot \nabla \mathbf{u} = -\nabla p + \frac{1}{\mathrm{Re}}\nabla^2 \mathbf{u} \tag{17b}$$

where $\mathbf{u} = (u, v)$ and ∇ is the two-dimensional gradient operator. We use $1/\omega$, L, $A_0\omega$ and $\rho^* A_0 \omega^2 L$ as the reference quantities for the time, length, velocity and pressure, respectively. Note that the reference length L used here represents a typical dimension of the obstacle. The Reynolds number Re defined as

$$\mathrm{Re} = \frac{\omega L^2}{\nu}$$

is assumed to be large. For the small value of ε, we expand

$$(\mathbf{u}, p) = (\mathbf{u}_0, p_0) + \varepsilon(\mathbf{u}_1, p_1) + \dots . \tag{18}$$

The leading-order equation of Eq. (17b) is then

$$\frac{\partial \mathbf{u}_0}{\partial t} = -\nabla p_0 \tag{19}$$

Therefore the leading-order solution is of potential flow. Moreover the solutions can take a separable form, e. g.

$$\mathbf{u}_0 = \mathbf{f}(x, y)\exp(\mathrm{i}t) \tag{20}$$

where the complex functions $\mathbf{f}$ must satisfy the continuity equation (17a) and $\mathrm{i} = \sqrt{-1}$ denotes the imaginary unit. Note that the inviscid region governed by these equations comprises most of the flow domain except the thin layer near the solid boundary.

Since the potential flow solution (Eq. (20)) does not satisfy the no-slip condition on the solid surface, we must consider a thin layer (called the Stokes layer) adjacent to the surface $n = 0$, where n refers to the local coordinate normal to the wall. In this thin layer, we use the strained coordinate Y defined as

$$n = \sqrt{2/\mathrm{Re}}\, Y$$

We also use the velocity components U and V along the local coordinates s and n, respectively (the coordinate s is along the surface). Then the boundary layer equation becomes

$$\frac{\partial U}{\partial t} - \frac{\partial u_\mathrm{e}}{\partial t} = \frac{1}{2}\frac{\partial^2 U}{\partial Y^2} - \varepsilon\left(U\frac{\partial U}{\partial s} + V\frac{\partial U}{\partial n}\right) \tag{21}$$

where $u_\mathrm{e}(s)$ denotes the tangential component of the potential flow velocity evaluated at the solid surface. We expand the velocity components as before.

$$(U, V) = \left(U_0, \sqrt{2/\mathrm{Re}}V_0\right) + \varepsilon\left(U_1, \sqrt{2/\mathrm{Re}}V_1\right) + \dots \tag{22}$$

The leading-order equation is

$$\frac{\partial U_0}{\partial t} - \frac{\partial u_{0\mathrm{e}}}{\partial t} = \frac{1}{2}\frac{\partial^2 U_0}{\partial Y^2}$$

whose solution takes the following form:

$$U_0 = u_{0\mathrm{e}}(s)\left[1 - \exp(-(1+\mathrm{i})Y)\right]\exp(\mathrm{i}t) \tag{23}$$

The normal component V_0 can also be obtained from the continuity equation. Note that this flow is still time periodic. The $O(\varepsilon)$ equation (21) then becomes

$$\frac{\partial U_1}{\partial t} - \frac{\partial u_{1\mathrm{e}}}{\partial t} = \frac{1}{2}\frac{\partial^2 U_1}{\partial Y^2} - \left(U_0\frac{\partial U_0}{\partial s} + V_0\frac{\partial U_0}{\partial Y}\right) \tag{24}$$

Here our interest is the time independent flow. Taking the time average of the above equation over one period of oscillation gives

$$\frac{1}{2}\frac{\partial^2 \overline{U}_1}{\partial Y^2} = \left\langle U_0\frac{\partial U_0}{\partial s} + V_0\frac{\partial U_0}{\partial Y}\right\rangle \tag{25}$$

The solution of this equation yields the streaming velocity at the edge of the boundary layer,

$$\overline{U}_{1\infty} = -\frac{3}{8}\left[(1-\mathrm{i})u_{0\mathrm{e}}^{\#}\frac{\mathrm{d}u_{0\mathrm{e}}}{\mathrm{d}s} + (1+\mathrm{i})u_{0\mathrm{e}}\frac{\mathrm{d}u_{0\mathrm{e}}^{\#}}{\mathrm{d}s}\right] \tag{26}$$

where the superscript # denotes the complex conjugate. This velocity then acts as a boundary condition for the exterior bulk region. The governing equation of the steady streaming flow takes the following form [1]:

$$(\overline{\mathbf{u}} + \overline{\mathbf{u}}_\mathrm{d})\cdot\nabla\overline{\mathbf{u}} = -\nabla\overline{p} + \frac{1}{\mathrm{Re}_\mathrm{s}}\nabla^2\overline{\mathbf{u}} \tag{27}$$

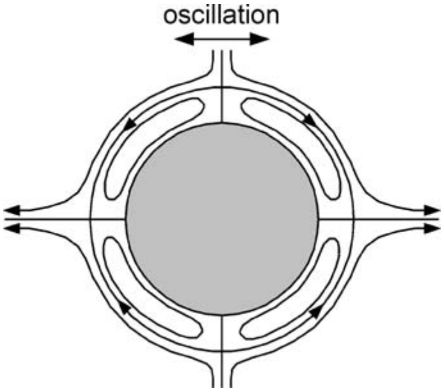
where Re_s is the streaming Reynolds number based on the streaming velocity at the edge of the Stokes layer; $\mathrm{Re}_\mathrm{s} = \varepsilon^2\mathrm{Re}$. This equation looks very similar to the Navier–Stokes equation, but here the convective velocity is replaced by the Lagrangian velocity $\overline{\mathbf{u}}_\mathrm{L} = \overline{\mathbf{u}} + \overline{\mathbf{u}}_d$.

The above formulation is effective and suitable when the streaming Reynolds number is large so that the Reynolds stress action is confined within the thin Stokes layer. In the microfluidic application, however, Re_s is usually small. So, the Reynolds stress term may be added to the streaming-flow equation (27) so that

$$(\overline{\mathbf{u}} + \overline{\mathbf{u}}_\mathrm{d})\cdot\nabla\overline{\mathbf{u}} = -\nabla\overline{p} + \frac{1}{\mathrm{Re}_\mathrm{s}}\nabla^2\overline{\mathbf{u}} - \mathbf{F} \tag{28a}$$

$$\mathbf{F} = \langle\, (\mathbf{U}_0\cdot\nabla)\mathbf{U}_0 + \mathbf{U}_0(\nabla\cdot\mathbf{U}_0)\,\rangle \tag{28b}$$

where the second term within $\langle\,\rangle$ on the right-hand side is nonzero for the compressible fluid case; for the compressible fluid case Eq. (28a) itself must be modified. This means that for the case with a low streaming Reynolds number, Eq. (28a) must be solved over the whole domain including the Stokes layer. Another important point for the incompressible flow is that the Reynolds stress vanishes when the primary oscillating flow is of the progressive-wave type. On the other hand, it should be noted that in



Acoustic Streaming, Figure 3 Sketch of the flow structure of the Eulerian streaming around a circular cylinder oscillating at a high frequency in a viscous fluid

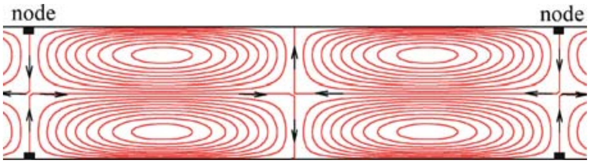
the microfluidic area no literature has taken into account the Stokes drift flow in the convecting velocity (i. e., the velocity $(\overline{\mathbf{u}}+\overline{\mathbf{u}}_{\mathrm{d}})$ in Eq. (28a)) in the numerical simulation of the streaming flow.

We can experience a typical example of the Eulerian streaming flow around a circular cylinder [5]. Here, the fluid surrounding the cylinder oscillates with high frequency; or the cylinder may oscillate in the otherwise quiescent fluid without fundamental difference in the results. The steady flow within the Stokes layer at high streaming Reynolds numbers shows four-cell structure around the circular cylinder as shown in Fig. 3. There are two streams coming out of the cylinder from both sides in the direction of oscillation.

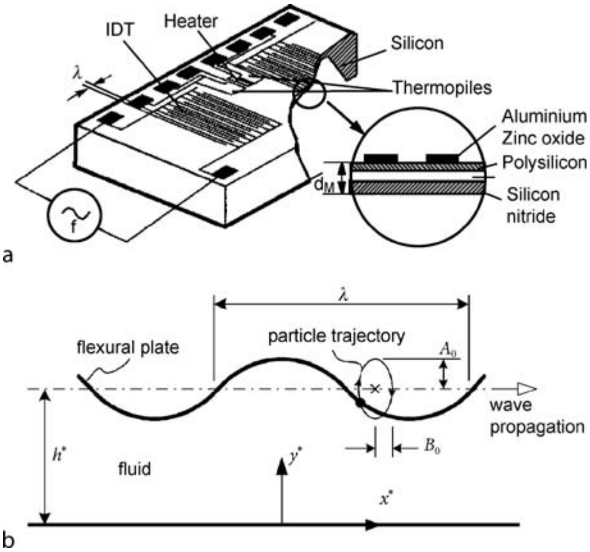
Kundt's dust pattern manifests another simple example of the Eulerian streaming flow given by the two-dimensional standing wave in a duct. When an acoustic standing wave is established in the duct with a compressible fluid, the steady streaming reveals four-cell structure over a half wavelength (or over the space between two neighboring nodes) as shown in Fig. 4. Near the duct wall, the steady streaming is toward the nodes, and near the duct center it is coming out of the nodes. Therefore dust within the duct should cluster near the nodal points of the standing wave. The detailed solution for this case has been given by Riley [1].

Stokes Drift Flow

Usually, by acoustic streaming we mean *Eulerian* streaming. However, the recent application of the flexural plate wave in microfluidics implies that the Stokes drift flow should also be considered as a type of steady streaming flow, because the net effect in the fluid transport is not discernable between the two. Here we derive the equations



Acoustic Streaming, Figure 4 Eulerian streaming flow occurring between two parallel plates when a standing wave takes place inside the duct. Distance between the nodes corresponds to a half wavelength of the standing wave



Acoustic Streaming, Figure 5 Microfluidic device utilizing the flexural plate wave. (**a**) Fabricated device; (**b**) shape of the flexural plate and the coordinates for analysis

as well as the solutions for the Stokes drift flow given by the flexural plate wave. The case of one-dimensional compressible flow has already been treated in this article.

Consider a viscous fluid confined between a flat wall at $y^* = 0$ and a flexural plate at $y^* = h^*$. The flexural plate oscillates showing a traveling wave with a high frequency ω by a well established piezoelectric vibration system. Fig. 5 illustrates the geometry of the flow model investigated in this article. The wavelength is λ and the wave propagation speed is $c^* = \omega\lambda/2\pi$. A particle attached on the flexural plate describes an ellipse with major A_0 and minor $B_0 = rA_0$ rotating clockwise when the wave travels toward the right-hand side as shown in Fig. 5 [2]. The ratio r is given from $r = \pi d/\lambda$, where d is the membrane thickness. A typical value of r is 0.1. The spatial coordinate x^* is along the wave propagation direction and y^* normal to it.

As before we use $1/\omega$ as the time scale, $\lambda/2\pi$ as the length scale, $A_0\omega$ as the velocity scale and $\rho A_0\omega^2\lambda/2\pi$ as

the pressure scale, then the dimensionless continuity and momentum equations take the form given in Eqs. (17a) and (17b). The equations for the particle motion on the flexural plate are

$$\delta x = -r\varepsilon \sin(x_0 - t) \tag{29a}$$

$$\delta y = \varepsilon \cos(x_0 - t) \tag{29b}$$

As a typical example, for $\lambda = 100\,\mu\text{m}$, $d = 3\,\mu\text{m}$, $A_0 = 6\,\text{nm}$, and the frequency $\omega/2\pi = 3\,\text{MHz}$, we have $A_0\omega = 113\,\text{mm/s}$, $\varepsilon = 3.8\times10^{-4}$, and $\text{Re} = 4760$. The boundary conditions are

$$u = 0 \qquad \text{at } y = 0 \tag{30a}$$

$$v = 0 \qquad \text{at } y = 0 \tag{30b}$$

$$u = r\cos(x - t) \qquad \text{at } y = h \tag{30c}$$

$$v = \sin(x - t) \qquad \text{at } y = h \tag{30d}$$

where h is the dimensionless depth of the fluid layer. The velocity conditions, Eqs. (30c) and (30d), are derived from Eqs. (29a) and (29b), respectively. In this derivation we simply replaced x_0 by x, which is valid for small r; later we will consider the higher-order effect.

As before, we neglect the nonlinear term in Eq. (17b). We also assume that Re is very large. Equation. (17b) then becomes

$$\frac{\partial \mathbf{u}}{\partial t} = -\nabla p \tag{31}$$

This indicates that the velocity field can be described by a potential function $\phi(x, y, t)$ in such a way that $\mathbf{u} = \nabla\phi$. As usual, this inviscid solution must satisfy the boundary condition for the normal component of the velocity at each of the walls but not the tangential component. This is the most important part of the analysis, because otherwise the leading-order solution is not of the progressive-wave type. Applying the conditions given in Eqs. (30b) and (30d) to the Laplace equation $\nabla^2\phi = 0$ and solving for ϕ, we obtain $\phi = (\cosh y/\sinh h)\sin(x - t)$ and

$$u = \frac{\cosh y}{\sinh h}\cos(x - t) \tag{32a}$$

$$v = \frac{\sinh y}{\sinh h}\sin(x - t) \tag{32b}$$

The bulk flow solution given by Eqs. (32a) and (32b) does not satisfy the condition for the tangential component of the velocity on the walls. So, we must expect boundary layers near each of the walls. First, near the top wall, $y = h$, we use the strained variable $Z = (h - y)\sqrt{\text{Re}/2}$. Then we obtain the appropriate x-momentum equation and solve for u to obtain

$$u = \coth h\,\cos(x - t) + (r - \coth h)\exp(-Z)\cos(x + Z - t) \tag{33}$$

A similar process leads to the following solution for u in the bottom boundary layer:

$$u = \frac{1}{\sinh h}\left[\cos(x - t) - \exp(-Y)\cos(x + Y - t)\right] \tag{34}$$

where $Y = y\sqrt{\text{Re}/2}$.

The analytical solutions obtained so far imply that the flow field driven by the oscillating flexural plate is progressive. This means that the Reynolds stress should vanish and so there should be no Eulerian streaming. On the other hand, it produces the nonzero Stokes drift flow. First we consider the bulk flow. Into the definition of the velocity components u and v, i. e., $\mathrm{d}x/\mathrm{d}t = \varepsilon u$ and $\mathrm{d}y/\mathrm{d}t = \varepsilon v$, we substitute Eqs. (32a) and (32b). Assuming the variables x and y on the right-hand side are constant, i. e. $x = x_0$ and $y = y_0$, we can integrate the equations to obtain

$$x = x_0 - \varepsilon\frac{\cosh y_0}{\sinh h}\sin(x_0 - t) \tag{35a}$$

$$y = y_0 + \varepsilon\frac{\sinh y_0}{\sinh h}\cos(x_0 - t) \tag{35b}$$

Now we substitute Eqs. (35a) and (35b) into Taylor expansions for u and v, i. e., Eqs. (32a) and (32b) about $(x, y) = (x_0, y_0)$ and take the time average over one period to obtain the steady velocity components $\overline{v} = 0$ and

$$\overline{u} = \frac{\varepsilon}{2\sinh^2 h}(\cosh^2 y + \sinh^2 y) \tag{36}$$

Next, we consider the top boundary layer. After some algebra we obtain $\overline{v} = 0$ and

$$\begin{aligned}\overline{u} = \frac{\varepsilon}{2}\Bigg\{&\left[\frac{\cosh y}{\sinh h}(1 - A) + rA\right]^2 \\ &+ \frac{\sinh y}{\sinh h}(1 - A)\left[\frac{\sinh y}{\sinh h}(1 - A) + A + r(y - h)A\right] \\ &+ B^2\left(r - \frac{\cosh y}{\sinh h}\right)^2 \\ &+ B^2\frac{\sinh y}{\sinh h}\left[\frac{\sinh y}{\sinh h} - r(y - h)\right]\Bigg\}\end{aligned} \tag{37}$$

where functions A and B are

$$(A, B) = \exp(-Z)(\cos Z, \sin Z)$$

Similar treatment can be done for the bottom boundary layer and we obtain $\overline{v} = 0$ and

$$\overline{u} = \frac{\varepsilon}{2\sinh^2 h}\left[1 - 2\exp(-Y)\cos Y + \exp(-2Y)\right] \quad (38)$$

Now, the complete formula for the streaming velocity applicable to all the regions including the two boundary layers is $\overline{v} = 0$ and

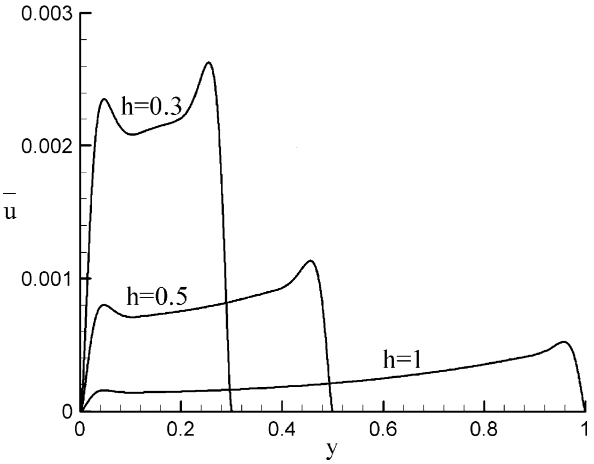
$$\begin{aligned}\overline{u} = \frac{\varepsilon}{2}\Bigg\{&\left[\frac{\cosh y}{\sinh h}(1-A) + rA\right]^2 \\ &+ \frac{\sinh y}{\sinh h}(1-A)\left[\frac{\sinh y}{\sinh h}(1-A) + A + r(y-h)A\right] \\ &+ B^2\left(r - \frac{\cosh y}{\sinh h}\right)^2 \\ &+ B^2\frac{\sinh y}{\sinh h}\left[\frac{\sinh y}{\sinh h} - r(y-h)\right] \\ &+ \frac{1}{\sinh^2 h}\left[\exp(-2Y) - 2\exp(-Y)\cos Y\right] - r^2\frac{y}{h}\Bigg\}\end{aligned} \quad (39)$$

As a typical example, for the case with $\lambda = 100\,\mu\text{m}$ and $h^* = 50\,\mu\text{m}$, we have $h = \pi$, and for $\varepsilon = 3.8 \times 10^{-4}$ and $\text{Re} = 4760$ we evaluate $\overline{u} = 3.8 \times 10^{-4}$ as the approximately maximum streaming velocity obtained from the bulk-flow solution (Eq. (36)) at $y = h$. When the velocity scale is $A_0\omega = 113\,\mu\text{m}$, this becomes $\overline{u}^* = 43\,\mu\text{m/s}$. This is not much different from the measured velocity (less than $100\,\mu\text{m/s}$) reported by Nguyen et al. [2], considering that the numerical result $1000\,\mu\text{m/s}$ obtained by them is more than 10 times the measured value for the same parameter set.

Figure 6 shows distributions of the streaming velocity for three depths of the fluid layer with the parameter set presented previously. The magnitude of streaming velocity increases on the whole as the depth decreases. Further decrease of h results in the overlap of the top and bottom boundary layers, and so the analytical solutions presented so far may not hold in that case.

The flow rate through the channel is given by

$$q = \int_0^h \overline{u}\,\mathrm{d}y$$



Acoustic Streaming, Figure 6 Distributions of the Stokes drift velocity across the fluid layer for three channel depths given by the flexural plate wave

Substituting the streaming velocity distribution (Eq. (39)) into this yields the following formula.

$$q = \frac{\varepsilon}{2\sinh^2 h}\left[\sinh h \cosh h - \sqrt{2/\text{Re}}\left(1 + \frac{7}{8}\sinh^2 h\right)\right] \quad (40)$$

At high Reynolds numbers, the second term within [ ] on the right-hand side of the above equation can be neglected and so the flow rate increases as the channel depth decreases, in line with the numerical result of Nguyen et al. [2]. On the other hand, when the second term is considered the flow rate shows a maximum value at a critical depth. Figure 7 shows the dependence of the flow rate on the depth at three Reynolds numbers and at the other parameter values the same as those presented previously. It indeed shows that at each of the critical depths, the flow rate has a maximum value. The critical depth increases as the Reynolds number decreases. It can be shown that the critical depth is given by the formula

$$h_c = \sinh^{-1}\left(\sqrt{\frac{8}{\text{Re} - 8}}\right) \quad (41)$$

For instance, at $\text{Re} = 4760$ we obtain $h_c = 0.041$ which corresponds to $h_c^* = 0.65\,\mu\text{m}$ at $\lambda = 100\,\mu\text{m}$. This is very small compared with the wavelength, but it is still far larger than the amplitude of the oscillation of the plate, $A_0 = 6\,\text{nm}$.

Key Research Findings

Acoustic streaming has been applied to various microfluidic areas. White's group [2] have developed micropumps that utilize the flexural plate wave as the actuator. They have conducted a numerical simulation but the deviation was significant; their simulation results had to be corrected by a factor of 7 in order to fit the measurement data. To date, no report has been given of a satisfactory agreement between the experimental measurements and numerical or theoretical predictions. The numerical computation for acoustic streaming is not as simple as it looks. There are two key factors which may degrade the numerical results: one arises from the thin Stokes layer and the other from the extremely low levels of the streaming velocity compared with the primary flow. These can be overcome when we put very fine grids near the Stokes layer and simultaneously use high-precision numerical values.

In order to apply acoustic streaming to fluid mixing, Yaralioglu et al. [7] designed patterns of piezoelectric transducers on the bottom wall of a microchannel. They verified experimentally that the transducers, by generating acoustic streaming inside the channel normal to the main flow, enhanced the mixing. The mixing effect was, of course, affected by the configuration of the electrode patterning. They also asserted that the fundamental problem of the formation of bubbles and unintended heating of the fluid was not expected to occur in their system.

Acoustic streaming has also been applied to electrochemistry. Compton's group [8] has tested the use of ultrasound to study the effect of the various configurations of the acoustic streaming on the limiting current from an electrode. It was shown that there was a critical diffusion layer thickness below which the layer no longer became thinner. Recently they performed a numerical simulation on the acoustic streaming over an electrode within an axisymmetric space. The streaming flow was generated by the Reynolds stress terms formulated by other investigators. They successfully verified the previous experimental results that acoustic streaming was the principle mechanism of enhanced mass transport in sono-electrochemical cells.

Ultrasonics and its universal effect (acoustic streaming) have been used to manipulate particles in microfluidic devices, e. g., trapping, collection, separation, and deposition. For instance, Petersson et al. [9] employed a microchannel system with one center and two side channels at the inlet and outlet, respectively, of the channel. Through the side inlet channels they put a medium, say fluid A, containing particles, and through the center inlet channel the fluid B containing no particles. They then applied ultrasound normal to the channel in such a way that a standing wave was established in the main channel where the two media contacted each other. Due to the Reynolds stress and recirculating streaming flows, particles were collected near the channel center and this pattern persisted all the way through the main channel. At the outlet, the particles flow with the fluid B. They implied that such a medium-exchange effect could be applied to blood washing.

Marmottant and Hilgenfeldt [10] have considered bubble-driven microfluidic transport for bioengineering applications. In their experiment, bubbles were adsorbed on the bottom wall of the microchannel. When the standing ultrasound wave was introduced within the channel, steady streaming flow was generated. They stressed that the flow pattern in bubble streaming was quite different from that induced by an oscillating solid object. More interestingly, close contact of a foreign solid particle to the bubble showed a significant effect in the overall steady-flow field due to superposition of the bubble and particle streaming fields.

Future Directions for Research

To date no numerical simulation of the acoustic streaming flow associated with application to the microfluidics has been successfully performed. The simulation can be performed only with the streaming flow by using the governing equation given as Eq. (27), but we also need to solve the full unsteady Navier–Stokes equations including not only the primary oscillatory flow component but also the secondary steady flow component. In this case locally fine grids must be adopted to deal with the thin Stokes layer adjacent to the solid surface.

We also need to analyze the case for the flexural-plate-wave flow in more detail and to simultaneously perform numerical simulations of the resultant flows. The results of the full numerical simulation may be used to prove that the steady flow components are generated by the mechanism known as the Stokes drift flow.

We also need to study the dissipation effect caused by the oscillatory flow. At present, in Lab-on-a-Chip design, we are usually interested in the feasibility of the functions provided by the transducers, but sooner or later the energy consumption may be one of the most important factors.

Dynamic mixing; Active mixing

Definition

The term “active mixer” or “active micromixer” refers to a microfluidic device in which species mixing is enhanced by the application of some form of external energy disturbance. Typically, this disturbance is generated either by moving components within the micromixer itself, e. g. magnetically-actuated stirrers, or by the application of an external force field, e. g. pressure, ultrasound, acoustic, electrohydrodynamic, electrokinetic, dielectrophoretic, magneto-hydrodynamic, thermal, and so forth [1].

Overview

Mixing occurs in many natural phenomena, including geophysical, ocean and atmospheric flows, and is also an important step in industrial processes involving chemical reactions, fermentation reactions, combustion, and so forth. Traditionally, industrial mixing applications have always been performed using large-scale apparatus. However, in recent years, micro-scale devices (commonly referred to as microfluidic devices) have been proposed as a means of constructing micro-total analysis systems (μ-TAS) and Lab-on-a-Chip (LOC) devices. However, achieving a rapid and efficient mixing of different reactants when performing chemical and biological analyzes in such microfluidic devices is highly challenging. Therefore, the problem of developing enhanced micromixing schemes suitable for microfluidic applications has attracted significant interest within industrial and academic circles in recent years. As a result, the literature now

contains a large number of studies concerning micromixers implemented using a variety of mixing strategies [1].
The characteristic size of the microchannels in microfluidic devices is very small (typically of the order of several hundred micrometers), and hence the flow is dominated by viscous forces. As a result, the flow is restricted to the low Reynolds number regime, and thus turbulence does not occur. The Reynolds number of microfluidic flows in a conventional straight microchannel is typically less than unity, and the resulting Stokes flow is unidirectional. Even in curved or twisted microchannels, the transverse component of the flow (i. e. the secondary flow) is very small compared to the streamwise component since the inertial effects induced by the microchannel geometry are very weak. Therefore, when the microchannels contain two or more fluid streams, mixing of the different streams is dominated by molecular diffusion effects. In microscale channels, the diffusive mixing process is very slow compared with the rate at which the fluid is convected along the channel. Typically, microfluidic flows have a high Péclet number, i. e. $\mathrm{Pe} = Ul/D$, where U is the average flow velocity, l is the channel dimension and D is the molecular diffusivity. The diffusive mixing time is given by $t_\mathrm{D} \sim l^2/D$ and the mixing channel length required to achieve an adequate species mixing increases linearly with the Péclet number ($L_\mathrm{m} \sim \mathrm{Pe} \times l$). For example, for an average flow velocity of $500\,\mu\mathrm{m/s}$, a channel dimension of $100\,\mu\mathrm{m}$ and a molecular diffusivity of $10\,\mu\mathrm{m}^2/\mathrm{s}$, the mixing time and length required to achieve a complete species mixing are of the order of 1000 sec and 0.5 m, respectively. However, many practical biochemical applications, e. g. immunoassays and DNA hybridization, require the rapid mixing of macromolecules characterized by relatively low molecular diffusivity. Therefore, the mixing performance obtained in typical microchannels is unsuitable for biochemical analysis applications. Accordingly, a requirement exists for enhanced microfluidic mixing schemes to support the development of μ-TAS and LOC devices. Typically, such schemes involve reducing the diffusion length (i. e. l) and the diffusion time by increasing the interfacial contact area between the mixing species.
Although it is difficult to induce turbulence (so-called Eulerian chaos) in microchannels, the mixing performance obtained in low Reynolds number flow regimes can be enhanced via the chaotic advection mechanism (or so-called Lagrangian chaos). Chaotic advection occurs in regular, "smooth" (from a Eulerian viewpoint) flows [2] and provides an effective increase in both the interfacial contact area and the concentration gradient by inducing a reduction in the striation thickness, and hence in the diffusion length. As a result, both the mixing time and the mixing length are considerably reduced. In the case of a linear reduction in the striation thickness within the flow path, the mixing time and mixing length exhibit a sub-linear dependence on Pe. The two parameters can be reduced to as much as $t_\mathrm{m} \sim \ln(\mathrm{Pe})$ and $L_\mathrm{m} \sim \ln(\mathrm{Pe})$, respectively, for chaotic flows in the limit of large Pe [2, 3]. Importantly, chaotic advection cannot occur in steady, two-dimensional flows, but is restricted to time-dependent two-dimensional and three-dimensional flows. Accordingly, a small cylindrical rotor spinning about its centre with a uniform angular frequency (i. e. Couette flow) fails to provide an efficient micromixing performance, whereas two such rotors turned on and off alternatively create a blinking vortex phenomenon which yields a powerful mixing effect [2]. In Couette flow, the fluid streams are only stretched. Hence, chaotic advection cannot be induced, and thus the mixing effect is very poor. However, in the two-rotor arrangement, the fluid streams are repeatedly stretched around one rotor and then folded around the other. As a result, chaotic advection is induced and a good mixing performance is obtained. In general, achieving an effective mixing of two or more fluid streams always requires a repeated stretching and folding of the fluid elements. In recent years, various active mixing approaches have been proposed using chaotic advection to enhance the mixing effect. The chaotic flows induced by such active approaches are time-dependent and are easily controlled using external mechanisms. As such, active mixers are eminently suitable components for reconfigurable microfluidic systems.

Basic Methodology

Flow Field

Applying the continuum assumption, microfluidic flows can be modeled by the continuity equation and by a momentum equation modified to include the body force term, i. e.

$$\nabla \cdot \boldsymbol{u} = 0 \tag{1}$$

and

$$\rho_f \left(\frac{\partial \boldsymbol{u}}{\partial t} + \boldsymbol{u} \cdot \nabla \boldsymbol{u} \right) = -\nabla p + \mu \nabla^2 \boldsymbol{u} + \boldsymbol{F} \quad , \tag{2}$$

where t, $\boldsymbol{u}$, p, ρ_f and μ denote the time, the fluid velocity, the pressure, the fluid density and the fluid viscosity, respectively. In Eq. (2), $\boldsymbol{F}$ represents the external driving force (i. e. the external energy source) associated with the specific active micromixer. For example, in an electrohydrodynamic/electrokinetic-based active mixer, $\boldsymbol{F}$ represents the Coulombic force produced by the presence of a free space charge, $\rho_e E$, where ρ_e is the net free charge

density in the bulk liquid or at the solid-liquid interface (i. e. the electrical double layer) and $\boldsymbol{E}$ is the intensity of the externally applied DC or AC electrical field. Meanwhile, for a magneto-hydrodynamic mixer, $\boldsymbol{F}$ is the Lorentz force induced by the coupling between the magnetic field $\boldsymbol{B}$ and the electrical field $\boldsymbol{E}$, ($\boldsymbol{J} \times \boldsymbol{B}$, where $\boldsymbol{J}$ is the current density). In the literature, Eqs. (1) and (2) are generally solved using well-known numerical methods such as the finite difference method (FDM), the finite volume method (FVM), the finite element method (FEM), and so forth.

In typical microfluidic applications, the Reynolds number is much lower than unity (i. e. $\mathrm{Re} = \rho_f Ul/\mu \ll 1$), and hence the flow can be approximated as a creeping flow (i. e. Stokes flow). Therefore, the convection term in Eq. (2) can be neglected, and the time-dependent flows in active micromixers are then governed by Eq. (1) and Eq. (3), i. e.

$$\rho_\mathrm{f} \frac{\partial \boldsymbol{u}}{\partial t} = -\nabla p + \mu \nabla^2 \boldsymbol{u} + \boldsymbol{F}. \tag{3}$$

Additionally, provided that the time required to reach the viscous diffusion time scale is much less than the oscillation time scale (ω^{-1}), i. e. $\rho_\mathrm{f} \omega l^2/\mu \ll 1$, the time derivative term in Eq.(3) can be neglected, and therefore the unsteady flow fields in active micromixers can be regarded as quasi-steady Stokes flow described by Eqs. (1) and (4), i. e.

$$0 = -\nabla p + \mu \nabla^2 \boldsymbol{u} + \boldsymbol{F} \quad . \tag{4}$$

Visualization of Mixing Process

Numerical studies relating to active micromixers generally visualize the mixing process and evaluate the mixing performance by solving the following convection-diffusion equation:

$$\frac{\partial C}{\partial t} + \boldsymbol{u} \cdot \nabla C = D \nabla^2 C \tag{5}$$

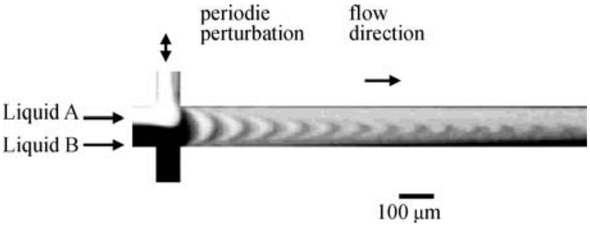
in which C and D represent the sample concentration and the diffusion coefficient, respectively. However, there are several drawbacks to this approach. For example, if the deformation of the species interface is complex and the mixing channel is very long, the equation solution may fail to identify the interface precisely due to numerical diffusion and natural species diffusion. Furthermore, in large Péclet number flows, convective transport dominates the diffusive mechanism and the sample dispersion in the flow field can be greatly enhanced by promoting the convective transport. In such diffusion-limited cases, the diffusion effects can be neglected, and the sample simply convects with the fluid along the local instantaneous streamlines. Under these conditions, the Lagrangian particle tracing technique, which introduces mass-less, non-interacting passive particles into the flow fields, provides a satisfactory means of observing the advection phenomenon within the fluid streams without solving Eq. (5). The motion of a tracer particle can be tracked by the following kinematic equation (dynamic system):

$$\frac{\mathrm{d}\boldsymbol{r}}{\mathrm{d}t} = \boldsymbol{u}\,(\boldsymbol{r}, t)\,, \tag{6}$$

where $\boldsymbol{r}$ is the location of the tracer particle and $\boldsymbol{u}\,(\boldsymbol{r}, t)$ is the Eulerian velocity field. The tracer particle position in the unsteady flow field at different times can be obtained simply by integrating Eq. (6). Many suitable integration methods are presented in the literature, ranging from the simple first-order Euler method to the fourth-order Runge–Kutta method, or even higher-order methods. Besides simulating the dispersion of a blob of samples, the particle tracing method also enables the stretching and folding of fluid elements in an unsteady flow field to be clearly observed.

Characterization of Chaotic Mixing

In order to optimize the fluid deformation phenomena in active micromixers during the mixing process, it is first necessary to understand the fluid stretching and folding mechanisms which take place, and to evaluate them in a quantitative manner. Over the past few decades, dynamic system analysis techniques such as Poincaré maps and Lyapunov exponents have revealed that the repeated stretching and folding of fluid elements results in a chaotic mixing effect. (Interested readers are referred to the text edited by Ottino [2] for details regarding the application of Poincaré maps and Lyapunov exponents to the exploration of mixing kinematics). The information provided by Poincaré maps and Lyapunov exponent analysis enables a thorough understanding of the characteristics of micro-active mixing systems. Specifically, Poincaré maps can be used to explain the transitions of the mixing system behavior from periodic or quasi-periodic to chaotic motion, while the Lyapunov exponents provide an indication of the strength of the chaotic behavior and can be used to quantify the effects of the amplitude and frequency of the perturbations on the chaotic response. Collectively, the data provided by Poincaré maps and Lyapunov exponents provide sufficient information to optimize the design and operation of micro-active mixing devices.



Active Mixer, Figure 1 Pressure perturbations induce lobe-like distortions of the interface and facilitate rapid mixing in the device with one pair of side channel

Key Research Findings

Many active mixing approaches have been proposed in recent years. Broadly speaking these approaches can be classified in terms of whether or not they use moving parts to generate a mixing effect. In those micromixers which do use moving parts, mixing is commonly achieved using micro stirrer bars, piezoelectric membranes, gas bubbles, and so forth. However, since the integration of these moving parts within the overall microfluidic system is challenging, and therefore expensive, researchers have paid increasing attention to active micromixers containing no moving elements. Numerous proposals for active mixing approaches have been presented in recent years, and space constraints prevent their detailed discussion here. Hence, the following provides no more than a high-level review of some of the more fundamental techniques. For a comprehensive discussion of active mixing schemes, interested readers are directed to the review presented by Nguyen and Wu in [1].

Pressure Perturbation Mixer

In pressure perturbation mixers, the species are perturbed by pulsing their velocities in some way. For example, Niu and Lee [4] presented an active mixer comprising a main channel and multiple side channels, in which the mixing species were stirred by pulsing the velocities of the fluids introduced through the side channels, as shown in Fig. 1. The resulting stretching and folding of the fluid elements in the main and side channels induced a chaotic advection mixing effect. A detailed particle simulation study was performed to examine the respective effects of the amplitude and frequency of the flow perturbations on the species mixing performance. Poincaré maps, constructed using the simulation data, showed that for a given parameter set, the fluid flow exhibited both chaotic and quasi-periodic responses. Additionally, Lyapunov exponent data were applied as mixing indices to evaluate the intensity of the chaotic mixing effect. The optimal operating parameters were then determined by plotting the Lyapunov exponent data against the amplitude and frequency of the perturbation.

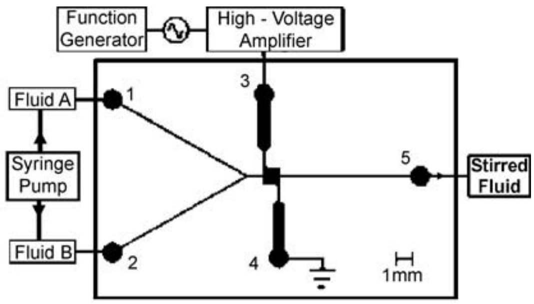
Electrohydrodynamic (EHD) Mixer

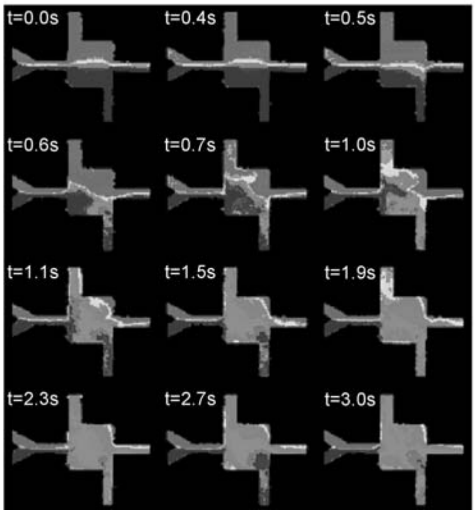
In electrohydrodynamic (EDH) mixers, a mixing effect is created by applying an external electrical field to a bulk flow containing both an electrical conductivity gradient and a permittivity gradient. In the micromixer proposed by Moctar et al. [5], two fluids with identical viscosity and density but different electrical properties were injected into the mixing channel by syringe pumps, and the electrodes were arranged in such a way that the electrical field was perpendicular to the species interface, as shown in Fig. 2(a), creating a transversal secondary flow. The mixing effects induced by both DC and AC electrical fields were explored in a series of experimental investigations. From Fig. 2(b), (c) and (d), it can be seen that the mixing becomes more chaotic as the intensity of DC electric field increases. The results revealed that the application of an appropriate voltage and frequency to the electrodes, yielded a satisfactory mixing performance within less than 0.1 sec over a short mixing distance, even at Reynolds numbers as low as 0.02.

Electrokinetic-Based Mixer

Oddy et al. [6] presented a micromixer in which AC electrical fields were used to induce the electrokinetic instability (EKI) phenomenon in microscale channels at very low Reynolds numbers, as shown in Fig. 3. EKI is similar



a



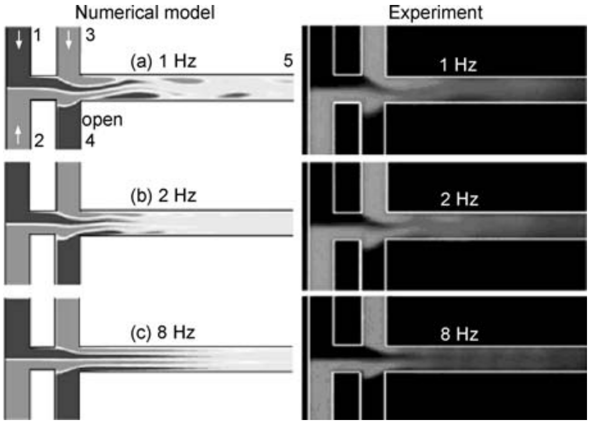
b

Active Mixer, Figure 3 (**a**) Configuration of electrokinetic instability mixer and (**b**) time-stamped experimental images of mixing process

to electrohydrodynamic instability, which can be induced by either AC or DC electrical fields when an electrical conductivity gradient exists in the bulk flow. The results showed that for a flow rate of 0.5 μl/min, the EKI flow field resulted in a rapid stretching and folding of the fluid and achieved an effective mixing performance within 3 seconds, corresponding to less than 1% of the time required to achieve mixing via diffusion effects in a conventional straight microchannel.

Fu et al. [7] periodically switched an external electrical field to carry out species mixing in a T-form electrokinetic microfluidic mixer by generating electrokinetic perturbation forces. The authors showed that the mixing performance of the microfluidic mixer was enhanced by increasing the contact area and contact time of the mixing fluids, and by creating irregular flow fields in the mixing channel. However, the results also indicated that an adequate switching frequency was required to achieve a satisfactory mixing performance, as shown in Fig. 4.

Qian and Bau [8] applied time-wise periodic alterations of the zeta potential along the microchannel walls to induce



Active Mixer, Figure 4 Numerical and experimental images of mixing for different switching frequencies for a constant driving electric field of 100 V/cm

an electroosmotic chaotic advection effect. It was shown that both a spatial and a temporal control of the zeta potential could be achieved by applying a field effect (i. e. a capacitive effect). The effect of periodically switching between several different flow fields at various periods was analyzed by performing particle tracking simulations (i. e. Poincaré maps). The results indicated that a more chaotic mixing effect was achieved at lower values of the switching frequency.

Magneto-Hydrodynamic (MHD) Mixer

Various researchers have employed the magneto-hydrodynamic (MHD) effect to implement micromixers. For example, Bau et al. [9] developed an active micromixer which used either DC or AC electrical and magnetic fields to generate Lorentz forces with which to stretch and fold the species fluids in a mixing chamber. The results indicated that an adequate mixing result was achieved within several seconds. A more sophisticated MHD mixer was developed by Yi et al. [10] based upon the two blinking-vortex arrangement used to induce chaotic advection. The proposed micromixer comprised a small cylindrical mixing chamber with an electrode deposited on its side wall and two copper-wire electrodes positioned eccentrically on the lower surface of the chamber. The chamber was orientated such that its axis was parallel to the direction of an applied magnetic field, and a mixing effect was generated by applying a potential difference of period T alternately between one of the wire electrodes and the circular side-wall electrode and between the second wire electrode and the side-wall electrode, as shown in Fig. 5. The particle tracing results revealed that the intensity of the chaotic mixing effect increased with increasing

T, resulting in a satisfactory mixing result within 40 periods.

Future Directions for Research

It seems likely that future micromixer designs will continue the current trend for implementing species mixing without the use of moving mechanical parts. Furthermore, it seems reasonable to speculate that the use of electrokinetic forces to induce a mixing effect will become increasingly common since this technique greatly simplifies the microfabrication process and reduces the cost and complexity involved in embedding active mixers within microfluidic systems. Electrokinetic forces have been widely employed in active mixing schemes in recent years, a case in point being the EKI mixer presented by Oddy et al. in [6]. However, current EKI-based mixers suffer the drawback of a high electrical voltage requirement. Accordingly, low-voltage, AC electrokinetic techniques are expected to receive increasing attention in coming years. Finally, it is known that the high flow rates required to achieve species mixing can be produced through various nonlinear electrokinetic phenomena. Therefore, the application of nonlinear electrokinetic techniques to realize active mixers is likely to emerge as a major research topic in the microfluidics community in the near future.

AFM

Definition

The *atomic force microscope* (AFM) is a very high-resolution type of scanning probe microscope, with demonstrated resolution of fractions of an Angstrom, more than a 1000 times better than the optical diffraction limit. The AFM is one of the foremost tools for imaging, measuring and manipulating matter at the nanoscale. The AFM consists of a microscale cantilever with a sharp tip (probe) at its end that is used to scan the specimen surface. When the tip is brought into proximity of a sample surface, forces between the tip and the sample lead to a deflection of the cantilever according to Hooke's law. Depending on the situation, forces that are measured in AFM include mechanical contact force, Van der Waals forces, capillary forces, chemical bonding, electrostatic forces, magnetic forces, etc. Typically, the deflection is measured using a laser spot reflected from the top of the cantilever into an array of photodiodes. Other methods that are used include optical interferometry, capacitive sensing or piezoresistive AFM probes.

Aging

Definition

Aging is known in material science as material fatigue. It is a permanent structural damage that occurs when a material is subjected to cyclic or fluctuating strains at nominal stresses that have maximum values less than (often much less than) the static yield strength of the material. These damages can although be effected by thermal stresses due to continuous heating and cooling.

Definition

Amperometry is one of a family of electrochemical methods in which the potential applied to a sensing electrode is controlled instrumentally and the current occurring as a consequence of oxidation/reduction at the electrode surface is recorded as the analytical signal. In its simplest form, the applied potential is stepped to and then held at a constant value; and resulting current is measured as a function of time. When *amperometric detection* is used in conjunction with separation techniques such as capillary electrophoresis or liquid chromatography, the sensing (or "working") electrode is placed at the end of the separation stream so as to permit detection of sample components as they emerge and pass over the electrode surface. The applied potential must be sufficient to cause facile oxidation or reduction of the target analytes; and, in general, the magnitude of the measured current is directly proportional to the analyte concentration.

Overview

Amperometric electrochemical (EC) detection was initially developed in the 1970s for conventional sized high performance liquid chromatography (HPLC) instrumentation [1]. However, as the principal micro/nanofluidic applications of the approach are most directly related to capillary electrophoresis (CE), it is the development of these latter systems that is of greatest relevance here. Amperometric detection was first introduced in conventional bench-scale CE in 1987 by Wallingford and Ewing [2] for the determination of catecholamine-based neurotransmitters. The detection was carried out by carefully placing a small carbon fiber electrode at the outlet of the separation capillary and recording the current transient caused by oxidation of each catecholamine as it emerged from the capillary outlet and passed over the fiber. Subsequently, dozens of papers have appeared both on novel instrument designs in CE/EC and on a wide range of CE/EC applications [3]. During the course of this work, amperometric CE/EC has been carried out on a variety of carbon and metallic electrodes and has been shown to offer both the high sensitivity (μM–nM) required by CE and a unique selectivity determined by the potential applied and the specific electrode used. In general, this detection approach is applicable to several important families of organics. In addition to catechols, these include carbohydrates, amino acids, thiols, phenols, and aromatic amines, as well as a variety of specific compounds of biological or pharmaceutical interest.

In amperometry, quantification of species concentration is possible because the magnitude of the current generated in any given experiment is determined by the number of molecules, of that species, oxidized or reduced at the surface of the sensing electrode and therefore is directly proportional to the concentration of the molecule detected as defined by Faraday's law (Eq. (1)).

$$i_t = \frac{\mathrm{d}Q}{\mathrm{d}t} = \eta F \frac{\mathrm{dN}}{\mathrm{d}t} \tag{1}$$

Where i_t is the current generated at the surface of the sensing electrode at time $= t$, Q is the charge at the surface of the sensing electrode, η is the number of moles of electrons transferred per mole of analyte, N is the number of moles of analyte oxidized or reduced, and F is the Faraday constant (96,487 $\mathrm{C mol}^{-1}$). Detection limits have been reported at the attomole and femtomole levels [4, 5], roughly corresponding to micromolar concentrations in the carrier fluid. Because this form of detection is coupled to the liberation or consumption of electrons, the application of this detection technique is limited to those species that are electroactive, i. e., those that can be oxidized or reduced at an electrode surface. While amperometry has been used for decades in benchtop scale analytical systems, the greatest attractiveness of this particular detection approach lies with the ability to miniaturize the necessary electrodes (working, reference, and auxiliary or counter) and incorporate them into miniaturized *Lab-on-a-Chip* devices. The simplicity of the supporting electronics for amperometry provides advantages as well compared to other detection systems (e. g., UV-visible absorbance, laser-induced fluorescence, mass spectrometry, etc.) that require a considerably larger ensemble of supporting equipment.

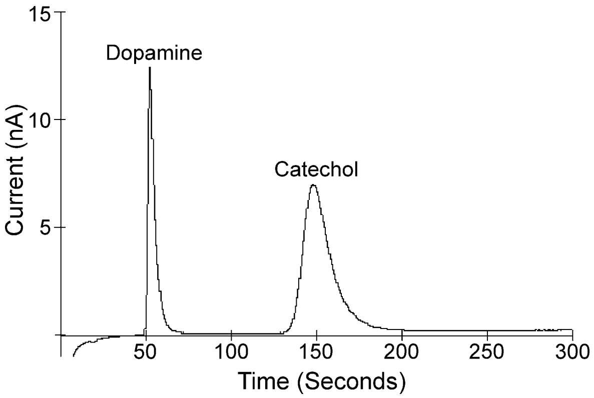
The specific fluidic system involved, while not the main topic of this chapter, is closely linked to the detection system and warrants a brief explanation. Separation techniques such as CE and HPLC utilize channels or columns that pass a fluidic medium carrying the analytes of interest. Bulk flow is actuated using either gravity or pressure, in the case of LC, or electroosmotic forces, in the case of CE. Separation of analytes occurs due to physical or chemical interactions with what is incorporated into the column (a packing material that completely fills the column or is coated onto the inner walls) for HPLC or differential electrical migration of the charged analytes toward the electrokinetic "drive" electrodes for CE. Many of these separation techniques are being downsized using microfabrication methods, referred to collectively as *microfluidics*.

Basic Methodology

In a redox reaction (Eq. (2)), electrons are removed from a solution species (oxidation) at one electrode and transferred to a solute (reduction) at the other:

$$\begin{aligned} &\alpha A \rightarrow \chi C + ne^- && \text{(anode)} \\ &\beta B + ne^- \rightarrow \delta D && \text{(cathode)} \end{aligned} \tag{2}$$

where A, B, C, and D are the reactants and products of the reaction α, β, χ, and δ are their stoichiometric coefficients, and n is the number of electrons. To carry out and monitor such a reaction, an electrochemical *cell* is used. These *cells* typically consist of three electrodes – the working, auxiliary, and reference electrodes – placed in electrolyte solution. Amperometric sensing is controlled by application of the desired potential or voltage solely to the working electrode. This is the electrode at which the redox reaction (either oxidation or reduction) of the analyte of interest occurs, and therefore it is the current flowing at this electrode that constitutes the analytical signal (Fig. 1). The function of the reference electrode is to provide a contact



Amperometric Techniques, Figure 1 Typical electropherogram for catechol and dopamine using amperometric detection on a microchip platform

whose potential remains constant during the amperometry experiment, and its chemical composition (saturated calomel, Ag/AgCl, etc.) is purposely selected to facilitate this. The role of the counter electrode is to provide a current path that completes the electrical circuit. Thus, the redox reaction occurring here is equal in size but opposite in direction (i. e., reduction or oxidation). Normally, this electrode consists of a simple metallic contact, most commonly platinum.

The chemical composition/structure of the working electrode can vary considerably, and a proper selection is often critical to achieving success in a given application. The minimum requirements are reasonable degrees of chemical inertness and electrical conductivity. Commonly encountered electrodes include metals, such as Pt, Au, or Hg, and carbon. In addition, the surface of these electrode materials can also be modified chemically by a number of different approaches in order to optimize performance for a specific electrochemical process [6]. For example, the charge, polarity, porosity, and specific chemical and biochemical reactivity can be adjusted by the addition of appropriate functional groups, self-assembled mono- and bi-layers, and polymer coatings.

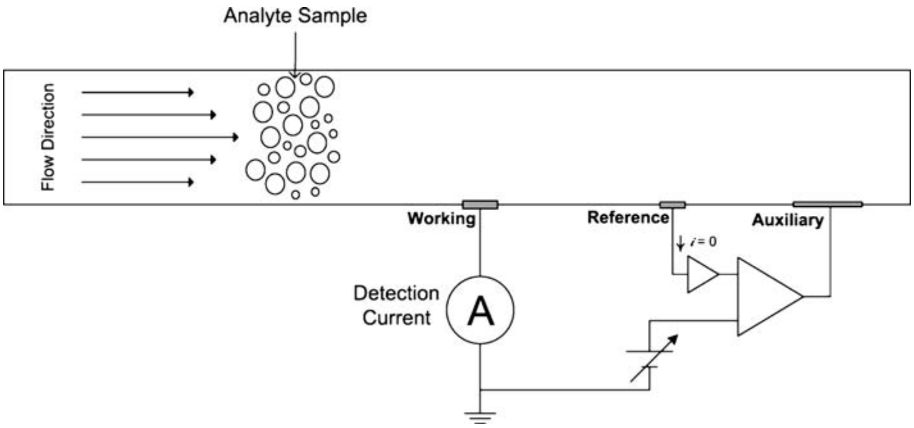
The function of the external electronic circuitry – or the "potentiostat" – in amperometric experiments is to supply the desired voltage difference between the working and reference electrodes and measure the resulting redox current instantaneously. The magnitude of the working electrode potential necessary to initiate the oxidation or reduction is ideally determined by the Nernst equation (shown in Eq. (3)) but can also be affected by factors such as the conductivity of the carrier fluid, the electron-transfer kinetics of the specific redox reaction, the composition of the detection electrode, and the relative distance between the working and reference electrodes.

$$E = E^0 - \frac{0.059}{|n|} \log \left(\frac{a_C^\chi a_D^\delta}{a_A^\alpha a_B^\beta} \right) \tag{3}$$

where E is the potential of the working electrode, E^0 is the standard potential for the redox reaction of interest, n is the number of electrons involved, and the a's represent the activities of the reactants and products. It follows from the Nernst equation that making the working electrode potential more negative favors the reduction process and is therefore said to be more "reducing" or "cathodic" while application of a more positive potential would be "oxidizing" or "anodic". Thus, in practice, amperometric detection involving analyte reduction is generally carried out by application of negative potentials, while analyte oxidation requires use of relatively positive applied potentials. Successful bench-scale CE/EC in the amperometric mode requires the accurate maintenance of EC potentials on the order of roughly ± 1 V at working electrodes placed in CE fields on the order of 5 – 30 kV and the measurement of EC currents typically pA in magnitude in the presence of μA-level background CE currents.

A representative three-electrode amperometric detection configuration and a simplified potentiostat circuit are shown in Fig. 1. The working and reference electrodes are placed in the amplifier feedback loops so that the voltage difference between them must match an adjustable external voltage source. Because the composition of the reference electrode is designed to maintain its potential at a constant value, the working electrode potential is just the selected external voltage compared to or "vs." the specific reference electrode used. The reference electrode is connected to a high input impedance buffer amplifier, which serves to limit the current flow through it to a negligible level, which in turn serves to keep its composition unchanged and its potential at its starting value. The working electrode is connected to an ammeter circuit, typically a sensitive transimpedance amplifier (current-to-voltage converter). The oxidation or reduction reaction occurring when an electroactive analyte passes the working electrode produces current flow in the ammeter that is then converted to a proportional voltage for display.

A simple electrical model of the solution as seen by the electrodes is shown in Fig. 3. Resistances are primarily determined by the ionic content of the electrolyte solution, which is typically in the 0.01 – 0.10 M range. When the electrodes are placed in an electrolyte solution, a charge separation or "double layer" forms spontaneously at the electrode-solution interface. This produces a capacitance, commonly referred to as the double-layer

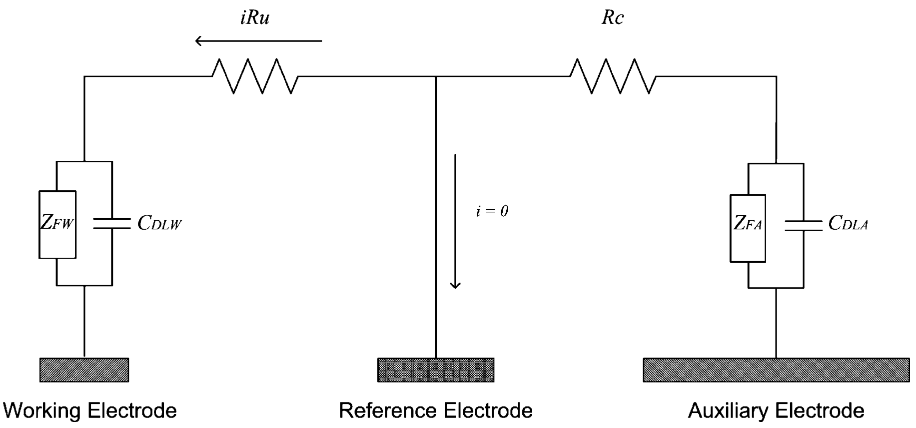


Amperometric Techniques, Figure 2 Schematic of amperometric detection cell (general representation for Lab-on-a-Chip (LOC) applications

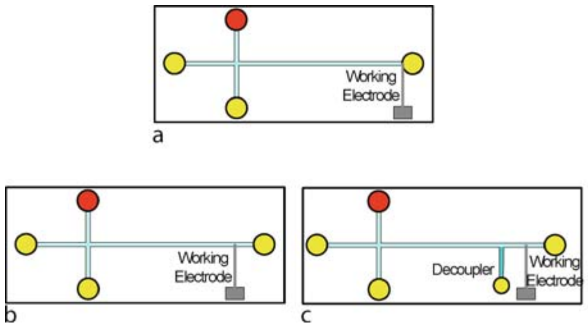
capacitance, C_{DL}. The size of this capacitance is a function of electrode area, electrode-to-solution potential, electrode material, and the ion concentration in solution. The potentiostat compensates only for capacitance, impedance, and resistance (C_{DLA}, R_c, Z_{FA}) within its control loop and allows these to be largely ignored experimentally. Therefore, the uncompensated resistor, R_u, which is outside the loop, causes an error in the working electrode potential, iR_u, as a result. However, given the very small amplitude currents usually involved in microfluidic systems and the relatively low resistivities of the aqueous electrolyte solutions normally employed, this error is seldom of any practical concern for amperometric measurements. Of course, the product $R_u C_{DL}$ represents the cell time-constant and largely determines the speed of response of the cell to any change in the applied potential. For typical amperometric detection applications where the applied potential is kept constant throughout the entire experiment, this also is of no concern; but, for the relatively few cases in which the potential is systematically scanned during the CE separation, limitations in accurate control of the working electrode potential due to charging of C_{DLW} must be considered.

Application of amperometric detection to HPLC instrumentation is usually straightforward, involving the placement of conventional size electrodes downstream from the column exit. Care must be given to keep the dead-volume entailed by the detection cell and connecting tubing small enough to avoid compromising the separation efficiency. For CE/EC systems, however, there are two specific issues that must be addressed experimentally: 1) physical alignment of the electrodes with the capillary or channel outlet; and, 2) electrical decoupling of the EC detection from the high-voltage CE field. The need to optimize capillary/electrode alignment arises from the very small dimensions involved – with the widths of both CE channels and EC electrodes typically in the 10 – 100 μ range. Thus, optimum sensitivity dictates that the working electrode is placed very near the channel outlet while acceptable reproducibility requires that this positioning, once established, be maintained throughout extended sets of experiments. With bench-top CE instrumentation, this usually requires the use of microscopes and 3D micro-positioners to align the fiber or wire with respect to the capillary. Alternative arrangements to ease this problem have been suggested such as the use of planar "wall-jet" electrodes that can be somewhat larger in size or the incorporation of the EC electrode onto the capillary by deposition of an appropriate metallic film onto its outside tip. Of course, one of the attractive features of Lab-on-a-Chip CE/EC systems is that the specific location, size, and shape of the EC electrodes can be absolutely controlled during the microfabrication process.

In amperometric detection, the placement of the working electrode in CE/EC detection systems can be divided into three different categories, *off-channel (or column)*, end-*channel (or column)* and in-*channel detection.* The purpose of this distinction is to indicate the location of the EC electrodes with respect to the CE electrodes and field (Fig. 4). This is an important consideration because of the possible interactions that might occur, as mentioned above, between the EC and much larger CE electric fields. "Off-channel" EC detection refers to the situation in which an electrically conducting "fracture" or thin crack, opening, or hole is created in the capillary or channel wall a short distance before the exit. This fracture allows the CE voltage and current to be dropped before the actual physical end of the system and permits the EC electrodes to be placed near or even inside the capillary exit for efficient analyte detection but nevertheless to remain



Amperometric Techniques, Figure 3 Electrical model of three-electrode cell (Z_{FW} is the faradaic impedance at the working electrode; C_{DLW} is the double-layer capacitance at the working electrode; Z_{FA} is the faradaic impedance at the auxilary electrode; C_{DLA} is the double-layer capacitance at the auxilary electrode; R_C is the resistance of the electrochemical cell; R_u is the uncompensated resistance; and, i is the current)



Amperometric Techniques, Figure 4 Schematic of EC electrode placement for the different detection electrode configurations: (**a**) end-channel detection; (**b**) in-channel detection; and, (**c**) off-channel detection

"off" or outside the influence of the CE field, commonly referred to as "decoupling" [7, 8]. The off-channel approach, which often may pose significant technical difficulties to implement, offers the possibility of very efficient detection of the analyte while it is still contained within the confines of the narrow separation channel and remains in the form of a relatively concentrated plug. "End-channel" detection refers to the more convenient placement of the EC detection electrode just beyond the end of the separation channel in the CE buffer reservoir. Thus, the EC cell is located within the high-voltage CE field, and electrical interactions between the two are still possible. However, as long as the CE capillary or channel width is sufficiently small, its ohmic resistance is high enough that the CE current is negligibly small and only a very small portion of the CE voltage extends beyond the exit and into the much larger volume detection compartment. Of course, an inherent problem with this technique is that the well-defined analyte plugs maintained within the capillary immediately begin to spread radially upon exiting and moving into the much larger volume detection reservoir. Therefore, care must be taken that the detection electrode, in this case, is located close to the exit of the channel, typically 25 – 100 μm, but not so close as to interact unduly with the residual CE voltage that does extend slightly beyond the separation channel. A detailed study of the residual post-capillary CE field, and the effect of end-channel electrode placement, has been reported by Klett et al. [9]. The in-*channel* approach has been employed by researchers, however, this approach is limited due to bubble generation in the channel, which can significantly decrease the signal-to-noise (S/N) ratio of the electrochemical signal, as well as the high electric field can significantly effect the resting background current generated at the surface of the working electrode.

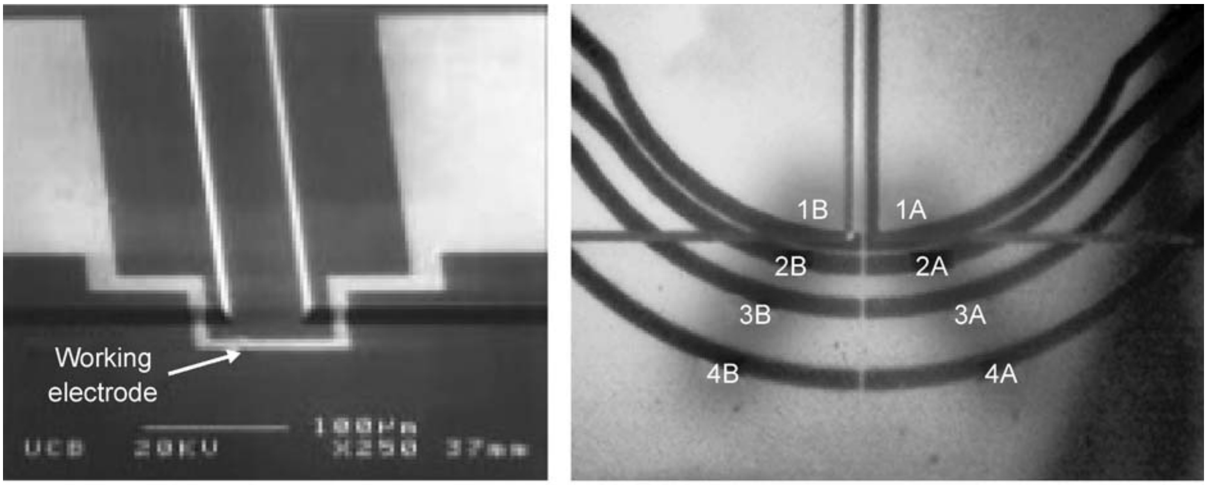
In regards to electrode geometry, the EC detector response is proportional to electron generation (or consumption) during the desired redox reaction. Therefore, increasing the area of the detection electrode will increase the detection signal. The tradeoff is that the background noise increases linearly as well. Due to the confined geometry of the microchannel, in-channel electrodes are limited to simple rectangular shapes determined by the channel width and exposed electrode area. This configuration is sufficient to maximize the contact of the analyte with the electrode surface. For an end-channel electrode configuration, however, a simple rectangular planar electrode is not the only option. The conventional planar geometry can be altered to match the shape of the radially migrating analyte so as to maximize the delivery of the sample to the detection electrode surface.

Key Research Findings

The first microfluidic *Lab-on-a-Chip* (LOC) devices were reported by Harrison and Manz in the early 1990s. These devices consisted of simple channels, several cm in length and 10 – 100 μm in width and depth, etched into glass microscope slides or silica plates via conventional micromachining techniques [10]. In this work, samples were injected onto the chip and moved as required through the channel network by electroosmotic flow; separations were carried out by electrophoretic mechanisms common to bench-scale CE instrumentation; and target analytes were detected and quantitated via fluorescence detection. Subsequent studies by these and other groups demonstrated unique advantages for the Lab-on-a-Chip approach: high separation efficiencies, short analysis times, minute sample and reagent consumption, high sample throughput, and easy automation.

In 1996, the first use of amperometric detection in microchip CE devices was reported by Wooley, Lao, Glazer and Mathies [11] who used off-chip CE driving electrodes together with a photolithographically patterned Pt electrode placed just outside the CE channel for on-chip detection of catechol neurotransmitters by direct oxidation and DNA fragments and PCR products indirectly by EC monitoring of an electroactive intercalating agent. In another end-channel approach, Baldwin and colleagues [12] were the first to demonstrate a Lab-on-a-Chip device that incorporated both CE high-voltage electrodes and all amperometric EC detection electrodes directly onto an integrated, microchip platform. Key features of their device were the formation of a "shelf or ledge" at the end of the separation channel to restrict the height of the detection reservoir near the working electrode and the radial pattern of the working electrodes. These features enabled optimization of EC detection by decreasing the electrical resistance and CE voltage drop in the detection region and increasing the residence/contact time of the analytes with the working electrode, respectively. Another novel CE microchip end-column approach has been reported by Ertl et al. [13], which integrates sheath-flow into the CEEC system to increase analyte velocity in the detection reservoir as it exits the CE separation channel. Their study further elucidated the importance of the spacing between the working and reference electrodes, with optimum detector performance achieved for a spacing of $\sim 20\,\mu m$. Using an electrically isolated potentiostat with a floating working electrode, Martin and coworkers [14] successfully detected catechol with minimum band-broadening effects by placing the working electrode just inside the separation channel but without any decoupling. Off-channel EC detection approaches have been also explored in microchip platforms. For example, the Lunte groups demonstrated two different methods for decoupling the CE field from the EC detection system. In the first, decoupling was achieved by laser-cutting a series of 20, 30 μm holes in the roof of the CE channel into the upper glass coverplate and then filling them with cellulose acetate [8]. In the second, a 500 μm wide Pd decoupler strip was fabricated via photolithography and sputter-coated onto the glass substrate that formed the bottom of the CE channels [15]. When placed directly in the CE channel and used as the CE cathode, the Pd was able to absorb the H_2 gas that is generated during normal CE operation and leads to the formation of bubbles in the channel. The key advantages of these approaches (and others like them) are that they allow microchips to operate at higher field strengths (up to 1700 V/cm) with superior limits of detection (~ 25 nM for dopamine with a carbon fiber electrode) and allow the EC working electrode to be placed in-channel where higher efficiency separations can be realized. Similarly, Lai et al. [16] integrated a Pd-film decoupler with a series-dual electrode to significantly enhance the oxidation current when switching between the single electrode mode and dual-series mode. In other work, Wu et al. [17] electrodeposited Pt nanoparticles on a Au ground electrode to construct the decoupler and achieved a limit of detection of 0.125 μM at a $S/N = 4$ for dopamine with a Au working electrode.

Compared to alternative detection approaches, amperometric methods are ideally suited to microfabrication processes since the electrodes themselves have the ideal dimensions (1 to 10 μm) for incorporation onto a microchip. Most importantly, patterning and construction of EC microelectrodes is extremely compatible with mainstream microfabrication technologies such as photolithography and sputter-coating. As a result, electrodes (and electrochemical cells) of different shape, size, location, and composition can be patterned directly onto glass, silica, and other substrates with a high degree of accuracy using the same photolithographic techniques employed to fabricate the microchip's CE channels, thereby allowing the detection operation to be fully integrated onto the chip (Fig. 5). In addition, multiple electrodes in different CE channels or multiple electrodes with different response characteristics can be created to allow the device to fit the intended application optimally (Fig. 5b). This level of integration does not exist with other detection approaches and has several performance and applications advantages. For example, with LIF, multi-channel detection requires either the use of multiple fluorescence systems or a means of scanning a single fluorometer across multiple spots on the chip.



a b

Amperometric Techniques, Figure 5 Examples of different electrode geometries that can be fabricated via photolithographic techniques: (**a**) rectangular working electrodes (Reprinted with permission from [11]); and, (**b**) multiple radial working electrodes (Reprinted with permission from [18])

Chip-based amperometric EC detection techniques have been utilized in several noteworthy analysis situations – most commonly in clinical (e. g., immunoassays and protein analysis) and environmental sensing. A recent review by Vandaveer et al. [19] provides an excellent overview of these applications.

Future Directions for Research

Considering the relative ease with which prototypes can be developed on the micro-scale, custom EC electrode configurations mated perfectly to the CE separation platform are possible. For example, devices with multiple separation channels may be outfitted with multiple EC cells, each identical to the other to establish redundancy for fail-safe detection. Each channel could run simultaneously and statistical calculations (running averages, standard deviations, etc.) could be used to enhance both the reliability of detection and the robustness of the detection system. The development of such advanced LOC instruments is expected to be central to their practical utilization in applications involving remote and unattended sensing.

Another possibility would be for each channel of a multiple channel CE/EC system to be configured with an EC cell specifically designed to detect a different analyte or analyte group. This could be accomplished, for instance, by maintaining each EC electrode at a different potential, fabricating each detection electrode out of a different substrate, or modifying each electrode chemically or biochemically. In this case, there would be no redundancy; however, a single experiment could yield results for a range of analyte components. Furthermore, alternative microfabrication techniques can be developed to create electrodes with alternative geometries, such as flow through or three-dimensional, large surface area detection electrodes. Increased surface area electrodes allow for a more complete interaction between the analyte and the detector which should be expected to enhance the signal-to-noise ratio and sensitivity.

A relatively new area which is likely to grow in importance is the construction/functionalization of the EC electrodes with alternative materials to enhance the reactivity toward the analyte or to allow detection of analytes that do not oxidize or reduce ideally at simple electrodes. For example, Marwan et al. [20] reported the functionalization of glassy carbon electrodes with metal-based species in order to elicit the electrochemical reduction of nitrates and oxidation of hydrogen peroxide. Similarly, Sarapuu et al. [21] have shown the modification of boron-doped diamond and highly oriented pyrolytic graphite electrodes with quinones to greatly enhance the rate of oxygen reduction, thereby allowing a highly sensitive determination of hydrogen peroxide. Biological molecules (DNA, antigens, etc.) which are often not inherently electroactive can be detected electrochemically by approaches such as Kavanagh's [22] in which a redox polymer and a single-stranded DNA probe were attached to a gold electrode; hybridization and formation of the double-stranded probe DNA altered the electrochemistry of the polymer and thereby permitted detection of the complementary DNA species. Continuing research into further functionalization of traditional and modified electrode materials will further enhance sensitivity and promote selectivity between ana-

lytes, especially in the areas of clinical and biochemical analysis.

An alternative approach gaining widespread attention is the addition of an electrochemically active tag or label to an electro-inactive biomolecule such as DNA, SNPs, etc. Similarly to fluorescence detection, in which a sample is treated with a natively fluorescent chemical marker in order to render it optically detectable, this technique tags the sample at a specific site with a molecule that undergoes oxidation/reduction at a well-characterized electrode system. Wooley, et al. [11] first proposed this promising approach in 1998. Since then, others have demonstrated the ability to carry out this technique on a microchip platform. Hebert and colleagues [23, 24] have detected a specific SNP (Single Nucleotide Polymorphism) site using an electrochemically active taggant in conjunction with sinusoidal voltammetry, while Wang and coworkers [25] labeled amino acids with electrochemically active 1-cyanobenz(f)isoindole derivatives to permit the detection of arginine, lysine, phenylalanine, glycine and cysteine. Given the inherent sensitivity of EC and the flexibility of microfabrication, this line of research is expected to have a major impact on the detection of many important biomolecules.

Anion Exchange Membrane

Definition

An ion exchange membrane that interacts with anions and typically consist of amine functionalities ($-NH_3^+$, $-NRH_2^+$, etc). These functionalities allow anions to pass through the membrane and prevents cations from passing through the membrane. The ability of the membrane to bind ions is greatly dependant on the pH of the solution and the ions of intrest.

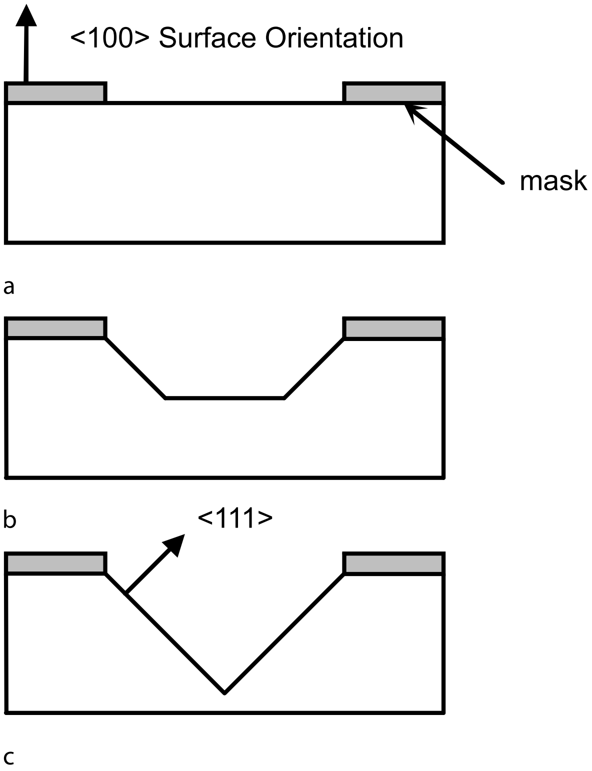
Definition

Anisotropic etching is a subtractive microfabrication technique that aims to preferentially remove a material in specific directions to obtain intricate and often flat shapes. Wet techniques exploit the crystalline properties of a structure to etch in directions governed by crystallographic orientation. Dry techniques utilize an inhibitor to protect the sidewalls of a cavity during ion bombardment to obtain high aspect ratios.

Overview

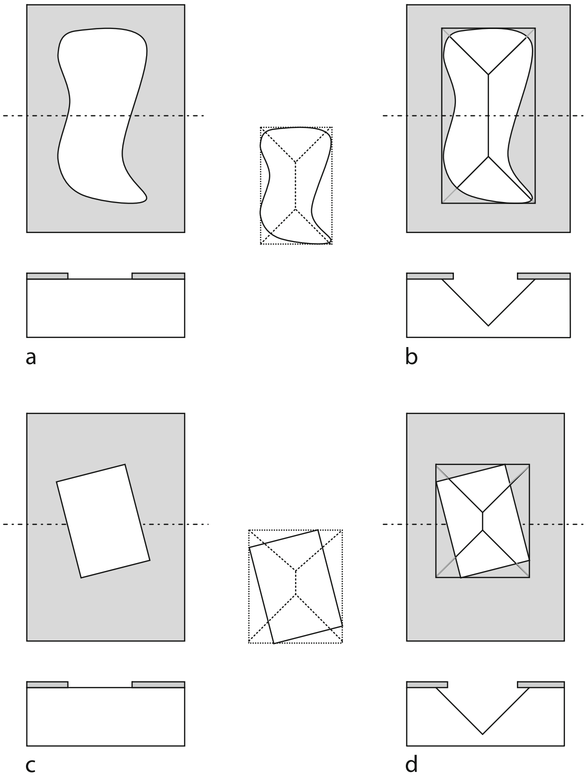
In contrast to isotropic etching, anisotropic etching is a fabrication technique that removes material in specific directions allowing for the production of geometric characteristics such as sharp corners, flat surfaces, and deep cavities. Relative to microfabrication, selectivity can be defined as the ratio of the etch rate of the target material to the etch rate of other materials. The definition can also be applied more specifically to single crystalline materials such as silicon where it would be considered the ratio of the etch rate in the target direction to the etch rate in other directions.



Anisotropic Etching, Figure 1 Example of a masked silicon wafer with a ⟨100⟩ surface orientation (**a**) before, (**b**) during, (**c**) and after exposure to a potassium hydroxide etch

Different etchants used in anisotropic wet etching have specific etch rates for each crystallographic plane in the material being removed. It is the difference in etch rates between planes that produce shapes within the material being etched that appear to follow the planes within the crystalline structure as seen in Fig. 1. For more information on the crystalline structure of silicon and how miller indices are used in designating crystal planes, see The MEMS Handbook [1]. It is commonly accepted that the ⟨111⟩ plane etches the slowest regardless of the etchant used. However, the crystal plane that etches the fastest depends on the etchant composition [2]. Ammonium hydroxide etchants (NH_4OH and TMAH) are frequently used to etch silicon due to their compatibility with certain metals involved in on-chip circuitry, whereas alkali hydroxide etchants (NaOH, CsOH) are used for their faster etch rates [3]. A commonly used alkali hydroxide etchant for silicon is potassium hydroxide (KOH) which provides a high level of selectivity between the ⟨100⟩ and ⟨111⟩ planes. Materials that are highly resistant to these etchants, such as silicon nitride and silicon dioxide are often utilized as etch stops in more complex designs. Detailed specifications for each etchant including etch rates in specific crystal planes, and recommended temperatures, concentrations and etch stops is available in the literature such as those of Nguyen and Wereley [2].

Careful design and alignment of the mask must be ensured when involving directional dependence in the etching process. Because the planes will continue indefinitely until they reach a surface or another plane, undercutting of the masking material is possible. A shape that does not align with the correct planes can produce an opening that circumscribes the original shape if etched long enough as seen in Fig. 2. The angle produced between the slow-etch plane and the surface after etching is clearly dependent on surface orientation and the crystalline structure of the material. Such angles are found in the literature and are utilized in design to achieve accurate depths and specific slopes (including vertical). Equipment used in wet etching can be easily obtained in most laboratories. The material being etched is suspended within a beaker containing the etchant while a magnetic stirrer ensures continuous transport of reactants to and products from the surface of the material. A simple temperature-controlled hot-



Anisotropic Etching, Figure 2 Examples of undercutting that is possible for (**a**,**b**) odd shaped masks and (**c**,**d**) misaligned masks relative to crystal planes

plate regulates the optimum temperature.

Anisotropic dry etching is a method for creating high aspect ratio trenches with nearly vertical walls. The two common techniques utilize a protective coating along the vertical walls of an etched trench such that the bottom of the trench etches at a faster rate allowing for large aspect ratios. Each is independent of crystal orientation. The first method forces the reactant gases to condense on the sidewalls of the trench by lowering the temperature of the materials with liquid nitrogen. Ions are then accelerated toward the trench by means of an electric field. This physical shower of ions results in an etching effect. After ion bombardment removes the bottom layer, it can be etched further while the sidewalls are protected by the cryogenically frozen inhibitor. Another novel approach, commonly referred to as the Bosch process (named after its inventor, Robert Bosch) alternates additive and subtractive microfabrication techniques. During the additive stage, chemical vapor deposition is used to coat the sidewalls of the trench with a polymeric passivation layer. Similarly to the previous method, ion bombardment is then used to sputter off the trench bottom, exposing the substrate to the chemical etchant [4]. Several companies specialize in the production of microfabrication equipment for various reactive ion etching processes. These processes, commonly referred to as deep reactive ion etching (DRIE) are capable of producing channels with a depth on the order of 500 μm and aspect ratios on the order of 30 : 1 [5].

Definition

Anodic bonding is a technique to produce hermetic seals between metals and glass insulators. Anodic bonding is mostly used for hermetic sealing of silicon and glass. Different from other sealing techniques, anodic bonding involves heating and applying an electrical field to a bonding pair.

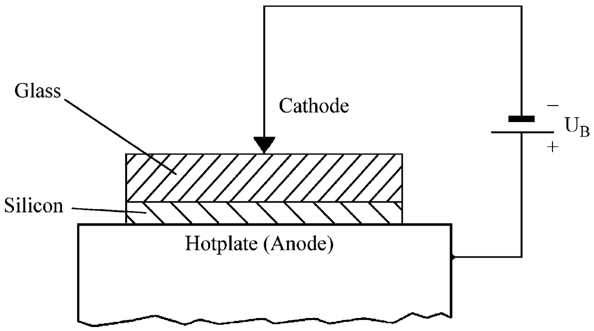
Overview

The anodic bonding technique was first reported in 1969, with the name of field assisted glass–metal sealing [1]. It has since been developed into a widely used hermetic sealing technique for a variety of MEMS devices and microfluidic devices. The equipment for anodic bonding can be simply a hot plate on which the bonding parts are heated to the sealing temperature between 300 and 600 °C and a DC power supply to apply a high voltage from 200 V up to 2000 V to the bonding parts. The bonding process takes only a few minutes. Figure 1 shows schematically the setup for anodic bonding, where the conductive part, in this case a silicon wafer, is connected positively to the applied voltage. The essential conditions for anodic bonding are:

1. The bonding surfaces should be flat and well polished to less than 5 nm in surface roughness. When the bonding pair is put together, the two parts are in intimate contact at the polished surfaces.
2. The materials of the bonding pair must have well matched thermal expansion coefficients.
3. Anodic bonding only occurs between conductive materials and glass materials.

The mechanism of anodic bonding is believed to be both physical and chemical. The physical mechanism is electrostatic force. At the typical bonding temperature, most glass materials contain mobile positive ions compensated by almost immobile negative ions. Upon applying high voltage, these positive ions migrate to the negative electrode connected to the glass and become largely neutralized, leaving a depletion layer with negative space charge at the contact interface. Figure 2 shows the typical electrical current profile during anodic bonding [2]. The initial rise of current represents the migration and neutralization positive ions at the electrode. Then the current drops and a depletion layer is built up at the interface. The contact interface, although well polished at both sides, initially has only a few points of physical contact. Therefore, there is a high electrostatic field generated from the negative charge layer at the gaps. The high electrostatic attractive force then pulls the surfaces into direct contact, which explains why the bonding always starts at the point contact of electrode and spreads radially. The radial spreading of the bonding front makes it impossible for air to become trapped between the bonding surfaces. The electrostatic force depends on a number of factors, such as the total applied voltage, the width of the gap, the concentration and distribution of ions in the glass, whether under the high field the negative ions will drift out of the glass or the positive ions will drift into the glass and possible formation of surface charge on the glass (the effect of such charge would partially shield the charge in the glass, thus reducing the field in the gap).

The chemistry of anodic bonding is an oxidation process at the interface. Due to the high electrostatic field, oxygen anions leave the glass and create Si–O–Si bonds, i.e., a thin layer of SiO_2 is formed. This gives the strong bond between silicon and glass, and the bonding becomes irreversible. The formation of thin SiO_2 layer at the bonding interface has been verified by Rutherford backscattering spectroscopy. It has also been demonstrated that the rate of oxygen release is directly proportional to the average current passing through the bonding area. In areas where silicon and glass are in direct contact due to electrostatic attractive force, the oxygen anions will oxidize the silicon into SiO_2 and form the anodic bond. The oxygen is therefore totally consumed. However, in areas where silicon is



Anodic Bonding, Figure 1 Schematic setup for anodic bonding of silicon to glass

Anodic Bonding, Figure 4 Schematic cross-section of a micropump assembled by anodic bonding of glass–silicon–glass

not in direct contact with glass, for example in the case of an etched cavity into the glass or silicon, oxygen evolution into the cavity can occur. This may have detrimental effects in some device applications [3].

The bonding strength for silicon–glass anodic bonding is measured typically at 10 – 20 MPa. Some have reported between 30 MPa and 40 MPa at higher bonding voltage [2]. The pull test has demonstrated that bonding strength is higher than the fracture strength of the glass, i.e., the break in the pull test occurs only in the glass and not at the silicon–glass interface.

Anodic bonding of glass and silicon has found many applications in microsystems, MEMS and microfluidics, including the fabrication of pressure sensors, accelerometers, micropumps and other fluid handling devices. A typical microfluidic device is shown in Fig. 3, which is a microreactor chip to perform chemical synthetic reactions [4]. The microreactor was made by wet or dry etching of silicon to form microchannels and sealed by anodic bonding of a glass slide on top with inlet and outlet holes. Anodic bonding can provide an airtight seal to ensure proper function of fluidic flow in the microchannels. Silicon is a preferred material in microfluidic systems because micromachining of silicon is the most mature fabrication technique. Complex structures can be made in silicon by either wet chemical or reactive ion etching. Anodic bonding of silicon with glass can also help in the building of multistack microsystems to perform complicated functions. Figure 4 shows an example of a micropump made by silicon/glass micromachining and anodic bonding [5]. This is a glass–silicon–glass multistack system. The top Pyrex glass provides a hermetically sealed cavity so that the polysilicon heater can heat up the air in the cavity. Expansion of the hot air in the cavity will compress the silicon membrane to perform a pumping action in the pumping chamber. The bottom Pyrex glass seals the pump chamber as well as provides the input and output holes for fluid flow in and out of the pump chamber.

Anodic bonding is the primary method for packaging silicon microstructures, for example packaging of pressure sensors, accelerometers and solar cell panels, because of

its relatively low bonding temperature. With bonding temperature being below the glass transition point, the glass thermal expansion coefficient remains constant, which enables stress-free packaging of silicon microstructures (provided the glass has a good thermal expansion match with silicon over the process temperature range). In addition, with the low bonding temperature there is no measurable flow of glass, which ensures sealing around silicon microstructures without any loss of dimensional tolerances. Apart from low bonding temperature, there are other attractive features of anodic bonding:

- Since glass is an electrical insulator, parasitic capacitances are extremely small.
- The bonding process can be readily performed in vacuum, allowing hermetic sealing or zero pressure reference cavity to be formed (or sealing with special gas mixtures).
- The transparency of glass allows optical inspection or detection of fluidic flow/reaction in microfluidic devices. It also facilitates alignment of microstructures in glass with microstructures in silicon.

Although glass–silicon sealing or assembly is the most common form of anodic bonding, the technique can also be applied to the sealing of many metals with a variety of glasses. Successful seals have been made with borosilicate glass, soda lime glass, potash soda glass, aluminosilicate glass, fused silica and fiber optical glass [1]. Strong seals have also been made to some ceramic materials. For those metals and alloys whose thermal expansion coefficients are matched to the above glasses, successful anodic bonding have also been made, such as tantalum, titanium, Kovar, Niromet 44, and to semiconductors such as germanium and gallium arsenide, in addition to silicon [1].

Basic Methodology

Although the principle of anodic bonding is simple, successful bonding depends on appropriate selection of bonding materials, good preparation of bonding surfaces, optimization of bonding conditions and inspection of bonded samples. These are explained in the example of silicon–glass anodic bonding.

Material Selection

Silicon material is normally of standard wafer sizes and thicknesses. As the anode part of the bonding pair, the silicon should be low in resistivity. However, some applications require an insulating layer to prevent electrical leakage in silicon. In this case, a thin layer of silicon dioxide or silicon nitride should be deposited on the silicon surface. The insulating layer does not prevent anodic bonding of silicon with glass. However, a thicker insulating layer can increase the bonding time dramatically. For example, for a 0.5 μm thick oxide layer a bonding time of approximately five times longer is required [2]. For anodic bonding with glass, p-type silicon wafers (boron doped) are preferred, as a high electrostatic field is much easier to build up, particularly at low temperature, at the silicon side of a silicon–glass interface for p-type silicon than for n-type silicon (phosphor doped) [6]. However, for high-temperature anodic bonding ($> 400\,^{\circ}$C) the doping type of silicon is no longer a factor.

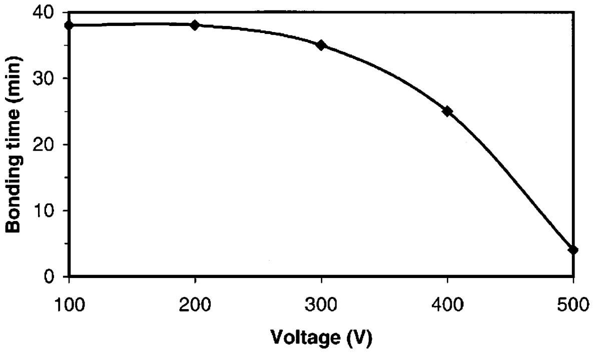
Borosilicate glasses such as Corning 7740 Pyrex glass, Schott Borofloat 33 glass and Hoya SD-2 glass are commonly used for anodic bonding with silicon. They are of almost the same coefficient of thermal expansion (CTE) as that of silicon. They also have the necessary electrical conductivity at the bonding temperature. However, some special applications require the glass to be high in resistivity (Corning 7070 glass) or high in spectral transmission (Pilkington CMZ glass). Glasses that have a CTE different from silicon or a low concentration of mobile positive ions are still able to be anodically bonded with silicon, but with special process conditions. For example, to bond Corning 7070 glass with silicon, much higher temperature and voltage are needed. To bond a Fisher glass slide whose CTE is very different from that of silicon, the bonding temperature has to be much lower (150 °C) and bonding time is much longer (60 min) [6].

Preparation of Bonding Surfaces

A well-polished surface is essential for a successful bonding. The average surface roughness (R_a) should be less than 5 nm. Commercial silicon wafers and glass substrates are normally polished to this standard. Although anodic bonding is fairly tolerant to particles and contaminations on the bonding surfaces, they still need to be cleaned prior to anodic bonding, unless the wafers are straight out of the box. A study has demonstrated that a $H_2SO_4 + H_2O_2$ acidic clean of bonding surface can significantly reduce the bonding time compared to a simple cleaning with acetone [6]. Thorough cleaning is even more important for structured wafers. Whether the bonding surfaces are hydrophobic or hydrophilic can also have an influence on bonding. At low temperature, a hydrophilic surface is easier to bond than a hydrophobic surface. However, such difference disappears at high bonding temperature [7].

Process Parameters

The basic process parameters for anodic bonding are temperature, voltage, clamping pressure, environment and bonding time.



Anodic Bonding, Figure 5 Bonding time as a function of applied voltage for silicon–glass anodic bonding

- Bonding temperature is normally in the range 300 – 500 °C. Higher temperature promotes better mobility of positive ions in glass, resulting in a faster bonding process. However, the temperature must be below the softening point of glass (glass transition temperature).
- Typical bonding voltage is in the range of 200 to 2000 V. High voltage helps to drive the positive ions in glass towards the cathode, leaving a negatively charged region at the bonding interface. The electrostatic force at the interface pulls the silicon and glass in direct contact, resulting in oxygen ions in glass oxidizing the silicon to form strong chemical bonds. Figure 5 shows the bonding time as a function of bonding voltage for anodic bonding of Corning 7740 glass with silicon [6]. It is apparent that higher voltage results in a shorter bonding time. For glasses with low concentration of sodium ions (Na^+), both high temperature and high voltage are necessary for a successful bonding. Higher voltage is also needed for thicker glass. High voltage also helps to reduce the temperature necessary for a good bonding.
- Standard silicon wafers are not completely flat but with $\pm 20 - 40$ μm bowing and wrapping. In order to make sure the silicon wafer is in intimate contact with the glass, a pressurized clamping is necessary. The clamping pressure is normally below 50 N.
- Anodic bonding can be carried out either in vacuum, or in a gaseous or atmospheric environment. However, bonding in air is much faster than in vacuum or in an inert gas environment [7]. This may be due to the oxygen in air which helps the oxidation process during anodic bonding. However, many applications require anodic bonding to be carried out in vacuum.
- Bonding time is typically 1–5 min for Corning 7740 glass and silicon. For special glasses, the bonding time may be longer. As mentioned before, both bonding temperature and voltage can influence the bonding time. After bonding, there is a cooling time. The cooling can be a few minutes with the help of purging inert gas. However, the cooling should be slow for materials with large difference in CTE.

Inspection and Testing

The bonding process can be visually monitored through the glass. Initially there will be an interference fringe pattern when the silicon and glass are in contact because of the microscopic gaps between them. As the bonding progresses the interference pattern recedes gradually, until a uniform color is seen across the whole bonding surface. Any defects in the bonding will show as voids at the bonding interface. Better inspection of bonding quality can be achieved by scanning acoustic microscopy (SAM). SAM can detect any loose contact at the bonding interface independent of visual errors.

The bonding strength can be tested in different ways, such as pressure testing, pull testing, shear testing and bending testing [2]. The pull test has demonstrated bonding strength in the range 10 – 20 MPa, which is greater than the fracture strength of glass. The upper limit of bonding strength is difficult to estimate, as the break in the pull test always occurs in the glass, not at the silicon–glass interface. However, for imperfect bonding, the bonding strength is poor and the glass often breaks along the boundary of voids.

Although anodic bonding can be done simply with a hot plate and a DC power supply, reliable and reproducible anodic bonding can only be performed with purpose-built systems. There are commercially available wafer bonders. With commercial systems, the bonding process can be either manual or automatic. The bonding is performed in a chamber of either vacuum or filled with gases. One of the key issues in anodic bonding is the alignment when both the silicon and glass have some fabricated microstructures. The alignment process in a commercial wafer bonder can be carried out either off-line or in situ. The in situ alignment is advantageous because high-accuracy alignment (± 5 μm) occurs only when the process temperature is reached, thus avoiding differential thermal expansion effects which can compromise alignment. It enables the user to make in situ adjustments and visual confirmation before finally committing to making the bond.

Key Research Findings

Anodic bonding is relatively simple in principle and has been well developed over the last few decades. Research in this area has been very much focused on solving practical and application-specific issues. One of the practi-

cal issues is dealing with anodic bonding of silicon–glass assemblies with shallow cavities. This is often encountered in microfluidic systems where microchannels are of high lateral-to-depth aspect ratio. Anodic bonding can cause the microchannels to collapse due to high electrostatic force at the bonding interface. Theoretical and experimental study indicated that the collapse can be avoided as long as the following condition is satisfied [8]:

$$\varepsilon_a V^2 a / E_{eff} d^3 < 1$$

where ε_a is the permittivity of air, V is the applied voltage for anodic bonding, E_{eff} is a material constant which characterizes the elastic stiffness of the materials, a is the half width of the channel and d is the channel depth. A similar problem happens when packaging pressure sensors, micropumps and accelerometers by anodic bonding. Most of these devices have micromachined silicon membranes, diaphragms or suspended beams. These micromechanical structures may stick to the glass when they are too flexible and too close to the bonding interface.

Although anodic bonding is a low-temperature process compared to fusion bonding which requires temperatures up to 1200 °C, the bonding process can still induce thermal residual stress in the silicon–glass assembly, causing bowing of the bonded wafer. The thermal expansion of Pyrex glass is not a constant but changes with temperature. The higher the bonding temperature the larger the mismatch between silicon and glass. For Corning 7740 Pyrex glass, the crossover point with silicon (where the thermal expansion of silicon is exactly the same as that of Corning 7740 glass) is around 300 °C. Experiments showed that bonding made at this temperature can be maintained flat within $\pm 5\,\mu m$ [3]. The crossover point is also dependent on the thickness of glass. Experiments indicated that for 0.5 mm thick glass (Corning 7740) the crossover temperature is at ~ 315 °C, while it becomes ~ 260 °C for 1.5 mm thick glass [7].

It is known that glass cannot be anodically bonded to glass. However, research has found that this can be realized by depositing an intermediate layer. The intermediate layer can be polysilicon, amorphous silicon, silicon nitride or silicon carbide [9]. This has opened an easy route to construct glass-based microfluidic systems which are widely used for capillary electrophoresis. Other investigations into anodic bonding have been on oxygen release into sealed cavities during bonding or proper seals for thin metal films which act as lead through electrodes [3].

Future Directions for Research

Anodic bonding is a fairly mature technique. Many basic issues have been dealt with. Future researches will mostly focus on widening its applications, particularly in microelectronic and microsystem (MEMS) packaging. Packaging can significantly influence the performance of final devices and systems. Therefore, anodic bonding has to be integrated as part of the manufacturing process and its influence should be fully taken into account at the design and manufacturing stages.

Anthrax

Definition

Anthrax is an acute infectious disease caused by the spore-forming bacterium *Bacillus anthracis*. Anthrax most commonly occurs in wild and domestic lower vertebrates (cattle, sheep, goats, camels, antelopes, and other herbivores), but it can also occur in humans when they are exposed to infected animals or tissue from infected animals.

Antibody

Definition

Antibodies are immune system-related proteins called immunoglobulins. An important component of the immune system, antibodies are found in the blood of all vertebrates. The synthesis, or manufacture, of antibodies is initiated when a foreign substance, referred to as an antigen, enters the body. Lymphocyte cells respond to the foreign substance by making an antibody with a molecular arrangement that fits the shape of molecules on the surface of the substance so that the antibody combines with it. Common antigens are the protein components of bacteria and viruses.

Antigen

Definition

An antigen is any substance that causes the immune system to produce antibodies against it. An antigen may be a foreign substance from the environment such as chemicals, bacteria, viruses, or pollen. An antigen may also be formed within the body, as with bacterial toxins or tissue cells.

Aperiodic AC Field

► Unbalanced AC field

Aperiodic Electrophoresis

Synonyms

Nonlinear electrophoresis; Field-dependent electrophoretic mobility

Definition

Aperiodic electrophoresis refers to the use of an unbalanced AC field to separate charged polarizable particles due to the Stotz–Wien effect of field-dependent electrophoretic mobility.

ANN

Definition

An artificial neural network is an information processing paradigm inspired by way the human nervous system processes information. It consists of an interconnected group of processing elements (neurons) which can exhibit a complex global behavior, determined by the network topology (the scheme used to connect elements together), and the algorithm (the rules) employed to specify the values of the weights connecting the nodes, the connections between the neurons. Based on *training rules* (whereby the weights of connections are adjusted on the basis of presented patterns), ANNs can be trained to generate an arbitrary number of outputs in response to an arbitrary number of inputs.

Definition

Bead based microfluidic platforms may be used for either particle manipulation or bead based sensing especially in cytometric bead based immunoassays. Bead based microfluidic platforms are often geared to biomedical research and diagnostics particularly in protein diagnostics through immunosorbent assays. For instance, in bead based immunosorbent assays, antigen–antibody reactions are induced on the surface of the bead in the solution and then, the binding event of the antigen–antibody is monitored by fluorescent labeling of either a secondary antigen or antibody. These assays are used to detect biomolecules by utilizing specific ligand-receptor binding reactions. The ligand-receptor binding events may then be quantified by quantifying changes in bead properties using either optical or physical sensing mechanisms. In order to optimize bead based reactions, there has also been considerable interest in developing microfluidic systems for efficient bead handling and manipulation.

Overview

Recently, there have been enormous efforts to transform conventional biological analysis methods into more efficient or sensitive assays through the use of Lab-on-a-Chip platforms. One of these representative efforts is found in the increased development of bead based microfluidic platforms [1]. The majority of bead based microfluidic platforms have been developed to detect specific biomolecules in an unknown sample by utilizing a ligand-receptor binding event. Bead based platforms have several potential advantages over conventional techniques. Bead based microfluidic platforms provide a larger binding surface area to sample volume ratio and thus may yield an improvement in the detection limit of a specific biomolecule over conventional techniques by allow-

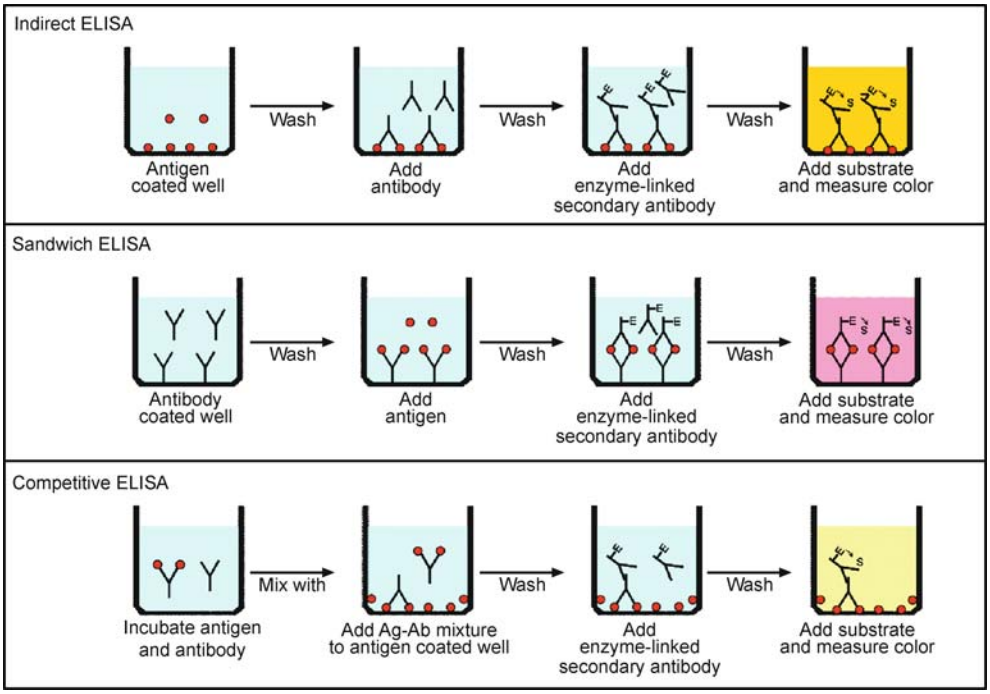
ing more available binding surface area per unit volume. This change in relative surface to volume ratio may also limit nonspecific binding and background interference due to other contaminating molecules which may also lead to improvements in detection limits of the desired analyte. In addition, bead based microfluidic platforms require less consumption of analyte sample as well as reagent volumes which may lead to less expensive assay platforms. There have been several reports which describe bead based microfluidic platforms for biomolecule detections [2–6] as well as novel methods which may be used for multiple particle manipulation and steering [7] within microfluidic environments. In the basic methodology section, the standard enzyme-linked immunosorbent assay (ELISA) is briefly introduced as a working principle for bead based microfluidic sensing platforms and the fundamentals of enzyme kinetics for ligand-receptor binding is also discussed as a theoretical background. Detailed discussions of case studies are presented in the Key Research Finding section.

Basic Methodology

ELISA (Enzyme-Linked Immunosorbent Assay)

The enzyme-linked immunosorbent assay (ELISA or EIA) is one of the most commonly utilized methods used in protein detection and analysis. An ELISA can provide quantitative information about antigen or antibody concentrations in solution by comparing the results of an unknown sample assay to a calibration curve based on known standard concentrations of the antibody or antigen of interest. Although, there are many variations in how ELISA may be performed, three of the most commonly used representative methods are discussed here (Fig. 1). The choice of which ELISA technique is used often depends on the nature of the antigen or antibody of interest, the availability of appropriate binding pairs, and the specificity of only the antigen of interest to a monoclonal antibody.

1. Indirect ELISA
   The concentration of an antibody (especially in blood plasma) can be quantitatively determined through the use of the indirect ELISA technique. In the indirect ELISA, an antigen is pre-coated within a microtiter well. Then a solution (e. g., blood plasma) containing the primary antibody of interest is added to the antigen coated microtiter well and allowed to incubate so that the two components may bind with each other. Afterwards a washing step removes any free primary antibody. Next, an enzyme-linked secondary antibody is added to produce a binding between the primary and secondary antibodies. The enzyme linked antibody often contains the catalytic protein of a horseradish peroxidase which cleaves a colorimetric substrate (such as *o*-phenylenediamine dihydrochloride) causing a color change in the substrate solution which may be monitored in a spectrophotometer by the optical density of the transmission spectra at the appropriate wavelength of light. Since the substrate produces a color change which is proportional to the amount of enzyme present through the binding reactions, the measured color change may be correlated with the concentration of the antibody of interest initially present in the solution which was analyzed. The concentration of antibody of interest can be determined by comparing the color change of the unknown sample against standards of known concentration.
2. Sandwich ELISA
   In a related technique, an antigen concentration can be determined by using a sandwich ELISA. In this technique, the antibody which binds to the antigen of interest is pre-coated in the microtiter well. Next, the sample containing the antigen of interest is added and allowed to bind with the pre-coated antibody. After the well is washed, an enzyme-linked secondary antibody specific to the antigen of interest is added and allowed to bind with the bound antigen. After washing any free secondary antibody away, the colormetric substrate for the enzyme is added. Again, by measuring the change of color in the enzyme reaction, as discussed before, the concentration of antigen can be determined by comparison with the color shifts of a predetermined standard calibration curve.
3. Competitive ELISA
   Another method to determine the concentration of an antigen is through the use of a competitive ELISA. In the competitive ELISA, a primary antibody is first incubated in a solution containing the antigen of interest. Through antibody-antigen binding the free antigen is captured by the antibody in solution. The larger the antigen concentration in the initial solution, the less free primary antibody that will be left after the antigen–antibody binding reaction. Next, the antigen–primary antibody mixture is added into an antigen pre-coated microtiter well. Now, only the free primary antibody left in the mixture will be able to bind with the antigen within the microtiter well. After a washing step, the antigen–primary antibody complex in the solution is removed and an enzyme-linked secondary antibody is added to produce a binding between the primary and secondary antibodies. As a final step, the colormetric substrate is added to the microtiter well and the amount of color change is measured and correlated to the known calibration curve. In the competitive assay, however, the concentration of the antigen of interest



Bead Based Microfluidic Platforms, Figure 1 Variations in the ELISA technique. Each assay can be used not only for qualitative but also for quantitative determination of the presence of antigen or antibody by comparison with standard curves prepared with known concentrations of antibody or antigen. The indirect ELISA is useful to determine antibody concentrations in solution. On the other hand, the sandwich ELISA is useful in determining antigen concentrations. In the competitive ELISA, the concentration of antigen is inversely proportional to the color produced by the substrate because the competitive ELISA is an inhibition-type assay

in the original sample is inversely proportional to the amount of color change because the antigen in solution reduces the amount of free antibody which is able to bind to the antigen coated in the microtiter well.

Key Research Findings

Many research groups have pursued bead based immunosorbent assays within microfluidic platforms. Here, instead of coating antigen or antibodies within microtiter wells, they are coated onto the surface of micron sized beads which act as the reaction vessels. Sato et al. [2] demonstrated a bead based immunosorbent microfluidic platform (Fig. 2). In their system, they used polystyrene beads for the solid phase reaction in order to maximize the available surface area for antigen–antibody binding. First, the beads were introduced into the microfluidic channel, which was designed with a barrier to trap the beads at a specific location within the device and create a packed bed. Next, an antigen (human secretory immunoglobulin A (s-IgA)) was infused through the microdevice to allow nonspecific adsorption of the antigen to the packed beads. After the unbound antigen is washed away, an antibody (anti-s-IgA) which had been conjugated with colloidal gold was infused to produce the antigen–antibody binding reaction. After a final wash step to remove the unbound antibody, the amount of binding between the antigen and antibody was detected by a thermal lens microscope (TLM). The TLM uses an excitation laser and a probe laser which is focused through the objective lens. The colloidal gold absorbs some of the excitation light and the rest of the energy is dissipated in the solution as thermal energy. The temperature change is monitored by a change in the solution refractive index monitored through a thermal lens. The larger the amount of colloidal gold, the lower the temperature change in the solution and thus a smaller change in the refractive index of the solution so the initial antigen concentration may be correlated to the temperature change in the solution monitored by the thermal lens. Based on this procedure, they were able to obtain a thermal lens signal down to 1 μg/ml of antigen (s-IgA) concentration with a linear dependency of thermal lens signal on the initial antigen concentration. In addition, the time needed for the antigen–antibody binding reaction was reduced by 90 fold which resulted in a shortening of the overall analysis time to less than 1 hr compared to 24 h for the standard procedure.

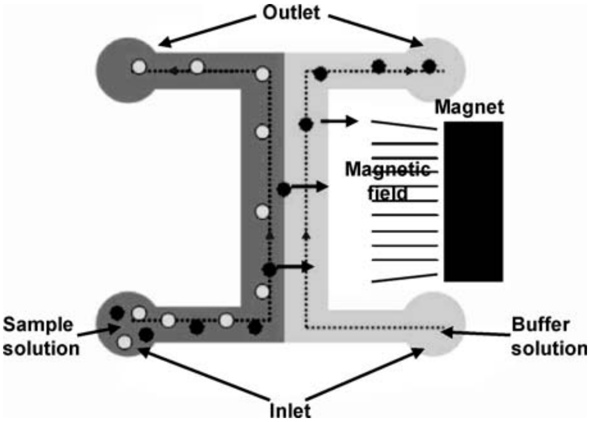
Bead Based Microfluidic Platforms, Figure 3 Conceptual illustration of bio-sampling and immunoassay procedure using magnetic bead approach: (**a**) injection of magnetic beads; (**b**) separation and holding of beads; (**c**) flowing sample; (**d**) immobilization of target antigen; (**e**) flowing labeled antibody; (**f**) electrochemical detection after adding enzyme substrate; and (**g**) washing out magnetic beads and ready for another immunoassay [3]

Next, Choi et al. [3] reported an integrated microfluidic biochemical detection system for rapid low-volume immunoassays. They utilized magnetic core beads as the solid support phase for the capture antibodies, and as carriers of captured target antigens. In order to detect target antigens, the working principle is based on a sandwich ELISA (Fig. 3). The antibody coated beads are first infused into the microfluidic channel with an integrated electromagnet. Once the magnetic beads are introduced, then they are attracted to the electromagnet and held in place. While holding the primary antibody coated magnetic beads within the magnetic field, target antigens are infused into the microfluidic channel. The antigen–antibody binding occurs while other free antigens not specific to the antibody used are washed away with the continuous flow. Next, enzyme-linked secondary antibodies are infused to produce a binding event between the bound antigen and secondary antibodies. The microfluidic channel is

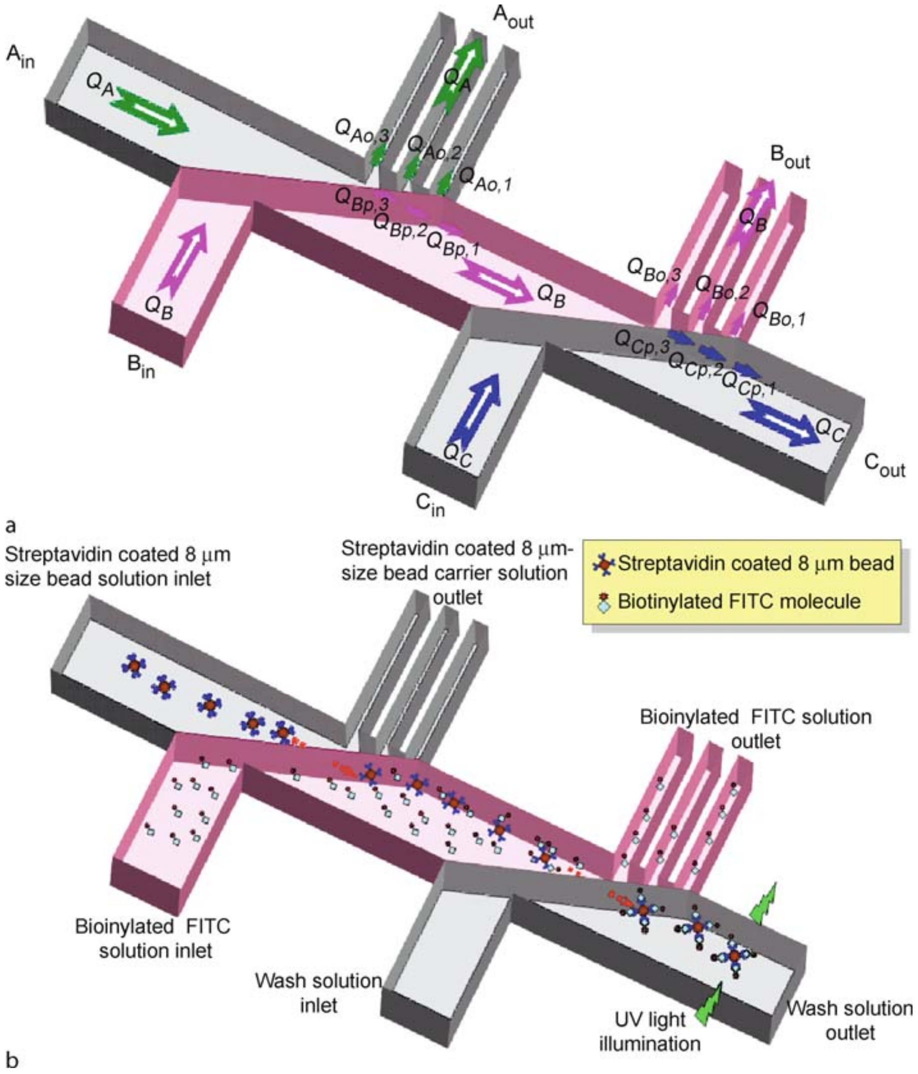


Bead Based Microfluidic Platforms, Figure 4 Proposed detection principle. Microbead conjugated with superparamagnetic nanoparticles (•). Unconjugated microbead (○) [4]

then washed to remove all unbound secondary antibodies. As a final step, a substrate solution, which reacts with the conjugated enzyme on the secondary antibody, is injected into the microfluidic channel. Electrochemistry is used as a detection method. To demonstrate this concept, they have used alkaline phosphatase (AP) and *p*-aminophenyl phosphate (PAPP) as the antibody bound enzyme and electrochemical substrate, respectively. AP converts PAPP to *p*-aminophenol (PAP). Thus, by applying an oxidizing potential to the patterned detection electrodes, PAP is converted into 4-quinoneimine (4-QI) by a 2-electron oxidation reaction. Therefore, by measuring the electrical current change by amperometry, it is possible to determine the concentration of the enzyme (AP) bound to the magnetic beads. By using mouse IgG as an analyte and applying the electrochemical detection principle, they were able to show a detection limit within their device of around 100 ng/ml of mouse IgG. Also, the total time required for an immunoassay was less than 20 min including sample incubation time, and sample volume wasted was less than 50 μl during five repeated assays.

Another good example of a bead based immunoassay is based on superparamagnetic nanoparticles (50 nm diameter) handling in microfluidic environments which was reported by Kim et al. [4]. In their report, the binding of antigen conjugated with superparamagnetic nanoparticles to antibody coated fluorescent microbeads (1 μm diameter) and the subsequent deflection of the magnetic nanoparticle bound fluorescent microbeads within a magnetic field were used as the signal for measuring the presence of analyte. To test their principle, the target analyte sample was conjugated with the superparamagnetic nanoparticles. The fluorescent microbeads were conjugated with antibodies to the analyte of interest by nonspecific adsorption. Then, the target nanoparticle conjugated analyte and the antibody coated microbeads are mixed together to produce antigen–antibody binding. Since the target analyte molecules are conjugated with the superparamagnetic nanoparticles, the fluorescent microbeads will be indirectly conjugated with the nanoparticles. The total amount of the superparamagnetic nanoparticles bound with the microbeads depends on the concentration of the target antigen. As shown in Fig. 4, a buffer and sample solution are both infused into a converging channel geometry where the sample solution contains the fluorescent microbeads with the bound superparamagnetic nanoparticles. A permanent magnet is placed on the buffer side of the microchannel geometry. Due to the presence of the magnetic field gradient, the nanoparticle bound microbead will be deflected towards the magnet and the deflection force will depend on the number of superparamagnetic nanoparticles presented on the microbeads. In this study, Kim, et al., assumed that if the concentration of the superparamagnetic nanoparticles bound to the fluorescent microbead increases, the velocity of the bead towards the magnet will increase. This implies that the bead velocity in the microchannel may be correlated back to the initial concentration of the target analyte. In addition, since the microbeads have specific optical properties, a multiplex analysis is also possible. Using this method, the magnetic force-based microfluidic immunoassay was successfully applied to detect both rabbit IgG and mouse IgG as model analytes. The detection limit of the system was determined to be 244 pg/ml and 15.6 ng/ml for rabbit IgG and mouse IgG, respectively.

Yang et al. [5] reported a novel concept in bead handling and serial reaction processing using a technique named "particle cross over" in microfluidic channels to accomplish continuous cytometric bead processing within a microfluidic device for bead based sensing platforms. The operating principle of the continuous biosensing is based on adapting the Zweifach–Fung effect [8, 9] in a novel manner. The Zweifach–Fung effect has shown that when a particle approaches a bifurcating region that all particles will flow into the daughter branch with the higher flow rate if the flow rate ratio between the two branches are greater than 2.5 : 1 when the particle diameter approaches the vessel diameter. Utilizing this mechanism involves moving cytometric beads through different regions within the microfluidic device where the bead is exposed to different solution environments so that antigen–antibody binding, washing and detection can occur without any significant sample dilution. When a micron-sized bead approaches a bifurcating region of microfluidic channel, it is possible for the bead to cross over from a carrier



Bead Based Microfluidic Platforms, Figure 5 (**a**) Conceptual drawing of microflow structures within a microfluidic network for the particle cross over within microfluidic channels. It is possible to achieve the particle cross over from one to another fluid streams without losing particles into multiple parallel channels. (**b**) Schematic sketch of a representative example of continuous biosensing using the particle cross over mechanism. The concentration of biotinylated FITC molecules can be determined by measuring the fluorescence intensity of the biotinylated FITC bound streptavidin coated 8 μm-diameter particle at the detection window using an epifluorescence microscope [5]

fluid into a recipient fluid streams by precisely controlling flow rate ratio between the two downstream channels. For instance, as shown in Fig. 5a, a microfluidic device can be designed to have a 1 to 1 of total flow rate ratio ($Q_A = Q_B = Q_C$) at each bifurcation region. Thus, all three fluid streams which are infused from each inlet can be transported into each designated outlet ($A_{in} \rightarrow A_{out}$, $B_{in} \rightarrow B_{out}$, $C_{in} \rightarrow C_{out}$). At the same time, it is also possible to design the outlets as a series of multiple parallel channels at each bifurcation region so that a micron-sized particle infused from the inlet is not able to follow its original fluid stream of the carrier fluid into the outlet and will cross over into the recipient fluid stream (A→B) because of the Zweifach–Fung effect. In this study, a streptavidin coated 8 μm-diameter particles and biotinylated FITC dye were used as a test system for demonstrating continuous biosensing in microfluidic channels. The biotinylated FITC molecules produce fluorescence light (532 nm) under UV light exposure due to the presence of the FITC (fluorescence dye). Thus, the higher concentration of biotinylated FITC in solution, the more biotinylated FITC which is bound to a bead through biotin-streptavidin binding, the higher the fluorescence intensity which can be detected. Figure 5b represents a concep-

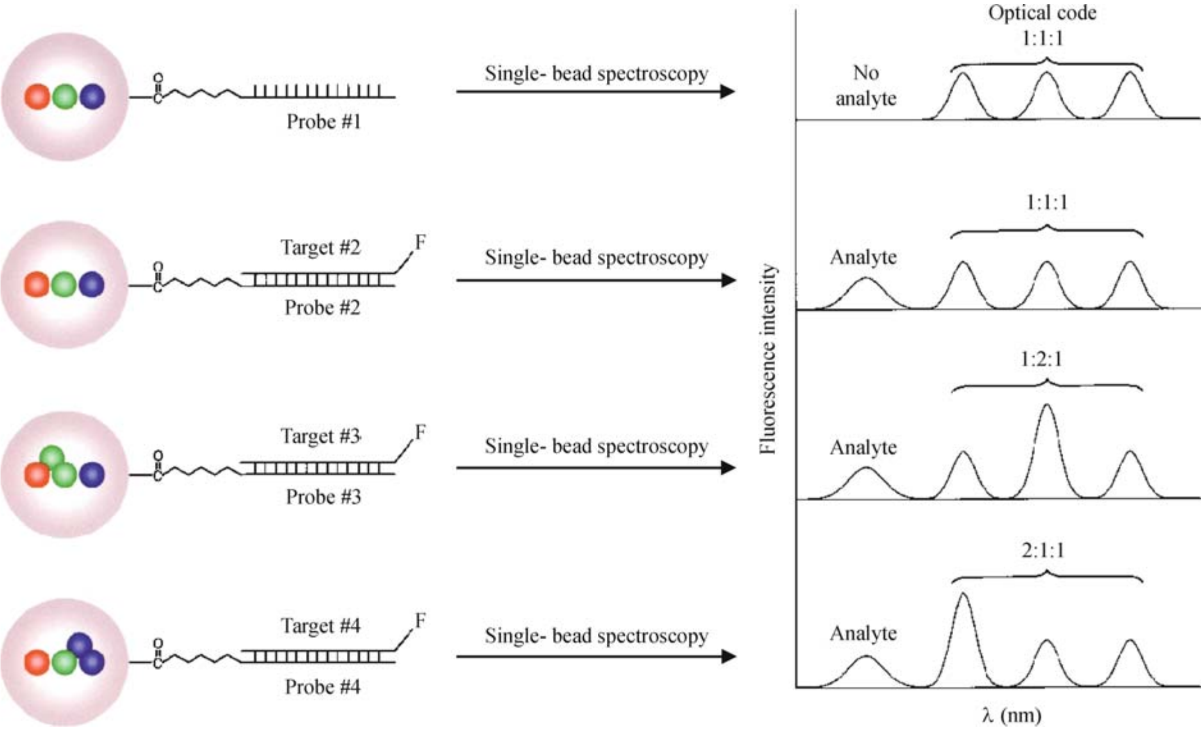
tual sketch of continuous biosensing based on the particle cross over mechanism. Once the streptavidin coated 8 μm-diameter beads in buffer media travel toward the 1st bifurcation region, then they can cross over into the biotinylated FITC solution without significant mixing of the two fluid streams. Once the streptavidin coated bead enters into the biotinylated FITC solution, the binding between the biotinylated FITC molecules and the streptavidin coated 8 μm-diameter beads occurs within the main channel. In addition, no significant serial dilution effect on biotinylated FITC solution is expected as would be expected by simply mixing the fluids together through a converging channel geometry and passive micromixing region because the old fluid infused from upstream of the main channel is removed at the bifurcation by maintaining a 1 to 1 total flow rate ratio between the two fluid streams. At the 2nd bifurcation, the biotinylated FITC bound streptavidin beads can then cross over to a wash solution by producing the same microflow structures. Finally, the fluorescence intensity of the biotinylated FITC bound streptavidin beads can be measured at a downstream detection window by an epifluorescence microscope. The fluorescence intensity of the beads can be assumed to be proportional to the concentration of biotinylated FITC dye in the solution. Since beads are continuously infused into the device from the bead inlet, it is expected that the bead fluorescence intensity will change in response to changes in biotinylated FITC dye concentration which can be tracked by plotting the bead fluorescence intensity as a function of time. Thus, the system can dynamically respond to changes in analyte concentration allowing continuous biosensing. Based on this concept, Yang, et al. demonstrated that the fluorescence intensity of the bead measured is linearly proportional to the analyte (biotinylated-FITC) concentration. The detection limit of the device was determined as a 50 ng/ml of biotinylated FITC concentration.

Another application area of bead based microfluidic platforms includes bead based DNA detections. Han et al. [6] reported quantum-dot-tagged microbeads for multiplexed optical coding of DNAs. Multicolor optical coding for DNA hybridization assays has been achieved by embedding different-sized quantum dots into polymeric microbeads at precisely controlled ratios. And then, as shown in Fig. 6, probe oligos were conjugated to the beads by cross linking. The target oligos were detected with Cascade Blue. After hybridization, nonspecifically bonded molecules and excess reagents were removed by a washing process. For multiplexed assays, they have optimized the oligo lengths and sequences so that all probes had similar melting temperatures ($T_m = 66\,°C - 99\,°C$) and hybridization kinetics (30 min). As a result, they have shown that the coding and target signals can be simultaneously read at the single-bead level with high uniformity and reproducibility. Also, they have shown that bead identification accuracies were as high as 99.99 % under favorable conditions.

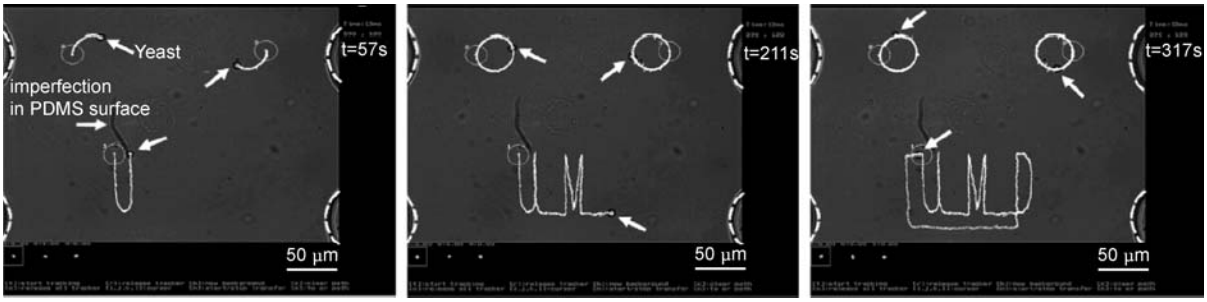
A final example of bead based microfluidic platforms is a novel concept in particle handling and steering. Armani et al. [7] recently reported very attractive results on steering multiple particles simultaneously within microfluidic environments. They combined electrokinetic based microfluidic platforms with vision-based feedback control to independently steer multiple particles with micrometer accuracy in two spatial dimensions. In their method, they have steered particles by creating an electroosmotic flow field that carries all the particles from where the particles are to where particles should be at the next time step. The flow is created by the biasing of multiple electrodes arranged around the active test area. In order to steer each particle independently, they constructed a vision-based feedback loop comprised of sensing, computation, and actuation to steer particles along user-input trajectories. Particle locations were identified in real-time by an optical system and transferred to a control algorithm that then determined each electrode voltage necessary to create the proper electroosmotic flow pattern to carry all the particles to their next desired locations. They have experimentally demonstrated that it is possible to steer not only neutral particles but also charged particles simultaneously by precisely controlling electroosmotic flow patterns. The neutral particles can be carried by the electroosmotic flow by controlling voltage applied on each electrode. The charged particles can be also steered by both electroosmotic and electrophoretic forces by controlling voltage applied on each electrode. For instance, as shown in Fig. 7, they were able to steer three yeast cells (5 μm diameter), which have a small surface charge (electrophoretic mobility $c = -23.3 \pm 6.9 \times 10^{-9}\,\mathrm{m^2V^{-1}s^{-1}}$) within an accuracy of less than 1 μm by controlling the potentials of eight electrodes. Since this type of particle steering permits noninvasive steering of any visible particle regardless of the charge status of particles, it is expected that this technique is useful for navigating beads and particles to localized sensors for cell sorting, sample preparation, and for combinatory testing of particle interactions with other particles, chemical species, and distributed sensors.

Future Directions for Research

Although a variety of technologies related to bead based microfluidic platforms are introduced here, there are still many challenges to producing efficient Lab-on-a-Chip bead based sensor technologies over the conven-



Bead Based Microfluidic Platforms, Figure 6 Schematic illustration of DNA hybridization assays using QD-tagged beads [6]



Bead Based Microfluidic Platforms, Figure 7 Steering of three yeast cells (5 μm diameter, Red Star, Giant Food) with small surface charge (electrophoretic mobility, $c = -23.3 \pm 6.9 \times 10^{-9}\ \mathrm{m^2V^{-1}s^{-1}}$) around two circles and a *UMD* path. The yeast cells are visible as small black dots with a white center (the three target cells are marked with a white arrow in each image), and the white curves are the trajectories that the target cells have traced out. The three beads are being steered to within an accuracy of one pixel (corresponding to less than 1 μm) [7]

tional sensing methods. For instance, although many bead based microfluidic immunosensing technologies have been demonstrated with faster throughput over conventional methods, these microdevices often still have higher concentration detection limits and higher variability when compared with the conventional macroscale methods. Thus, most laboratories still utilize standard ELISA protocols or more recently cytometric bead based flow cytometry assays. This implies that there still needs to be substantial improvement and standardization in the future development of these bead based platforms for truly realizing the promise of Lab-on-a-Chip bead based microfluidic sensing and handling platforms which can outperform the standard macroscale technologies.

Bimorph

Definition

A structure composed of two active layers and one or more passive layers. Typically the active layers work through either thermal expansion, hygrothermal expansion, or piezoelectric expansion via an externally-applied electrical field. Bimorphs are used in the latter case to amplify the low maximum strain possible in piezoelectric materials while reducing the output force.

Biofuel Cell

Synonyms

Biocatalytic fuel cell; Enzymatic fuel cell; Microbial fuel cell

Definition

Conceptually similar to a battery, a fuel cell is an electrochemical device that converts chemical energy stored in a fuel and an oxidant into electrical energy. The fundamental difference between a fuel cell and a battery is that fuel and oxidant are supplied from outside the reaction chamber and waste products are removed. Fuel cells that utilize biological catalysts are collectively termed biofuel cells. There is a common misinterpretation that biofuel cells are named as such because they use biological fuels, which is ambiguous as the same fuel (e.g., methanol) may originate from both biological and non-biological sources. A biofuel cell mimics electrochemical processes occurring in nature to harvest a useful electrical current, without the use of precious electrocatalysts such as platinum. There are two main categories of biofuel cells: microbial biofuel cells and enzymatic biofuel cells. Microbial biofuel cells utilize entire living cells or microorganisms combined with redox intermediates to catalyze the oxidation of a fuel. Enzymatic biofuel cells, on the other hand, catalyze the chemical reactions using biological redox enzymes that can be isolated and purified from suitable organisms, thus extracting the core part of the cell that enables catalytic activity.

Bioimmobilization

Definition

Bioimmobilization is the process of immobilizing biomolecules onto sensor surface to provide the biospecificity to the biosensor. Biospecificty is the property of the biorecognition membrane of the biotransducer that is conferred by the purposeful use of a bioactive receptor. The major purpose of bioimmobilization is to confer the molecular recognition and specificity inherent to the bioactive receptor to the biotransducer in a manner that maximizes the sensitivity of the physicochemical transducer that lies beneath. Amongst the various bioimmobilization approaches are:

- adsorption (physical, chemical and electrostatic),
- adsorption followed by covalent cross-linking,
- covalent tethering, and
- entrapment (physical or covalent) within host matrices (e. g. polymers, polymeric hydrogels and sol-gels).

Regardless of the specific linking chemistry and substrate employed, the key goals in all biomolecule immobilization strategies are:

- reproducible, high density coverage of the biomolecule on the substrate,
- the orientation of the biomolecule for efficient kinetics of the biological reaction,
- minimal background and non-specific adsorption to the support or substrate,
- improved sensitivity, and
- long term stability (retained bioactivity) of the immobilized biomolecule.

Definition

Biomimetics is the study of how to apply the methods and principles found in nature to modern science and engineering.

Overview

Biomimetics has become a more modern approach in various fields of engineering design. Advocates of the field believe optimized solutions for ecological systems resulting from thousands of years of natural evolution can provide today's engineers with limitless applicable technologies. Julian Vincent, a well-established researcher and the director of the Centre for Biomimetics and Natural Technologies proclaims that there is only a 10% overlap between biology and technology in terms of the mechanisms used [1]. This vast technological potential has resulted in many innovative creations throughout history.
Possibly the most well-known application of biomimetics was by a Swiss inventor, George de Mestral, who observed the efficient manner in which cocklebures adhered themselves to clothing and fur and designed a material capable of mimicking the plant's trait, ultimately leading to the patent of VELCRO® [2]. Another familiar application can been seen in the parallel field of bionics which focuses heavily on the anatomy and physiology of humans and animals in the design of robotic components to obtain stable fluid-like motions while reducing energy expenditure [3, 4]. In the area of computer science, many forms of imitating nature to optimize engineering systems are utilized. Genetic algorithms utilize evolutionary theories formulated by Charles Darwin that force a program to iterate toward optimal solutions. Often used concurrently with genetic algorithms are artificial neural networks. Modeled after biological neural networks, this form of software design can adapt to closely model relationships between inputs and outputs of a system. On a smaller scale, biomimetics is used in the area of nanostructured materials as Wendell et al. observe cellular processes and apply novel phenomena to synthetic polymer membrane systems [5]. In the field of BioMEMS, the physiological process of hemostasis is being recreated chemically in a microfluidic system to design self-repairing devices [6]. Another area that is having significant influences on microfluidics is electrowetting-based actuation. The idea of optimizing the wetting properties of a surface to control a fluid is utilized by the lotus plant to self-clean itself as water droplets roll off the leaves [7].

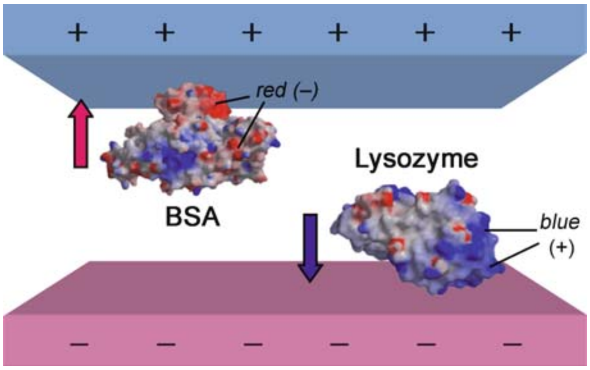
Definition

Biomolecular adsorption in microfluidics usually refers to the *nonspecific* adsorption of biomolecules (amino acids, peptides, DNA, RNA, proteins, and cells) onto the surfaces of microfluidic devices. In this sense, this is often referred as *biofouling in microfluidics*. This causes many problems including reduced device sensitivity, poorer detection limits and selectivity, and diminished device lifetime. Among the above adsorbing species, proteins (including protective proteins of cells) cause the biggest problems resulting from irreversible adsorption and subsequent denaturation.

Overview

The microfluidic device is probably the most popular lab-on-a-chip, and major breakthroughs have been made for its development over the last five years. Microfluidic devices have been demonstrated for many chemical and biological assays [1]. In the early 1990s, several problems in microfluidic actuation were identified. One problem was water stiction: the adhesion of water to microchannel walls made of hydrophilic materials such as glass, which perturbs the desired flow and prevents the channels from being rinsed for reuse [2]. This problem can be solved by passivating the channel walls, typically through modifications that alter the wettability of the surface [2]. Another serious problem is that biomolecules tend to adsorb from solution onto many of the materials commonly used for microfluidic devices [3]. The adsorbing species may include amino acids, peptides, proteins, DNA, RNA, and cells. Among these species, proteins cause the biggest problems, because they often denature and become very difficult to remove [3].

This entry reviews the physicochemical properties of microfluidic devices, mechanisms of biomolecular adsorption and denaturation at microfluidic device interfaces, and methods to minimize or to prevent biomolecular adsorption. The trade-offs between methods to reduce water stiction will also be discussed.



Biomolecular Adsorption in Microfluidics, Figure 1 At pH 7.2, bovine serum albumin (BSA) has negative net charge and is electrostatically attracted to the positively charged top surface. At that pH, lysozyme has positive net charge and is attracted to the negatively charged bottom surface

Basic Methodology

The interactions between protein molecules and solid surfaces can be classified into: hydrophobic interactions, electrostatic interactions, hydrogen bonding (a special type of electrostatic interactions), and van der Waals interactions [4].

Van der Waals and Electrostatic Interactions

Van der Waals interactions are a combination of several types of very weak, short-range interactions: dipole–dipole, induced dipole–induced dipole (London dispersion forces), dipole–induced dipole, and the Born repulsion. Van der Waals interactions are weak compared with electrostatic interactions, and are difficult to control through the choice of experimental conditions [4]. Hydrogen bonds, a special type of dipole–dipole interaction, are stronger and play important roles in protein folding, solvation, and adsorption. Electrostatic interactions arise from Coulombic attraction or repulsion between charged groups. Portions of protein surfaces are positively charged from terminal or side chain ammonium groups (colored blue in Fig. 1), while other portions are negatively charged from terminal or side chain carboxyl groups (colored red in Fig. 1) [4]. Depending on the pH, the net charge on a protein molecule can be positive or negative, or neutral at the isoelectric point (pI). Charged protein molecules adsorb on surfaces having the opposite charge, as illustrated in Fig. 1 [3].

Hydrophobic Interactions

In general, nonpolar substances such as hydrocarbon oils and polyethylene are considered hydrophobic. The hydrophobic effect refers to the phenomena that such species are more soluble in nonpolar solvents than in water. The effect is at least partly due to the tendency of water to form a hydrogen-bonded network structure that excludes nonpolar or non-hydrogen-bonding moieties. An attempt to transfer nonpolar moieties into the hydrogen-bonded water structure results in a decrease in entropy ($\Delta S < 0$) and almost no change in enthalpy ($\Delta H \approx 0$ at room temperature), thus leading to an increase in Gibbs free energy ($\Delta G > 0$), corresponding to a nonspontaneous process. The hydrophobic effect is especially important in biological systems. When a protein folds, the interior consists predominantly of hydrophobic domains, while the exterior is more hydrophilic.

In water, nonpolar and non-hydrogen-bonding moieties associate through hydrophobic interactions. Hydrophobic interactions can cause protein molecules to aggregate (even to the point of precipitating out of solution), and also play a major role in protein adsorption from water onto hydrophobic surfaces. At room temperature, protein molecules in solution diffuse by Brownian motion. When they come in contact with hydrophobic surfaces, they tend to remain there, adsorbing, unfolding, and eventually denaturing. Protein aggregation in solution and protein-surface hydrophobic interactions are maximized at the isoelectric point of a protein (pI), while electrostatic interactions with water are minimized at that pH [4].

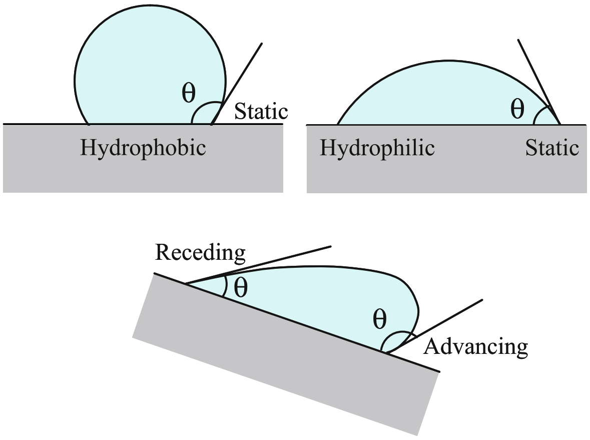
Surface Wettability of Materials Used for Microfluidic Device Surfaces

Whether a surface is hydrophilic or hydrophobic, surface wettability can be assessed by measuring the contact angle, θ, of a sessile water droplet on a smooth surface. The contact angle is a consequence of the surface tensions (γ) at the liquid–vapor (LV), solid–vapor (SV), and solid–liquid (SL) interfaces, as shown by the Young equation,

$$\gamma_{SL} = \gamma_{SV} - \gamma_{LV} \cos\theta \,. \quad (1)$$

Figure 2 illustrates how static, advancing, and receding contact angles are defined. A larger contact angle indicates the surface is more hydrophobic than a reference surface.

Table 1 summarizes contact angles for water on various materials that are frequently used in direct contact with liquids for microfluidic devices. The values shown in this table are not definitive, as surface treatments such as plasma etching can dramatically change the contact angle. The advancing contact angle $\theta_{advancing}$, obtained by tilting



Biomolecular Adsorption in Microfluidics, Figure 2 Static, advancing, and receding contact angle as measures of surface wettability

the surface, by adding more liquid to a droplet, or by using the Wilhelmy plate method, is generally larger than the static contact angle θ_{static}; the difference depends on the surface homogeneity and roughness (Fig. 2). In general, on etching or roughening a surface, the contact angle θ typically increases, but it may decrease.

Glass, silicon dioxide (SiO_2), and poly(ethylene glycol) (PEG) are hydrophilic. Their static water contact angles are $\leqslant 30°$ as shown in Table 1. Many clean metal surfaces, including gold, show contact angles close to 0° [5]. Ordinarily, metal surfaces are contaminated, resulting in higher contact angles ($\sim 60°$ for gold) [6]. Polystyrene (PS), alkane-terminated self-assembled monolayers (SAMs), polydimethylsiloxane (PDMS), and Teflon are hydrophobic, with static water contact angles $\geqslant 90°$. All the other materials shown in Table 1, including ordinary gold, protein films, polyesters such as poly(methyl methacrylate) (PMMA), and polycarbonate (PC), can be considered as intermediate between hydrophilic and hydrophobic.

Nonspecific Protein Adsorption on the Surfaces of Microfluidic Devices

Proteins such as antibodies and enzymes can be deliberately anchored on microfluidic device surfaces by covalent bonds or molecular recognition in order to fabricate array biosensors. Nonspecific adsorption is the (usually) undesirable adsorption of molecules on the surface, and it ends up with loss of analyte. In nonspecific adsorption, the molecule–surface interactions are initially weaker, so the adsorption process is both slower and more difficult to control. Subsequent denaturation leads to stronger adhesion [7], as well as to changes in the surface hydrophilicity and roughness [8]. It is important to understand the mech-

Biomolecular Adsorption in Microfluidics, Table 1 Advancing and static water contact angles on common materials used for microfluidic device surfaces [18–43]

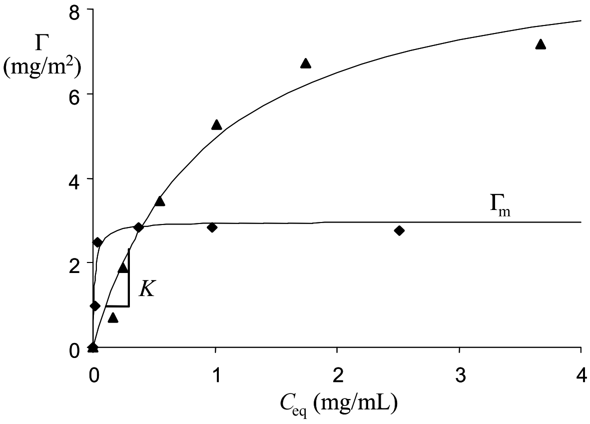
anisms of nonspecific protein adsorption in order to minimize the problems it can create.

Analyzing Protein Adsorption

Although protein adsorption from aqueous solutions onto various types of surfaces has been studied for several decades, no models accurately describe the process in detail [4]. Protein adsorption is typically analyzed by measuring a series of surface coverage data (Γ, usually in $mg \cdot m^{-2}$) against either the equilibrium protein concentration (C_{eq}, usually in $mg \cdot mL^{-1}$) or the time elapsed (t). Γ can be evaluated by measuring the amount of protein remaining in solution in contact with a particulate surface in a series of test tubes or in a stirred cell. Alternatively, the amount of protein adsorbed to an ordinary (non-particulate) surface can be measured directly by total internal reflection fluorescence (TIRF), surface plasmon resonance (SPR), ellipsometry, optical waveguide lightmode spectroscopy (OWLS), or a thickness shear mode (TSM) resonator.

A plot of Γ vs. C_{eq} is an adsorption isotherm. Data for protein adsorption are frequently modeled by the Langmuir equation, although the validity of using this equation for



Biomolecular Adsorption in Microfluidics, Figure 3 A typical Langmuir-type adsorption isotherm, for bovine hemoglobin adsorbing from 10 mM phosphate buffer (pH 6.8) onto sulfonated polystyrene microparticles: ♦ = 0.14 sulfonate groups nm^{-2}, ▲ = 2.1 sulfonate groups nm^{-2}

protein adsorption remains an open question:

$$\Gamma = \Gamma_m \frac{KC_{eq}}{1 + KC_{eq}} \,. \tag{2}$$

This isotherm is characterized by the linear rise at low concentrations (slope $= K$, the equilibrium constant for adsorption) and the subsequent plateau ($\Gamma_m =$ the saturated surface coverage of protein), as shown in Fig. 3. K is associated with the ratio of the adsorption to desorption rates, and is related to the work of adhesion: the energy required to desorb the protein from the surface. A larger K indicates slower desorption than adsorption, leading to irreversible adsorption.

To get some control over protein adsorption, one has to understand the protein-surface interactions in advance. To this end, adsorption isotherms have been obtained for a wide variety of surfaces, from hydrophilic to hydrophobic. Techniques for controlling the surface wettability include varying the terminating groups of SAMs or the ratio of monomers in copolymers. The effects on protein adsorption of factors such as liquid polarity, temperature, pH, solute type (e. g. electrolyte), and solute concentration have been widely studied [4].

Several adsorption isotherm studies [9] have shown that K, associated with the ratio of the adsorption to desorption rate, is larger for hydrophobic surfaces than for hydrophilic surfaces, indicating proteins adsorbs irreversibly to hydrophobic surfaces. This irreversibility is closely associated with the extent of structural changes of proteins adsorbed on surfaces, which will be discussed in the following section.

Structural Changes of Protein Molecules at Water–Solid Interfaces

Once a protein molecule makes contact with a hydrophobic surface, conformational fluctuations at the outside of protein molecule cause hydrophobic residues to be exposed, some of which adhere to the surface, ultimately leading to unfolding and/or flattening [4]. This conformational change is a spontaneous process ($\Delta G < 0$), driven in part by entropy gain ($\Delta S > 0$). This unfolding has been shown through circular dichroism (CD) experiments to involve a decrease in α-helix and increase in β-sheet and unordered conformations [7]. This denaturation is, for the most part, responsible for the irreversibility of adsorption through hydrophobic interactions. Protein adsorption leads to the formation of a bumpy layer, or even to the formation of irregular aggregates of protein molecules adsorbed on the surface. For example, Locascio et al. have identified large, irregular aggregates of protein molecules adsorbed on the microchannel surface in a capillary electrophoresis system [8].

Association and dissociation of protein molecules on hydrophobic surfaces may also take place. Small proteins comprised of a single polypeptide chain, such as lysozyme, associate to form dimers upon adsorption on hydrophobic surfaces, especially near the pI of 11. Proteins that have a quaternary structure, such as hemoglobin, can dissociate into subunits upon contacting a hydrophobic surface, as the subunits are held together by hydrophobic interactions.

However, such structural changes have also been found for hydrophilic surfaces, when the surface is fully covered with proteins [7] and when the proteins are in contact with the surface for a long period of time (more than several hours) [3], indicating the participation of other interactions towards structural changes.

Key Research Findings

Small Solute, DNA, and Cell Adhesion to Microfluidic Device Surfaces

DNA is a negatively charged polyelectrolyte, and so sticks to positively charged surfaces, but not hydrophobic surfaces. Ions and water-soluble polymers also do not stick to hydrophobic surfaces.

The adhesion of cells to surfaces is different from that of proteins and DNA. Cell adhesion and spreading are believed to depend primarily on the hydrophobicity of both cells and surfaces. Cell surface hydrophobicity is usually associated with the presence of fibrillar structures on cell surfaces and specific cell wall proteins. Adhesion, spreading, and growth of mammalian cells are generally promoted on hydrophilic surfaces ($\theta_{\text{static}} \approx 30-40°$) [10], while those of bacterial cells are generally promoted on hydrophobic surfaces [11]. The latter can be distinguished from mammalian cells by the existence of fibrils and a large number of cell wall proteins. Other factors that affect cell adhesion include surface topography [10] and the presence of certain proteins (especially albumin and fibrinogen) that may interact with cell wall proteins.

Surface Materials Used in Microfluidic Applications

To prevent biomolecular adsorption and water stiction, the surface materials for a microfluidic device should be carefully chosen with consideration of the actuation method (hydrodynamic or electrokinetic) and analytes to be manipulated (small solutes, DNA, proteins, and/or cells). Tables 2 and 3 summarize the surface materials that have been used in microfluidic applications.

Minimizing Biomolecular Adsorption with Hydrodynamic Actuation

Hydrodynamic actuation methods include pressurizing a microchannel with a syringe pump or from a nitrogen tank (pumping), applying different pressures for inlets and outlets of microchannels (ΔP), centrifuging the microchannel tubes, and utilizing gravity or osmosis. In the absence of externally applied electrical potentials, hydrophobic interactions become dominant over electrostatic interactions, unless the surface is highly polarized. Since charged analytes (ion, dye, water-soluble polymer, and DNA) and mammalian cells do not have hydrophobic interactions, all types of surfaces, including hydrophilic (glass, SiO_2, and PEG), intermediate (PC and PMMA), and hydrophobic surfaces (PDMS), can be used for hydrodynamic actuation of these species, as shown in Table 2. Among these surfaces, PDMS can prevent water stiction that leads to fluctuation in the flow rate in microchannels. However, PDMS is not the optimal choice for the solutions of proteins or bacterial cells, because they adsorb on PDMS surfaces through hydrophobic interactions. PDMS also has some swelling issues, especially with nonpolar solvents.

Minimizing Biomolecular Adsorption with Electrokinetic Actuation: Electroosmotic Flow

The most common method of electrokinetic actuation is capillary electrophoresis (CE), in which electrophoresis of analytes and electroosmotic flow (EOF) of bulk fluid usually occur at the same time. Figure 4 illustrates the working principle of CE. The surface of fused silica capillaries is negatively charged at the pH values commonly used

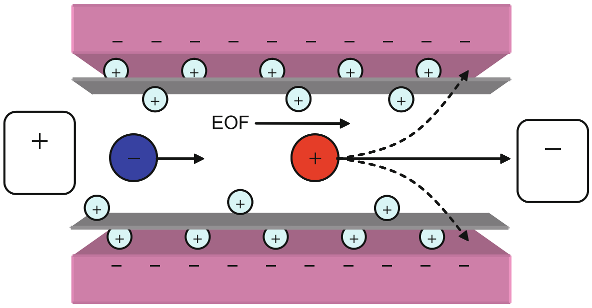
in CE. A diffuse double layer of cations is attracted to the stationary negative changes on the wall. EOF occurs when an electric field is applied, which causes the outer layer of cations to migrate towards the cathode, dragging along the bulk buffer solution. In many cases, the electroosmotic force is stronger than the electrophoretic force, which causes all analytes to migrate toward the cathode, regardless of their charge. Under these conditions, as shown in Fig. 4, analyte molecules are separated according to their charge.

Because the surfaces of microchannel walls have to be ionized for EOF, they may have electrostatic interactions with charged analytes. That is, charged protein molecule could adsorb through Coulombic interactions. Because EOF scales with the charge density on the channel walls, biomolecular adsorption originating from electrostatic interactions also depends on the rate of EOF [12]; whether the surface is originally hydrophilic or hydrophobic is less important. This explains why many materials ranging from glass (hydrophilic) to PDMS (hydrophobic) can be used for chip-based CE systems, as shown in Table 3.

CE-based methods that do not utilize electrophoresis include capillary electrochromatography (CEC) or micellar electrokinetic chromatography (MEKC). In CEC, EOF acts as a pump to move analytes past a stationary phase; analytes partition into the stationary phase with different affinities, enabling separation. Other CE-based methods that do not utilize EOF include capillary isoelectric focusing (CIEF) or capillary gel electrophoresis (CGE). CIEF works on the same basic principle as IEF. The capillary is treated with polyacrylamide or methylcellulose, so there is no EOF, ensuring that the relative movement of proteins depends solely on differences in their pI values. There are no electrostatic interactions between charged analytes and the microchannel surface, so hydrophobic interactions are



Biomolecular Adsorption in Microfluidics, Figure 4 Capillary electrophoresis (CE). Cations on a microchannel wall are pulled toward the anode, generating electroosmotic flow (EOF); positively and negatively charged analytes are separated by their differences in their electrophoretic mobilities. Depending on the rate of EOF, analytes may be attracted to a microchannel wall through electrostatic attraction, shown as dashed arrows

the dominant factor for separation. Materials commonly used for CIEF include polyacrylamide, cellulose, gold, and PMMA, as shown in Table 3. These materials are either hydrophilic or intermediate, and are capable of minimizing protein adsorption through hydrophobic interactions.

Surfaces of intermediate hydrophobicity, such as PC, PMMA, and protein film, are most commonly used for CE-based microfluidic chips, as they minimize water stiction as well as protein adsorption through hydrophobic interactions to some extent. The popularity of PDMS is

attributable to its ease of fabrication. However, PDMS has several problems for electrokinetic actuation. One is that CE in a PDMS channel supports lower EOF than glass or quartz because there is little negative charge on the surface. A more serious problem is that PDMS is gas permeable, allowing water vapor formed by Joule heating to permeate into the bulk material, changing the buffer concentration and the EOF rate. Salts may precipitate in PDMS channels, and affected devices have to be discarded. Another significant problem is that proteins adsorb to hydrophobic PDMS through hydrophobic interactions, leading to unstable EOF, peak tailing, and loss of sample [13].

To summarize, there is no definitive surface to be used for all types of analytes. Surfaces should be carefully chosen or modified, depending on the type of analyte and the method of actuation.

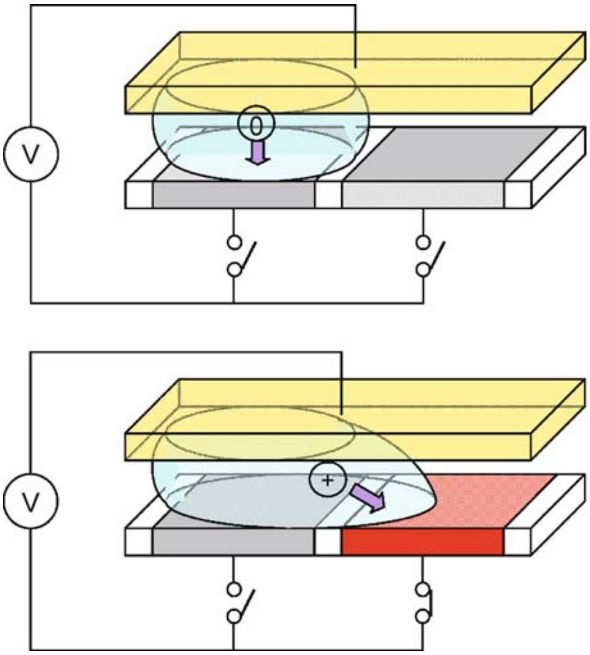
Modifying Surfaces to Prevent Biomolecular Adsorption and Water Stiction

Several microfabrication processes limit the choice of materials, and sometimes one is forced to use hydrophobic materials such as PS and PDMS. These hydrophobic surfaces can be made more hydrophilic by copolymerizing with hydrophilic monomers or coating with PEG or poly(ethylene oxide) (PEO) films [14]. The common feature of these hydrophilic modifications is the absence of functional groups that can act as hydrogen bond donors. Coating with protein films that resist certain biomolecules has also been demonstrated [15].

Water stiction on hydrophilic materials such as glass or silicon wafers can also be prevented. The surfaces can be passivated by depositing thin hydrophobic layers such as hydrocarbon/perfluorocarbon SAMs or Teflon. The nonstick nature of Teflon coatings found in many household products refers to the prevention of water stiction; the coatings do not prevent protein adsorption. Micropatterning these passivated hydrophobic layers can also be utilized to achieve microfluidic actuation of water. Zhao et al. [2] and Kataoka and Troian [16], for example, have patterned the hydrophobic surface to have a gradient from hydrophobic to hydrophilic, or alternating surfaces of hydrophobic and hydrophilic structures, to let the liquid flow over these surfaces. This *surface-directed* flow has thus far been demonstrated only for pure water. There are potential problems with protein solutions since proteins adsorb preferentially on rough rather than smooth surfaces.

Preventing Protein Adsorption in Electrowetting-Based Actuation

In several types of microfluidic actuation, hydrophobic surfaces have been used to control the rate of EOF or to manipulate droplets [3]. As noted earlier, however, it has not been possible to prevent protein adsorption that occurs through hydrophobic interactions. One way around this problem is to make the surface hydrophobic to prevent water stiction, while utilizing electrostatic repulsion to prevent biomolecular adsorption. We have recently demonstrated this strategy in electrowetting-based microfluidic actuation [3].



Biomolecular Adsorption in Microfluidics, Figure 5 Electrowetting-based actuation. Illustration of fluid motion induced by applying an electrical potential across dielectric-coated electrodes below a liquid droplet. By switching on the voltage at an electrode adjacent to the droplet, the surface tension is lowered, causing the droplet to move to the right. Biomolecules with neutral net charge may be attracted to electrodes while no voltage is applied. Biomolecules with positive (or negative) net charge may be attracted to electrodes while voltage is applied

Electrowetting-on-dielectric (EWOD) is a new method for moving liquids in biofluidic chips through electrical modification of the surface hydrophobicity (Fig. 5) [3]. We have demonstrated prevention of protein and DNA adsorption by minimizing hydrophobic interactions through careful choice of the bias, magnitude, and duration of the applied voltage, and by introducing electrostatic repulsions between charged proteins and the device surfaces.

Future Directions for Research

Summary of Current Approaches

The surfaces of microfluidic devices can be classified into three groups based on their surface wettability: glass, gold, Si wafer, SiO_2, and PEG as hydrophilic; PS, SAM,

PDMS, and Teflon as hydrophobic; and protein films, PMMA, and PC as intermediate. The common analytes in microfluidic devices can be classified into two groups based on their type of interactions with surfaces: small charged solutes and DNA interact primarily through electrostatic interactions, while proteins exhibit both electrostatic and hydrophobic interactions. In hydrodynamic actuation, biomolecules adsorb on surfaces largely through hydrophobic interactions. Hence small charged solute and DNA solutions are relatively easy to manipulate, as they have negligible hydrophobic interactions. For actuating protein solutions, the surface should be modified so as to be hydrophilic. In electrokinetic actuation, however, hydrophilic modification cannot be used since there are both hydrophobic and electrostatic interactions. An intermediate surface can be one possible solution, but a better way appears to be faster actuation (e. g. high EOF rate), utilizing electrostatic repulsion or changing device configuration, which have been demonstrated for electrowetting-based actuation.

Future of Biomolecular Adsorption in Microfluidics

The above summary addresses the adsorption of individual biomolecules in microfluidics. Biomolecular adsorption from real-world liquid samples such as blood will be much more complicated and probably almost impossible to prevent or control. However, we need to remember that biomolecular adsorption is not a problem unique to microfluidics; people have been working on antifouling coatings since the 1950s [17]. The future direction of this research will be related to or inspired by the research on biomaterials (e. g., prosthetic devices). Collaborations with orthopedic surgeons, dentists, and cell biologists are expected, which scientists are not really exploiting at this stage [17].

Definition

Biological molecules, such as proteins and peptides, oligosaccharides, nucleic acids, lipids and their related

compounds are widely used for biomaterial and pharmaceutical applications. These compounds are expensive, not so stable for long-term storage and do not require extremely large-scale synthesis. Also, the use of hazardous compounds is required in many cases. Therefore, the microreaction process is considered as a new approach which can overcome these restrictions in the synthesis of biomolecules. Several organic and biochemical syntheses have been performed using the microfluidic platform.

Overview

Biomolecules, fine chemicals and pharmaceuticals are high-value products that are produced in modest quantities. They are usually seasonal products that are customer specific and have a short shelf life. These characteristics usually place significant constraints in their production, such that it is not uncommon to see labor-intensive batch processes being used instead of the more efficient continuous process. This usually leads to a significant waste generation during the scale-up from the laboratory to production scale. In addition, the use of hazardous and often toxic homogeneous catalysts makes product purification and waste disposal important issues as regards today's stringent environmental regulations.

The microfluidic reaction system for biochemical synthesis was developed as miniaturization system of conventional synthetic chemistry. The development of microreaction processes has been much slower than that of μTAS. Lab-on-a-chip for synthetic applications is still a young research field as compared to the mature μTAS. To date, a number of gas- and liquid-phase reactions have been carried out in microfluidic systems and such microfluidic-based reactions are increasing tremendously. In this article, typical examples of biochemical syntheses within a microfluidic reactor are presented and discussed.

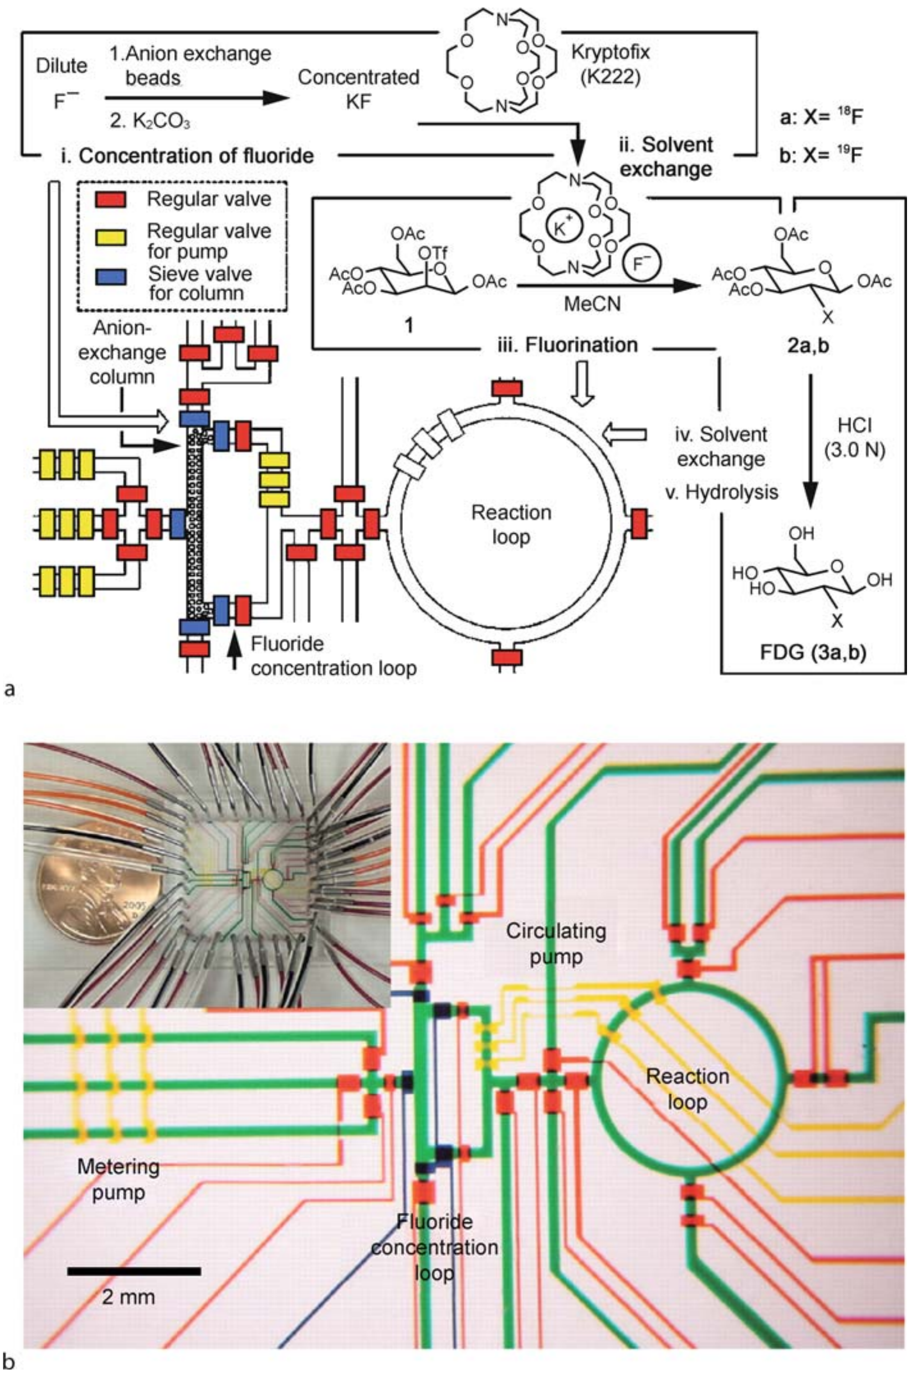
Peptide and Protein Synthesis

Peptide synthesis using a microfluidic reactor was reported by Watts et al. [1]. The synthesis of β-peptides has been successfully performed using a borosilicate glass microreactor (Fig. 1), in which a network of channels was produced using photolithographic and wet etching methods. The reagents were mobilized by electroosmotic flow (EOF). The microreactor was initially evaluated using a carbodiimide coupling reaction to form a dipeptide. The methodology has been extended such that the peptides may also be produced via the pentafluorophenyl ester derivatives of amino acids. It was found that performing the pentafluorophenyl ester reactions in the microreactor resulted in an increase in the reaction efficiency over the traditional batch method. Watts et al. postulated that the enhancement in the rate of reaction is an electrochemical phenomenon, due to the reaction being performed in an electric field, which is unique to microreactor systems. It has also been demonstrated that selective deprotection of the resultant dipeptides can be achieved. This approach has been used in the synthesis of a tripeptide.

Synthesis of another β-peptide was also performed. Seeberger et al. performed the synthesis of oligo β-amino acid using amino acid fluoride in a silicon microreactor [2]. They developed a method for high-efficiency synthesis that is capable of large-scale production.

Miyazaki et al. reported possible use of a microreactor as an active reaction vessel for carrying out biochemical reactions [3]. An important feature of the microchannel systems is their superior controllability of fluids, which cannot be achieved in the batchwise reactions using large reaction apparatus. The effects of a microfluidic system on chemical reactions of two different miscible solutions were examined using amino acid substitution as a model reaction. Substitution of phenylalanine in a microreaction system using separate solutions was more efficient than the batchwise reaction and microchannel reaction using a homogeneous solution. Substitution of other amino acids showed that this enhancement is caused by localization of hydrophobic amino acids at the dimethylformamide (DMF) – H_2O interface. By using the rapid Michael addition reaction of the SH group of cysteine to a maleimide group, it was demonstrated that such reaction involving hydrophilic compounds diminished in a microfluidic system. These results show that the microreaction system is a novel apparatus for regulating chemical reactions, depending on the structure of the reactant molecules, by controlling the mixing of two different solutions.

In addition to these organic syntheses, biochemical production of compounds in microreactors has also been performed. A microreactor array which enables high-throughput cell-free protein synthesis was developed [4]. The microreactor array is composed of a temperature control chip and a reaction chamber chip. The temperature control chip is a glass-made chip on which temperature control devices, heaters and temperature sensors are fabricated with an indium tin oxide (ITO) resistive material. The reaction chamber chip is fabricated by micromolding of polydimethylsiloxane (PDMS), and is designed to have an array of reaction chambers and flow channels for liquid introduction. The microreactor array is assembled by placing the reaction chamber chip on the temperature control chip. The small thermal mass of the reaction chamber resulted in a short thermal time constant of 170 ms for heating and 3 s for cooling. The performance of the microreactor array was examined through experiments on cell-free protein synthesis. By measuring



Biomolecular Synthesis in Microfluids, Figure 1 (**a**) Schematic representation of a chemical reaction circuit used in the production of 2-deoxy-2-fluoro-D-glucose (FDG). Five sequential processes are shown: (i) concentration of dilute fluoride ion with the use of a miniaturized anion exchange column located in a rectangle-shaped fluoride concentration loop, (ii) solvent exchange from water to dry MeCN, (iii) fluorination of the D-mannose triflate precursor 1, (iv) solvent exchange back to water, and (v) acidic hydrolysis of the fluorinated intermediate 2a (or 2b) in a ring-shaped reaction loop. Nanogram amounts of FDG (3a, 3b) are the final product. The operation of the circuit is controlled by pressure-driven valves, with their delegated responsibilities illustrated by their colors: red for regular valves (for isolation), yellow for pump valves (for fluidic metering circulation) and blue for sieve valves (for trapping anion exchange beads in the column module). (**b**) Optical micrograph of the central area of the circuit. The various channels have been loaded with food dyes to help visualize the different components of the microfluidic chip; colors are as in (**a**), plus green for fluidic channels. The inset shows an actual view of the device; a penny (diameter 18.9 mm) is shown for comparison. (Reproduced from [5])

the fluorescence emission from the products, it was confirmed that green fluorescent protein (GFP) and blue fluorescent protein (BFP) were successfully synthesized using *Escherichia coli* extract.

Synthesis of Sugar and Oligosaccharides

Synthesis of radiolabeled glucose has been achieved (Fig. 2) [5]. Quake et al. reported the synthesis of an [^{18}F]fluoride-radiolabeled molecular imaging probe, 2-deoxy-2-[^{18}F]fluoro-D-glucose ([^{18}F]FDG), in an integrated microfluidic device. Five sequential processes – [^{18}F]fluoride concentration, water evaporation, radiofluorination, solvent exchange and hydrolytic deprotection – proceeded with high radiochemical yield and purity and with shorter synthesis time relative to conventional automated synthesis. Multiple doses of [^{18}F]FDG for positron emission tomography imaging studies in mice were prepared. These results, which constitute a proof of principle for automated multistep syntheses at the nanogram to microgram scale, could be generalized to a range of radiolabeled substrates. Synthesis of oligosaccharides is one of the challenges in the field of synthetic organic chemistry. Generally, glycoside formation depends on the conformation, sterics and electronics of both reaction partners. The challenge in accurately predicting the reactivity of the coupling partners makes it difficult to foresee the outcome of the reaction. In addition, reaction variables such as concentration, stoichiometry, temperature, reaction time and activator play indisputable roles in the outcome of a given glycosylation. Jensen and Seeberger used continuous flow microreactors to systematically study the glycosylation reaction as an example of a challenging organic transformation (Fig. 3) [6]. A five-port silicon microreactor was designed with three primary inlets to mix and react glycosylating agent, nucleophile (acceptor) and activator (Fig. 4). Glycosylation reactions were performed rapidly over a wide range of conditions using this microreaction system. This microfluidic system enables easy handling of hazardous reagents such as trimethylsilyl trifluoromethanesulfonate at microliter scale.

In a different approach, transgalactosylation, which is the reverse reaction of the hydrolysis reaction by ►glycosidase, was carried out in organic solvent–buffer system as a reaction solvent to reduce the water concentration, and consequently the equilibrium of the reverse reaction was shifted [8]. The reaction was performed in a poly(methyl methacrylate) microreactor with two different inlets. The enzyme and reagents were loaded from these inlets by simple syringe pumping, and the reaction was terminated by heating. The reaction gave three kinds of stereoisomers, i. e. *p*-nitrophenyl-2-acetamide-2-deoxy-3-*O*-(β-D-galactopyranosyl)-β-D-glucopyranoside, *p*-nitrophenyl-2-acetamide-2-deoxy-4-*O*-(β-D-galactopyranosyl)-β-D-glucopyranoside and *p*-nitrophenyl-2-acetamide-2-deoxy-6-*O*-(β-D-galactopyranosyl)-β-D-glucopyranoside. The ratios between those isomers in the products were not determined, but the total amount of the disaccharide mixture (galactosylated *p*-nitrophenyl-2-acetamide-2-deoxy-6-*O*-(β-D-galactopyranosyl)-β-D-glucopyranoside; Gal-GlcNAcPNP) gave better yield when the reaction was conducted in the microreaction channel compared with that in the micro-test tube. This result suggests that the microreactor is an effective device for enzymatic transglycosylation.

Oligonucleotide Synthesis

The polymerase chain reaction (PCR) is the most widely used technique for oligonucleotide synthesis. Microchips/microdevices for PCR are studied extensively, and thus great progress has been made in the development and scope of microchip components of microchip-based PCR analyzers such as on-chip micromachining (fabrication, bonding and sealing), choice of substrate materials, surface chemistry and architecture of reaction vessel, handling of necessary sample fluid, control of three- or two-step temperature thermocycling, detection of amplified nucleic acid products, integration with other analytical functional units such as sample preparation, capillary electrophoresis (CE), DNA microarray hybridization, etc. The two general strategies for microchip-based PCR are flow-through and stationary chamber formats. The topic of microchip-based PCR, however, is well summarized in another article.

Chemical synthesis of oligonucleotide was also performed using a microfluidic platform. A microfluidic DNA oligonucleotide synthesizer made of PFPE which performs reaction cycles adopted from the widely used phosphoramidite method was reported [8]. PFPE is an elastomer with excellent chemical compatibility which makes it pos-

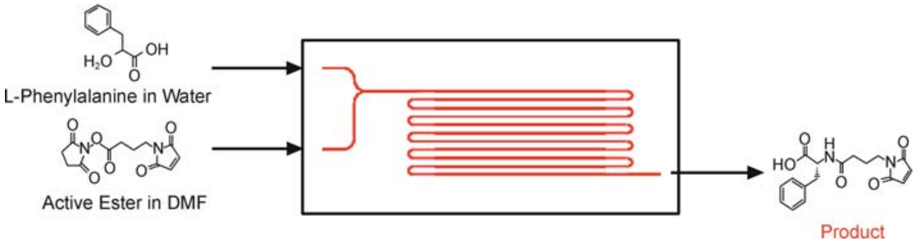
sible to perform organic chemical reactions. The device is capable of synthesizing 60 pmol of DNA oligonucleotides while consuming less than 500 nL of 0.1 mol L^{-1} phosphoramidite solution in each reaction cycle. The reduction of reagent consumption is significant: a 60-fold reduction over conventional automation. This approach demonstrates the usefulness of integrated micromechanical valves for complicated multistep organic synthetic reactions and enables automated chemical experiments with a wide variety of solvents.

Synthesis of Prodrugs and Other Bioactive Compounds

A microfluidic reaction system has also been used for the production of prodrugs. A multichannel membrane microreactor was fabricated and tested for ▶ Knoevenagel condensation of benzaldehyde and ethyl cyanoacetate to produce α-cyanocinnamic acid ethyl ester, a known intermediate for the production of an antihypertensive drug [9]. Knoevenagel condensations of carbonylic compounds and malonic esters yield several important key products such as nitriles used in anionic polymerization, and the α,β-unsaturated ester intermediates employed in the synthesis of several therapeutic drugs that include niphendipine and nitrendipine. Unlike most condensation reactions, Knoevenagel condensation is base-catalyzed. Strong bases such as sodium and potassium hydroxides and piperidine are traditionally used for these reactions. However, basic zeolites such as Cs-exchanged faujasite NaX and faujasite GeX, as well as amino-modified mesoporous silica are also able to catalyze these reactions. The use of heterogeneous catalysts significantly simplifies product separation and purification. It also eliminates the need for solvents. However, the water formed by the reaction is a poison for zeolite catalysts, and its removal is a must if we are to expect optimum catalyst performance. The removal of water has the added benefit of increasing the conversion for this equilibrium-limited reaction. By using Cs-exchanged faujasite NaX as the catalyst, the membrane microreactor could achieve supra-equilibrium conversion at higher product purity.

Another prodrug synthesis using a microfluidic reaction system is that of the antibiotic ciprofloacin [10]. A microreaction system developed by CPC systems (CYTOS) was used as a reaction apparatus. This system is the size of a videotape with a hold-up of 1.8 ml. The high surface-to-volume ratio for the mixing section as well as for the temperature-controlled reaction channels allow heat transfer coefficients of up to 2000 $W m^{-2} K^{-1}$. The synthesis has demonstrated the potential for faster development, particularly in the preparation of relevant quantities for development studies, such as clinical trials, using the microreaction systems.

Enzymatic syntheses within the microfluidic platform were also reported. The construction and novel compound synthesis from a synthetic metabolic pathway consisting of a type III polyketide synthase (PKS) known as 1,3,6,8-tetrahydroxynaphthalene synthase (THNS) from *Streptomyces coelicolor* and soybean peroxidase (SBP) in a microreactor were performed (Fig. 5) [11]. THNS immobilized to Ni-NTA agarose beads was prepacked into a microfluidic channel, while SBP was covalently attached to the walls of a second microfluidic channel precoated with a reactive poly(maleic anhydride) derivative. The result was a tandem, two-step biochip that enabled synthesis of novel polyketide derivatives. The first microchannel, consisting of THNS, resulted in the conversion of malonyl-CoA to flaviolin in yields of up to 40% with a residence time of 6 min. This conversion is similar to that obtained in several-milliliter batch reactions after 2 h. Linking this microchannel to the SBP microchannel results in biflaviolin synthesis. During the course of this work, we discovered that the substrate specificity of THNS could be manipulated by simply changing the reaction pH. As a result, the starter acyl-CoA specificity can be broadened to yield a series of truncated pyrone products. When combined with variations in the ratio of acyl-CoA and



Biomolecular Synthesis in Microfluids, Figure 6 Microreactor setup used in the reaction of amino acid with active ester [3]

malonyl-CoA (extender substrate) feed rates, high yields of the pyrone products could be achieved, which is further structurally diversified from self- and cross-coupling in the SBP microchannel. The ability to rapidly evaluate the effects of reaction conditions and synthetic multienzyme pathways on a microfludic platform provides a new paradigm for performing metabolic pathway engineering, such as reconstruction of pathways for use in new compound discovery.

A monolith entrapped enzyme process was also applied to the microfluidic platform [12]. Several 10 cm long capillary tubes (made of poly(ether ether ketone) (PEEK)) with inside diameters of 0.1 – 2.0 mm were filled with silica monolith-immobilized protease derived by in situ sol–gel transition from a 1 : 4 mixture of tetramethoxysilane and methyltrimethoxysilane. ▶ Transesterification between 20 mM (*S*)-(−)-glycidol and 0.4 M vinyl *n*-butyrate in an organic solvent was used as the test reaction. The substrate solution flowed through the column at a flow rate of 0.0004 – 5.0 ml min^{-1}. The substrate conversion in the microbioreactor was higher than that in the batch reactor at high liquid flow rate. When three tubes were connected in series, the conversion at a fixed ratio of the mass of the enzyme to the liquid flow rate was increased by approximately 50% because of the tripling of the flow rate as compared to the setup with only a single tube. Changes in the tube diameter had no influence on the conversion at a fixed superficial liquid velocity. Further, the conversion increased with a decrease in the enzyme content. These results were ascribed to the apparent effect of liquid–solid mass transfer and were analyzed quantitatively using a simple mathematical model.

Basic Methodology

Basically, biomolecular synthesis reaction in a microreaction system was performed by organic synthesis or biochemical conversion. The reaction was performed by simple loading of substrate and enzyme solutions into separate inlets using syringe pumps.

Preparation of Microreaction Device

A brief overview of device fabrication was summarized to help readers, particularly the would-be microreactor users. Details can be found in other articles of this encyclopedia. From hard lithographic techniques to soft lithography and in-house-built devices, a concise description is given, and readers should refer to the appropriate articles for more details.

The foundations of microfluidic fabrication techniques lie in the well-established field of semiconductor microelectronics. For instance, the microfabrication tools of lithography, resist layers and wet and dry etching have been instrumental in the fabrication of many microfluidic systems. These methods have been used to create microfluidic systems through both direct and indirect ways. In the direct method, the microfabricated component is used directly as a channel in a device. Direct methods have the disadvantage of producing only one device for one completed fabrication. However, if the fabrication is fast, this can allow rapid prototyping of many designs. On the other hand, indirect methods use the microfabricated component as a master to transfer the design to a secondary material in a replication step. This molded material is then used as the final device. Indirect methods have the advantage of needing only one master to create many (up to hundreds) of final devices. In biomolecular synthesis, the reactions are mainly performed in organic media; therefore, silicon or glass has been widely used as the material for device preparation. These are mainly fabricated by direct method such as lithography or milling.

Performing a Microreaction

Generally, chemical syntheses using microreaction devices are performed by simple loading of reagents into the microchannel. Biomolecular synthesis depends on the molecular conformation, steric hindrance and electronics of both reaction partners. The challenge in accurately predicting the reactivity of the coupling partners makes it difficult to foresee the outcome of the reaction.

In addition, reaction variables such as concentration, stoichiometry, temperature, reaction time and activator play an indisputable role in the outcome of a given synthesis. In this article, the reaction of amino acid with active ester is shown as an example [3]. This reaction was a simple condensation reaction between amino group of amino acid and carboxyl group of active ester.

A ceramic microreaction device with a microchannel (width 400 μm × depth 400 μm × length 40 cm) was fabricated by micromachining. From two separate inlets, the solutions of active ester in DMF and amino acid with triethylamine (added for deprotonation of amino group of amino acid) in water were loaded separately by syringe pumping (Fig. 6). The resulting solution was collected and directly analyzed by HPLC to estimate the conversion rate. Each peak obtained by HPLC was confirmed by ESI-TOFMS. In the case of reaction between phenylalanine with *N*-(4-maleimidobutyloxy)succinimide (GMBS), the reaction did not proceed at higher flow rates (< 1 min, $> 50\,\text{ml min}^{-1}$). However, the reaction yield increased at slower flow rate and even exceeded 90% in a 10 min reaction time. This result indicates that the reaction rate in the microdevice is improved dramatically over batchwise reaction which gave 80% yield after 12 h.

Key Research Findings

In the last decade, many reactions for biomolecular synthesis were performed within microfluidic reactors. The use of microreactors provides several advantages over conventional reaction systems. A microfluidic reactor allows control of mixing reagents and reaction time. This can be achieved by controlling the length of the microchannel or integrating a micromixing device. Such control of fluid enables regulation of reaction by mixing. Generally, rapid micromixing enhances the reaction yield in a microfluidic system. However, some biomolecules such as peptides are amphiphilic, and these molecules prefer the interface of organic solvent and water. In a laminar flow system, mixing of two miscible solutions occurs gradually in a straight microchannel. Construction of mixing devices enhances mixing. Also, creation of repeating tight turns produces Dean vortices and disrupts the interface. Addition of these structures in a microreaction system strongly affects the reaction yield in the synthesis of biomolecules, as in the amino acid substitution [3]. Therefore, a proper design of the microchannel structure and precise fluid control are essential for the development of efficient microreaction systems for biomolecular synthesis.

Control over thermal or concentration gradients within the microreactor allows new methods for efficient chemical transformations with high space–time yields. PCR for oligonucleotide synthesis is a typical case. Also, in most cases, chemical reaction is sensitive for factors like temperature and concentration of reactant molecules. The narrow dimension of microfluidics brings attractive mass transfer and heat flow advantages. These attributes contribute to achieving efficient chemical synthesis. Often, reactions performed within a microreactor invariably generate relatively pure products in high yield, in comparison to the equivalent bulk reactions, in much shorter times and in sufficient quantities to perform full structural characterization. These are advantageous for the optimization of reaction conditions, especially biomolecular synthesis, which is expensive in most cases. Overall, microfluidic reactors are perceived as a useful tool for the synthesis of biomolecules.

Future Directions for Research

As noted above, the great advantages of microfluidic technology have been identified as ability to achieve higher yields and selectivities, more effective use of resources and much enhanced reaction control compared with conventional systems. Most biomolecules are expensive, and therefore high reaction yield and efficiency are desired for their synthesis. To achieve this, the technology of microreaction synthesis offers a wide range of solutions. Some biomolecules and their related compounds are bioactive molecules which are important for drug development. The development of a single microreactor enables small-scale production by numbering-up; therefore, the development of synthetic microreaction processes may become a popular area of research for drug development.

In addition, a microreaction device can be constructed by an integration of various components for chemical reactions such as synthesis, analysis, extraction, separation and concentration. This possibility opens access to elegant combined reactor arrangements. The development of integrated microreaction devices is an emerging field in biomolecular synthesis.

Definition

Bioprinting on chip concerns the fabrication of so-called ►microarrays or ►biochips. It comprises the deposition of a multitude of fluidic or dissolved biological agents onto solid substrates with subsequent coupling, i. e. fixation, of the organic molecules on the substrate surface. The biological substances are arranged as hundreds to hundreds of thousands of small chemical reaction areas, so-called spots, in a predetermined spatial order (ranging from the hundreds of micrometre down to the submicrometre range) to provide a 2D array. *Bioprinting on chip* involves printing techniques, microarrayers and criteria that comply with the requirements for high-quality microarray fabrication.

Overview

Generally, microarrays can be regarded as highly parallel sensors used in biomedical applications, chemical sciences, life sciences or drug discovery for studying a multitude of complex biological interactions simultaneously to determine the presence and/or amount of nucleic acids (e. g. oligonucleotides, genes, gene fragments) or proteins (e. g. antibodies, antigenes) in biological samples, e. g. in blood, cell extract or tissue extract, to investigate, for example, gene expression levels or for proteomics studies [1, 2]. Key technical challenges in creating high-content microarrays include advances in array fabrication. Additionally, to address those versatile applications, high-quality microarrays as well as high-quality microarray processing and data analysis are crucial to produce meaningful results. Quality control is needed for the whole process, including definition of microarray content, biological sample preparation, sample purification, sample quality, printing, coupling, washing, microarray quality, hybridisation, scanning, data acquisition, image analysis and data analysis [3–5]. This article focuses only on the transfer of biological molecules onto substrates.

The basic idea of all microarrays is a spatially, miniaturised arrangement of a multitude of different unique immobilised capture molecules on a two-dimensional substrate. Figure 1 shows the typical life cycle of a microarray experiment. One microarray contains hundreds to hundreds of thousands of spots. Typical substrates are glass, membranes or silicon wafers. The arranged multitude of biological agents acts as capture probes to bind molecules out of a complex biomedical sample to be

analysed in a high-throughput and parallel manner. The complex biological interactions are identified by mapping the binding event at a certain location to the specific capture molecules that were previously immobilised at that place. After hybridisation of labelled complementary molecules, i. e. binding of sterically compatible molecules, a scanning microscope detects the bound, labelled sample and measures the visualised probe to ascertain the presence and/or amount of the specific type of complementary molecule in the complex sample. Detection methods are mainly fluorescence based, but chemiluminescence, radioactivity, mass spectrometry or electrochemistry are also used.

In principle there are three main types of microarrays: DNA, protein and cell microarrays. Historically DNA microarrays were the first focus of research and gained a key position in medical and biological research. Typical applications are gene expression profiling, genotyping, sequence analysis and further gene investigations on their localisation, structure, modifications, interactions and function [6]. The proteome is the functional entity of encoded proteins by the genome. Proteins are the true targets of medicine and thus the pharmaceutical industry. Thus protein microarrays are powerful tools to provide quantitative data on a large number of samples to perform proteomics studies. The third type of microarrays, cell microarrays, provides additional functionalities not available through protein arrays where full protein functionality is only given in living organisms, e. g. through posttranslational modifications or for transmembranal proteins. Cell microarrays are intended to detect environmental toxins, to identify potential drug targets or to evaluate the specificity of drug leads by functionally characterising large numbers of gene products in cell-based assays.

The high impact of microarrays as a large-scale and high-throughput tool for biomedical applications in basic research, diagnostics and drug discovery as well as their commercial success have led to enormous efforts of different companies to provide the most suitable microarrayer system. Because of the extensive and time-consuming preparation of the precious printing agents, the reliable and effective processing of microarrayer systems is imperative. The bases for high-quality microarray printing are standardised biological and technological processes to guarantee robust biochip printing and with it reproducible microarray fabrication. Additionally, the multitude of samples shows different liquid properties which greatly influence the deposition behaviour. In contrast to the commercialized ink-jet technology, where the ink as printing medium is adapted to the printer, an ideal microarrayer would be able to deposit any liquid sample with arbitrary liquid properties. Not only the samples but also the solid substrates onto which the samples have to be deposited vary in a wide range.

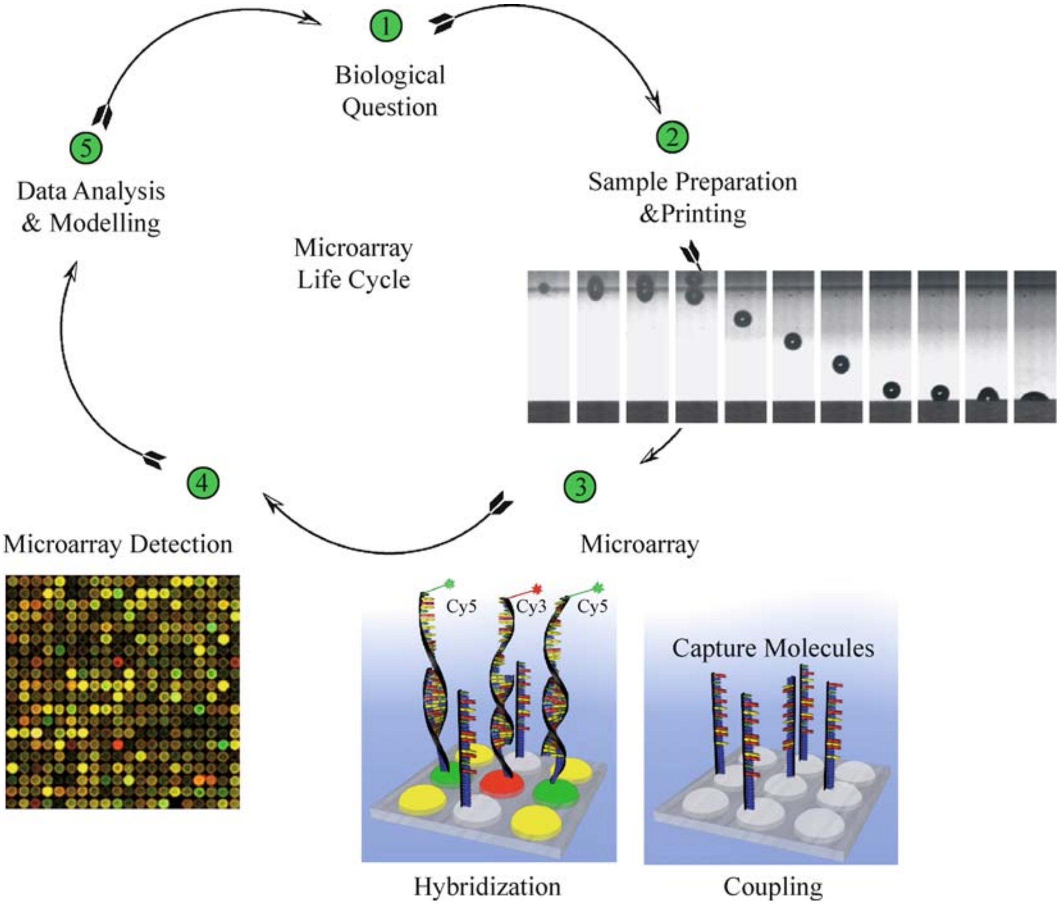
Depending on the specific application, the general needs that a microarrayer should fulfil are

- to enable uniform, identical and reproducible spots in a regular array pattern with exact controllability of microarray position,
- reliable exclusion of cross-contamination (between samples) and carry-over (between successive printing processes),
- fast microarray production (speed, frequency, parallelism of printing, automation capability, short machine down times for washing steps and machine movements),
- flexibility of printing (chip layout, medium property independence, adjustability of spot size),
- minimum consumption of sample and of substrate area,
- cost-effective microarray production,
- avoid damaging of microarrayer, sample and surface chemistry of substrate,
- integrated quality control and
- robust, automated systems that are easy to handle and to maintain.

Preconditioned that the microarrayer printing properties lead to optimal results, other characteristics are crucial for high-quality microarray production. High coupling efficiency and homogeneity of the biological agent on the substrate are essential. To obtain high-quality microarrays with homogeneous spots, a further feature is homogeneous surface modification of the substrate. Environmental operation requirements include dust-free fabrication, control of temperature and relative humidity whilst printing and subsequent drying process. Associated with the wide variety of different microarray types in combination with very heterogeneous biological agents (e. g. nucleic acids, proteins, cells) there is a vast complexity of coupling types depending on coupling chemistries for the fixation of diverse biological molecules. For each application all interacting parameters have to be optimised to each other. For high binding efficiency of printed molecules onto different microarray surfaces the printing buffer has to be adapted to the kind of biological molecules and to the substrate surface chemistry. When an adequate parameter set is found, standard operating procedures enable robust microarray fabrication.

Basic Methodology

For the production of different types of microarrays a wide variety of microarray production techniques and specialised microarrayers are available. This article will focus on the three basic techniques commonly used: on-chip



Bioprinting on Chip, Figure 1 Principle of microarray experiment. The microarray life cycle shows the five main steps needed for a microarray experiment [2]. (1) The biological question is the first step followed by (2) sample preparation including printing of the biomolecules onto the substrate. (3) The coupling of the capture molecules localised at predefined positions – so-called spots – finalises the microarray fabrication followed by the microarray reaction. A complex analyte liquid (sample) is brought into contact with the fixed capture molecules where hybridisation of matching molecules takes place. (4) In most instances the microarray analysis is fluorescence-based detection. (5) The last step includes data analysis and modelling by employing bioinformatic tools

synthesis and contact and non-contact printing techniques. In the following, currently available microarray production methods are presented, but the discussion does not claim to be exhaustive.

On-Chip Synthesis of Biomolecules

For the on-chip approaches the features of the microarray are synthesised directly on the substrate (Fig. 2). Oligonucleotides are assembled using sequential printing of oligonucleotide precursors or by photolithography approaches. On-chip approaches using printing are used exclusively by *Agilent Technologies* and called *SurePrint* technology [7]. Instead of printing the readily synthesised oligonucleotides onto the microarray surface, they are actually synthesised base by base in repeating print layers using standard phosphoramidite chemistry. An inkjet print cartridge with four heads is used, each one filled with one of the four different phosphoramidite nucleotides (A, C, G, T), the building blocks of in situ nucleic acid synthesis. The iterative oligonucleotide synthesis loop starts when the first nucleotide of each oligonucleotide is printed onto an activated glass surface. The protective 5′-hydroxyl group of the printed nucleotide is removed chemically and oxidised to activate it enabling it to react with the 3′-group of the nucleotide printed in the next print layer. The excess of unbound nucleotides is washed away so that they will not randomly react later in the synthesis. The process of printing a nucleotide followed by de-protection, activation and washing is repeated 60 times resulting in 60 mer oligonucleotide arrays. Available microarray formats on 1 in. by 3 in. microarray glass slides

include various content microarrays, e. g. whole genome microarrays of different model organisms, as well as fully customised microarrays. Microarray densities range from 1.9 K to 244 K (K means kilo features) per array; microarray formats for multiplexed arrays on single slides include 1×244 K, 2×105 K or 4×44 K, 4×22 K, and 8×15 K features. The printing process involves multiple real-time quality control feedback mechanisms of each printed layer of nucleotides. This guarantees the proper synthesis of the desired oligonucleotide sequence.

In an on-chip approach using photolithography *Affymetrix* uses a process to produce high-density oligonucleotide microarrays by a combinatorial on-chip approach. Affymetrix floods the phosphoramidites and uses light-activated deprotection by the use of masks. For each oligonucleotide synthesis step another photolithographic mask is needed. Oligomers with a length of up to 25 bases and a minimum feature size of 5 µm can be produced. Up to 100 masks have to be used for the fabrication of so-called *GeneChips*. *Affymetrix* offers a multitude of high-density microarrays for whole genome, targeted genotyping, sequencing analysis, quantification and regulation of gene expression and clinical applications. The product catalogue includes microarrays from various species like human, mouse, rat, and non-mammalian model species (e. g. yeast, plants, worms). Customised arrays are also available.

For higher flexibility *NimbleGen* and *Febit* use controllable micromirror arrays instead of masks for selective deprotection. The *NimbleGen* system is based on the Digital Micromirror Device (DMD), a solid-state array of micromirrors, which are able to pattern up to 786,000 individual pixels of light, enabling minimum feature sizes of 17 µm. These flexible virtual masks replace the physical chromium masks of the *Affymetrix* approach. This on-chip approach enables a more flexible production of small batches of high-density microarrays with different array layouts. *NimbleGen* was taken over by *Affymetrix* that now is offering both technologies.

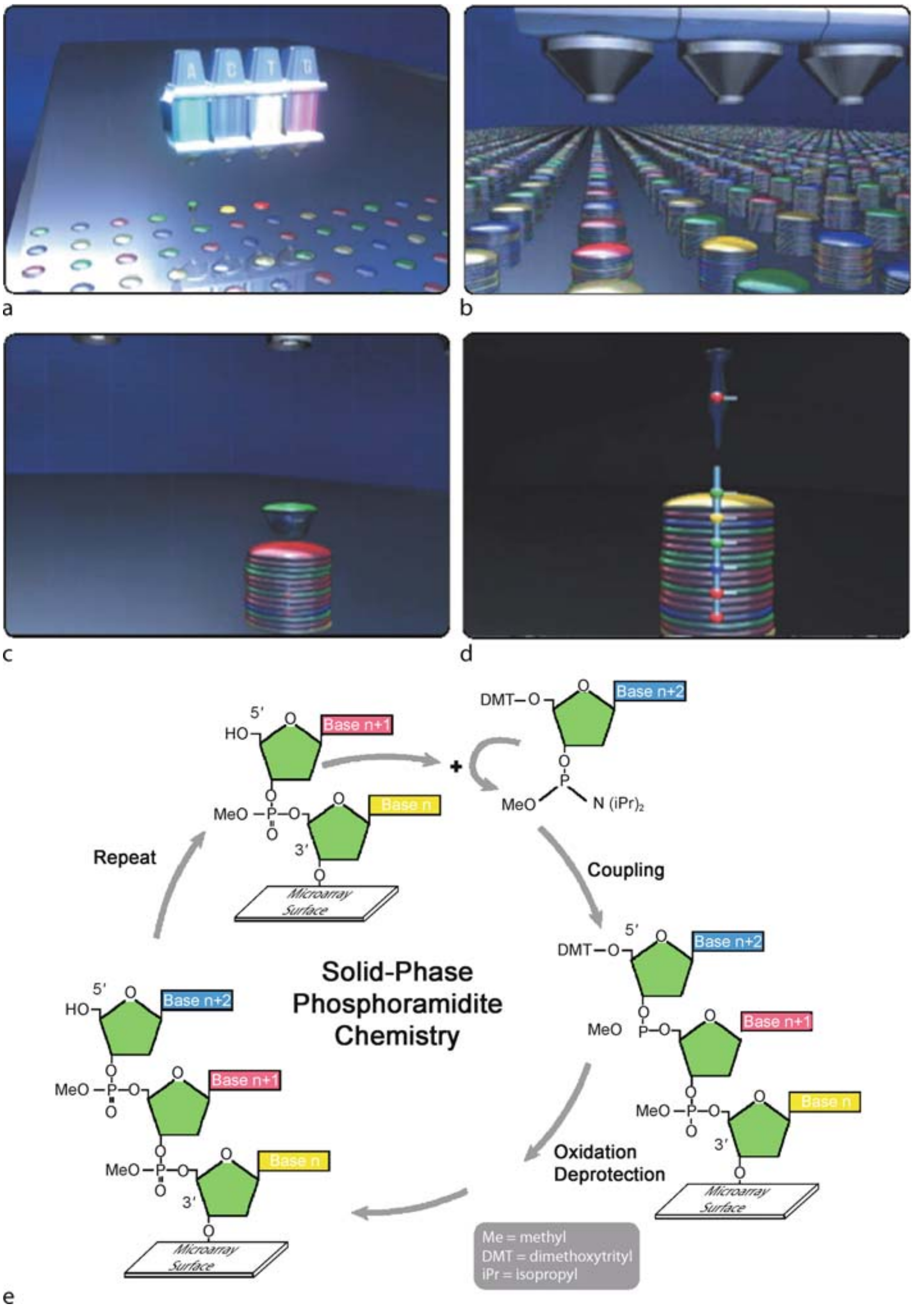
Another company called *Febit* has integrated the DMD approach providing a highly versatile platform using a set of eight microchannel structures called *DNA processor*™. A freely user designable oligonucleotide microarray is built up inside these meandering microfluidic channels overnight in their *Geniom* device. After the oligomer building process, the hybridisation and analysis by fluorescence detection is also done in the same device. It allows the synthesis of up to eight times 6000 oligonucleotides. The major applications of *Geniom* are SNP genotyping (single nucleotide polymorphism) and gene expression profiling. Others include sequencing by hybridisation, de novo genotyping and epigenetic analysis.

Advantages of the on-chip approaches are that the systems are well established and very uniform processing is practicable. But these approaches can only be applied for the production of oligonucleotide microarrays. So far, only scientific but no commercial approaches hav been undertaken to produce peptide microarrays by an on-chip approach. Additionally, depending on the specific application, low-density microarrays and only low microarray numbers are sufficient to answer particular biological questions; thus, often small batches (hundreds) of microarrays with low density (a few hundred spots) are needed. In research applications the array layout needs to be flexible. The production of protein or cell microarrays is in high demand as well.

Contact Printing

The more commonly used approach for microarray fabrication is the deposition of pre-synthesised molecules by a microarray printer onto substrate, so-called contact and non-contact microarray printing (Fig. 3a,b). Contact arrayers use different shaped steel pins for direct deposition of droplets onto the substrate by touching the surface with the pins. Non-contact arrayers are similar to commercial piezo-driven ink-jet printers and deposit a droplet onto the substrate without coming into contact with the substrate surface. Microarrayers which use other technical approaches are also commercially available and will also be discussed.

Contact printing technologies were used from the beginning of microarray technology. They are based on pin tools, which are dipped into the sample solution and take up a small volume of sample. Then they are brought in contact with the slide surface where they deliver the sample as a small spot. Whilst moving the pins away from the surface, the adhesion forces between sample and substrate lead to retention of small volumes on the substrate. In this system the spot volume metering is determined by the interaction between the pin, the transferred fluid and the substrate. *TeleChem International* is one of the major pin suppliers for contact printing [8]. The catalogue includes pins and printheads of different brands like *ChipMaker, Stealth, ArrayIt* and printheads for *BioRobotics, Robodesign, Genetix* and *NanoPrint* robots. Their pins deliver spot volumes from 0.5 nl to 12 nl, resulting in spot diameters from 62.5 µm up to 600 µm. After each deposition solid pins need to be re-dipped for sample loading. Thus, specially shaped pins were developed to allow several depositions with one dipping action, e. g. capillary tubes, tweezers, microspotting pins or split pins. They are available with reservoir capacities from 0.25 µl to 1.25 µl of sample solution. Another way to circumvent re-dipping



Bioprinting on Chip, Figure 2 On-chip synthesis of oligonucleotide microarrays using *SurePrint* technology of *Agilent Technologies* [7]. A schematic of the general mechanism via ink-jet printing shows (**a**) the first layer of nucleotides being deposited on the activated microarray surface. (**b**) The growth of the oligonucleotides after multiple layers of nucleotides have been precisely printed. (**c**) A close-up of one oligonucleotide as a new base is being added to the chain, which is shown in (**d**). (**e**) The general cycle of oligonucleotide synthesis via phosphoramidite chemistry (courtesy of *Agilent Technologies*)

is the pin-and-ring technology. A small ring is dipped into the sample solution. The surface tension of sample is used to form a fluid layer within the ring. A solid pin is pushed through the fluid layer and the trapped sample is deposited onto the surface. After retraction of the pin the fluid film is still intact and fluid is replenished from the ring. Commercially available contact printers are offered, for example, by *Genemachines*.

The contact printing technology is currently most commonly used to produce DNA microarrays. The advantage of pin-based printing technologies is the robust transfer of liquid by direct contact of the tip of the pin with the surface to be printed on. But this implies the risk of damaging the substrate surface by mechanical load during printing. To avoid this, the microspotting pins deposit samples without touching the pin to the substrate. Spots are produced with a 25 μm distance between pin and substrate surface. To produce a high number of arrays in a reasonable time, it is necessary to use many pins in parallel, typically up to 48. An accurate and precise volume deposition depends on the interaction between the pins, the sample and the slide surface. Therefore only mechanically very precisely produced pins will deliver the same volume consistently and reliably. Additionally, a careful pre-selection process of the pins combined with an accurate adjustment is needed to obtain a set of pins that are uniform in size, shape and height. Due to the adhesion force dependence of the contact printing process the printing media should be similar in media properties to produce equal spot sizes.

Non-Contact Printing

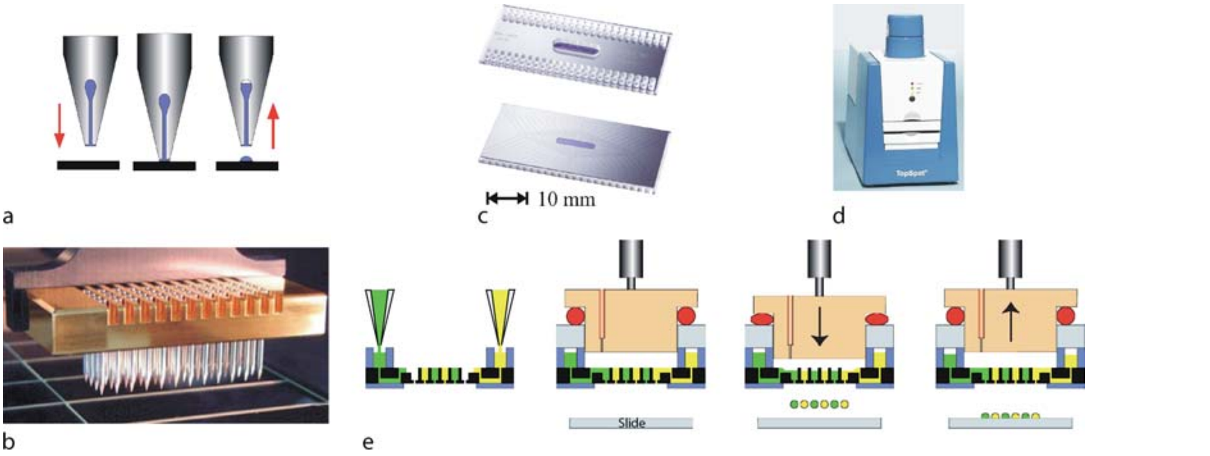
In non-contact printing techniques the liquid metering is not determined by the complex interplay of the pin, the liquid and substrate, but is separated from the substrate, because no contact between the printing tool and the substrate occurs (Fig. 3c–e). The fluid is ejected as a flying droplet or jet towards the surface from a certain distance, which makes metering more precise in many cases. Usually the dispensing units of non-contact printers come with a reservoir, enabling the dispensing of thousands of droplets without the need of interim refilling. Capillary forces or active pumping mechanisms are used to transport the liquid through microchannels or tubes from reservoirs to the dispensing orifices.

One concept of non-contact printing is based on syringe–solenoid-driven printers. In the syringe–solenoid concept a reservoir and a high-speed microsolenoid valve are connected to a high-resolution syringe (e. g. *synQUAD* system provided by *Genomic Solutions*). Within the *synQUAD* dispensing platform *PreSys 4040XL* containing an eight channel dispense head the system is filled with system liquid. Operating the syringe causes the sample to move into the tip. The syringe pressurises the system and if the microsolenoid valve is opened, droplets are dispensed out of the tip. This system delivers volumes from 20 nl to 20 μl per ejection process.

Further non-contact microarrayers are piezoelectrically driven. Companies like *MicroDrop*, *PerkinElmer*, *Scienion* and *GeSim* use a technology that is similar to ink-jet printer technology. The printers of *MicroDrop, PerkinElmer* and *Scienion* are based on glass tips. Each glass tip is surrounded by a piezo actuator. The dispenser tip of *GeSim* consists of bonded silicon and glass layers. A piezo actuator is fixed at the top of the dispenser tip. In all piezo tip systems the samples are aspirated into the tip by applying a slight vacuum at the back end of the capillary. The squeezing of the tip forced by the piezo actuation induces droplet ejection out of the capillary. The fast response time of the piezoelectric crystal permits fast dispensing rates (kilohertz range). The small deflection of the crystal generates droplet volumes from hundreds of picolitres to a few nanolitres.

For higher throughput, parallel systems were built with four (*PerkinElmer Piezorray*) and sixteen piezo tips (*GeSim Nano-Plotter NP 2.0*). Horizontal alignment of all tips to the substrate surface is not as critical as for contact printers. However, each tip has its own specific piezo actuator necessitating calibration of each tip to enable homogeneous droplet ejection. Usually the tips are produced in small batches in a handmade process, so an accurate quality control of tips is needed to ensure the high precision of tip geometries. Overall non-contact printing approaches provide less spot-to-spot and chip-to-chip variability than contact printing methods.

Another non-contact microarrayer using the *TopSpot* technology is offered by *Biofluidix* [9]. This technology enables high-throughput printing of microarrays. The *TopSpot* technology can be applied to the production of custom made low- to mid-density microarrays containing up to several thousands of different probes on a substrate. A key element of the *TopSpot* technology is the micromachined printhead which can be loaded with 24, 96, or up to 384 different samples. The reservoirs comprise one to several microlitres of printing medium. All liquids are printed onto a substrate simultaneously by a micronozzle array contained in the printhead. The microarray is then formed by the individual droplets on the substrate having a pitch of 500 μm. For each droplet only about one nanolitre of liquid is consumed. Therefore a printhead can create several thousand microarrays with one filling. The printhead is operated in the so-called print module, which is designed to apply a pressure pulse to the printhead via a piston such that droplet generation is initiated. For this purpose the piston is driven with a high velocity by a piezo actuator. The major advantage of the *TopSpot* technology over other nanolitre dispensing systems (e. g. an ink-jet printer) is that each nozzle can be supplied with another printing medium. The inherent parallelisation of the printhead increases the speed without the need of complicated automation systems. By using only one actuator unit to generate the pneumatic driven droplet dispensing out of



Bioprinting on Chip, Figure 3 Contact and non-contact printing. Contact printing mechanism of *TeleChem International Inc.* [8]. (**a**) *Micro-spotting pins* enable high-speed manufacture of microarrays. The pins have flat tips and defined uptake channels, which allows a thin (25 μm) layer of sample to form at the end of the pin, and printing to proceed by gentle surface contact. Printing occurs as a simple three-step *ink-stamping* process as follows: (left) downstroke, (centre) contact, and (right) upstroke. (**b**) Printing with 48 pins in parallel using the *ArrayIt*® microarray technology equipped with a *Stealth 48 printhead* fitted with *48 SMP3 microarray spotting pins* ((**a**), (**b**) by courtesy of *TeleChem*). Non-contact printing of microarrays using *TopSpot*® technology of *Biofluidix GmbH*. (**c**) Core of the *TopSpot*® technology [9] is the microfabricated printhead ((top) top view, (bottom) bottom view of a 96 position printhead) allowing highly parallel microarray fabrication. (**d**) The benchtop *TopSpot*® machine operating one printhead within a print module. (**e**) Schematic cross-section of the operating principle in four steps starting with filling of the printhead reservoirs. Via a piezostack actuator an air pressure is generated within the actuation chamber above the nozzle array that simultaneously affects all nozzles resulting in droplet ejection of 96 droplets ((**c**), (**d**), (**e**) by courtesy of *Biofluidix*)

all nozzles simultaneously, no calibration of multiple actuator units is needed. Several printheads can be lined up to generate microarrays with higher content.

Other Deposition Methods

In addition to on-chip approaches and contact and non-contact printing of agents onto microarrays there are further methods for microarray fabrication. Two examples are the protein profiling chips offered by the company *Zyomyx* and the electronic microarrays offered by the company *NanoGen*.

Zyomyx offers an all-in-one system for protein profiling. The system is provided as a comprehensive package that includes an assay workstation, a biochip scanner, data analysis software, assay reagents containing the calibration analytes and internally validated biochips. Each biochip is designed to assay up to 200 different proteins in each one of six separate flow cells. Every flow cell can be run with a sample volume of 25 μl. The chips are provided ready-to-use, and fully loaded with specified capture antibodies. The protein profiling biochips are fabricated by silicon micromachining. Every flow cell contains an ordered array of 200 micropillars, each one with a height of 150 μm and a diameter of 50 μm. Specific capture agents are directionally bound to the top of each pillar.

The core of *NanoGens* technology is the *NanoChip Electronic Microarray*. It consists of a silicon chip capable of rapid identification and analysis of biological molecules. The technology utilises the natural positive or negative charge of most biological molecules. Applying an electric current to individual test sites on the *NanoChip* enables rapid movement and concentration of the molecules. Molecular binding onto the test sites is accelerated 1000 times compared to traditional passive methods. Currently *NanoChips* with 100 or 400 test sites for DNA and RNA analysis are commercially available. The sites have diameters of 80 μm and a pitch of 200 μm. The *NanoChip* microarray technology provides an open platform that allows customers to run common assays as well as customise their own assays. Applications include SNP analysis, and insertion, deletion and mutation analyses.

Another deposition method for fabricating microarrays containing functional proteins for surface immunoassays is so-called microcontact printing. The Delamarche group [10] uses a microfluidic chip that comprises a number of independent capillary systems, each of which is composed of a filling port, an appended microchannel and a capillary pump. Each capillary system fills spontaneously driven by capillary forces, the flow through the channels being driven by evaporation employing Peltier-controlled cooling and heating. The sandwich fluores-

cence immunoassay takes place on the surface of a polydimethylsiloxane (PDMS) slab, which is placed across the microchannels. After precoating of the PDMS surface with capture antibodies the binding sites of analyte molecules are localised by using the chip, then the captured analyte molecules are bound to a second fluorescently labelled antibody using a second chip that is directed orthogonally to the first chip. The assay results in a mosaic of fluorescence signals on the PDMS surface which are measured using a fluorescence scanner.

Coupling of Capture Biomolecules

An indispensable factor for high-quality microarray fabrication performed with contact or non-contact printing is the efficient and homogeneous fixation of biological molecules on the substrate surface, so-called coupling. The printing system in combination with other interacting parameters like substrate surface chemistry, type of biological agents, printing buffer composition, immobilisation protocols and washing procedures have to be optimised to each other. It is important to distinguish between, for example, nucleic acid or protein or cell microarrays.

Nucleic Acid Microarrays

Within the above mentioned microarray categories further partition into sub-categories makes it even more complex. Nucleic acids comprise various configurations and lengths, e. g. oligonucleotides, cDNA, RNA and plasmids, with diverse properties leading to different coupling requirements. First of all the choice of substrate combined with adequate surface chemistry is relevant to couple nucleic acids onto the substrate surface. For high-sensitivity measurements an important precondition is the low autofluorescence of substrate and coating and the absence of non-specific background to ensure high signal-to-noise ratios. Most commonly used are glass substrates on which functional aminosilanes are deposited to form layers on the substrate to which the capture molecules can be bound. Some examples of such functionalised organosilane compounds are APTES (3-aminopropyltriethoxysilane), AEA (*N*-(2-aminoethyl)-3-aminopropyltrimethoxysilane), AEEA (3-(2-(2-aminoethyl)-ethylamino)-propyltrimethoxysilane) and GOPS (3-glycidoxypropyltrimethoxysilane). These monovalent and multivalent cations are known to condense DNA into higher ordered structures. Another glass substrate modification is the NHS ester modification to couple the proteins by EDC-NHS chemistry (EDC is *N*-(3-dimethylaminopropyl)-N'-ethylcarbodiimide; NHS is *N*-hydroxysuccinimide). Thereby NHS-esters react with amines to form amide bonds. EDC is a cross-linker that effects direct coupling between carboxylates (−COOH) and primary amines ($-NH_2$). A third method is the coating of glass substrates with functional epoxy groups to react with amino-functionalised biomolecules. Substrates other than glass are nitrocellulose, nylon or cellulose acetate membranes, and polymer substrates such as COC (cyclo-olefin copolymer) or PMMA (poly(methyl methacrylate)). As for all kinds of microarrays, the coupling chemistry used has to be optimised relating to all interacting parameters like capture molecules, substrate, printing buffer, immobilisation protocol, etc. Besides a stable, reproducible and established production process, strict internal manufacturing controls are crucial for low batch-to-batch variations. The quality of biomolecule coupling onto the slide surface depends on coupling chemistry of the substrate surface and the reproducibility of the surface properties.

Parameters that have to be adapted to the specific application are printing buffer, including buffer system (e. g. phosphate, carbonate, borate based; corresponding acid–base pair; salt components), concentration, pH value and additional supplements such as DMSO (dimethylsulfoxide) and betaine. The printing buffer composition has to be optimised according to the printing molecules, the substrate surface and the immobilisation protocol used. Within this protocol varying parameters that have to be adapted are, for example, incubation times, temperature curves and relative humidity. Commonly used approaches for immobilisation are incubation in a heated water bath or in an oven. Additionally the washing procedure to remove unbound molecules after coupling has to be adapted.

Protein Microarrays

Proteomic profiling will yield more direct answers to the current biological and pharmacological questions, because the majority of known biological effector molecules, diagnostic markers and pharmaceutical targets are proteins, not mRNA or DNA. Protein microarrays are expected to significantly expedite the discovery of new markers and targets of pharmaceutical interest, and to have the potential for high-throughput applications. In particular, antibody and cell lysate microarrays have the potential to revolutionise protein expression profiling. Where functionality is only given in living cells, also cell microarrays become relevant. The main precondition for protein and cell microarrays is that the capture proteins or cells are kept in a functional state after being immobilised to the microarray substrate by exclusion of protein denaturation or cell lysis.

Protein microarrays can be classified into three general categories regarding their applications: expression profiling, interaction profiling and functional identification. Protein expression profiles reflect the concentration profile

of proteins depending on the cell or tissue status (e. g. cell type, age, environmental conditions, disease state). Antibody arrays are the main tool to perform protein expression profiling. Protein interaction profiling is most critical to drug discovery since many drugs and toxins affect protein–protein interactions. With so-called proteome arrays, which are microarrays with the whole proteome or a subset of it immobilised to the substrate surface, protein interactions can be categorised at a large scale. At the same time more precisely specific domain–domain interactions can be identified. Besides purified proteomes and proteome subsets, interaction profiling can be based on various other immobilised capture molecules, e. g. antibodies, antibody fragments, engineered binding proteins or even aptamers. Also microarrays of immobilised antigens have been developed, e. g. for profiling the reactivity of antisera. The spots of protein microarrays can also consist of complex samples, such as blood sera or cell lysates, which can be probed, for example, against a single antibody. The microarrays of this approach are termed reverse phase microarrays. The most seminal field is the decoding of protein function. At present only for a small population of proteins is the function known. The identification of the particular function for each protein connected with manifold interactions among each other is the goal of proteomics studies and to utilise the knowledge gained about regulatory processes for the healthcare and pharmacological industry.

In contrast to DNA microarrays, production of protein microarrays is an immense technological challenge. The first challenge derives from the limited availability of proteins for the fabrication of vast amounts of protein microarrays. Whereas for DNA with the *polymerase chain reaction (PCR)* a routine method exists to enormously increase the number of DNA copies and automated processes are established for oligonucleotide synthesis, for proteins such methods are missing; hence, proteins are produced in very small quantities. Furthermore, the biochemistry of proteins is orders of magnitude more complex than DNA biochemistry, so that the production of protein microarrays is much more difficult. Whereas DNA is a relatively simple polyanion and can be modified and easily immobilised on solid surfaces based on electrostatic interactions or covalent bonding, protein bonding is much more delicate. The complexity derives from a multitude of biochemical properties. Protein molecules possess particular three-dimensional structures, varying chemical and physical properties (e. g. hydrophilic and hydrophobic domains, ionic interactions) and the activity and function as well as the partial charge of domains depend on the local physical and chemical microenvironment. Additionally, complexity is further increased by posttranscriptional modifications of protein conformation; hence the well-established on-chip approaches of oligonucleotide microarrays are not applicable to protein microarrays. For protein microarray production four major requirements have to be fulfilled:

- speed of protein production and accurate purification,
- minimisation of background caused by unspecific protein binding to obtain high signal-to-noise ratios,
- native protein conformation and orientation on substrate surface and
- protein detection and identification.

A protein interacts with other molecules through specific functional domains. Hence, native conformation and orientation of the immobilised capture molecules are indispensable for meaningful results from protein microarrays. The most problematic factor is the potential of inadvertent masking or degradation of epitopes of antibodies, active sites of enzymes or binding sites of receptors. Thus surface chemistry plays a critical role in protein microarrays where the surface chemistry should provide an inherently inert surface that resists non-specific binding in combination with integrated functional groups that ensure facile, highly specific and oriented immobilisation of native proteins.

For protein immobilisation the most commonly used method is the EDC–NHS affinity ligand coupling chemistry as described for DNA bonding to glass substrates. An advanced surface coating method for protein microarrays was developed by the company *MicroSurfaces*. A *poly(ethylene glycol)* (PEG) surface coating, arranged as a high-density brush to provide a zero background surface, is functionalised with molecules that mediate biomolecular binding. The kind of molecules depends on the interaction mode and the application. Surfaces are functionalised with biotin or streptavidin, chelated copper, epoxy functional groups or NHS to mediate binding of streptavidin- or biotin-labelled proteins, polyhistidine-tagged proteins (with Cu^{2+}). The epoxy functional groups are used to covalently attach proteins in purified form via amine groups.

Cell Microarrays

For cell microarray printing additional elementary demands have to be addressed by the printing technology. A highly reproducible number of living cells per spot on microarray slides and an optimised printing process that is qualified for reproducible production of cell microarrays along with keeping their vitality and function for analysis are essential. There are two fundamental methods to produce cell microarrays. The indirect method was developed by J. Ziauddin and D.M. Sabbatini (2001) [11]. To produce

transfected cell microarrays a mixture of gelatine, acting as an anchor, containing different DNA molecules for transfection purposes is printed onto a glass substrate using a standard pin printing arrayer. After drying of gelatine–DNA spots the substrate is incubated with a cell suspension containing the transfective agent. This induces incorporation of DNA into the cells, resulting in cell microarrays of differently transfected cells. In the direct method the different cell types themselves are printed onto the substrate. In some publications contact-based microarrayers are used, but more often non-contact-based devices like modified ink-jet printers or piezo-driven tips are used.

The construction of chemically modified solid supports is of particular importance in cell-based microarrays. For cell immobilisation on substrates the most commonly used method is the binding to poly-L-lysine-coated slides. Binding of cells results from ionic interactions between the cell membrane and the positively charged poly-L-lysine surface. This method is most effective for adherent cell types. To promote cell adhesion, surfaces coated with extracellular matrix (ECM) proteins such as collagen or fibronectin have also been employed. In some cases, polymer-treated surfaces are used in conjunction with the above mentioned compounds to reduce non-specific adhesion.

Companies that offer microarrays and associated services are *Affymetrix, Agilent Technologies, GE Healthcare Bio-Sciences, Applied Biosystems Applera, BD Biosciences Clontech, BF-BIOlabs, BioCat, Biomol, Biozym Scientific, Cambrex Bio Science, Chemicon, Chipron, CLONDIAG chip technologies, Clontech Laboratories, Eppendorf, Gene Expression Center, Genetix, Greiner Bio-One, Hypromatrix, Invitrogen, KFB, Merck Biosciences, Miltenyi Biotec, MoBiTec, MWG Biotech, Panomics, Randox Laboratories, Schleicher&Schuell BioScience, Scienion, Sigma-Aldrich Chemie, SIRS-Lab* and *VBC-GENOMICS*, to name just a few.

Key Research Findings

Accelerated Molecule Interaction Research

After more than fifteen years of microarray research the technology holds a momentous position ranging from fundamental screening to clinical diagnostics. The first paper reporting the use of microarrays was published in 1989 by Ekins and co-workers. The microarray technology has since undergone numerous refinements, iterations and adaptations regarding the steadily increasing number of applications. The number of interactions to be measured and with it the variety and diversity of microarrays steadily increases. Fields of application include the investigation and treatment of various diseases (e. g. cancer, infectious diseases, autoimmune responses) to improve diagnostic accuracy and to predict treatment efficiency. This is supported by advanced elucidation of regulatory processes including cell signalling pathways, molecular interaction studies and regulation of transcription and replication where malfunction may also lead to disease development. Advanced identification of biomarkers and pharmacological target discovery accelerates pharma research and development.

Gene Expression Profiling, Deciphering Whole Genomes and the First Clinically Accredited Arrays

Most early microarrays provided gene expression profiling studies in order to identify genes of interest that may be over- or underexpressed in some defined biological condition. Fabrication of those microarrays required cloning of complementary DNA (cDNA) sequences copied from isolated messenger RNA (mRNA) out of cells or tissues, followed by subsequent amplification by PCR. The PCR product from each clone was then deposited on microarrays. The subsequent concept of oligonucleotide arrays allowed scientists a higher degree of flexibility for microarray design because of the independence of available clone sequences. Further advantages of oligonucleotide arrays vs. cDNA arrays are better reproducibility, streamlined workflow and lower fabrication costs. In combination with the complete mapping of the human genome early in 2001 (further refining of sequencing is still ongoing) and other genomes of various model organisms (e. g. the bacterium *Escherichia coli*, the yeast *Saccharomyces cerevisiae*, the roundworm *Caenorhabditis elegans*, the fruitfly *Drosophila melanogaster*, the laboratory rat *Rattus norvegicus* and the laboratory mouse *Mus musculus*) the microarray technology has opened new perspectives. Nowadays several companies (e. g. *Agilent Technologies, Affymetrix, TeleChem/ArrayIt, Applied Biosystems*) offer products that enable scientists to probe gene expression from entire genomes on one single microarray. The knowledge gained improves DNA diagnostics, genotyping, proteomics as well as pharmacogenetics studies. By data analysis using clustering tools, the resulting signatures allow typing of genes linked with, for example, cancer pathogenesis and metastasis and with it to guide treatment options and to avoid ineffective treatment. *Agendia* (based on *Agilent Technologies'* custom microarray) is the first company worldwide to be granted the ISO 17025 accreditation (2005) for its *MammaPrint* gene expression service to classify breast cancer patients as at low or high risk of developing distant metastasis in a ten-year period. In 2006 a further accreditation for *Agendias CupPrint,* to identify cancer of unknown primary that concerns 4% of all cancer diseases, was granted.

Encoded Proteins Manifest Gene Function

Additionally, research has greatly benefited from the post-genomic era. Despite the success of DNA microarrays in gene expression profiling or mutation mapping, it is the activity of encoded proteins that directly manifests the gene function. So protein microarrays have been applied in biomarker discovery, protein profiling, protein–protein interaction analysis and peptide mapping applications. It seems that especially antibody microarrays have the potential to revolutionise the progress in protein expression profiling. With it, for example in drug discovery, one seeks to develop a biological or chemical entity that will improve the disease symptomatology or actually treat the underlying pathophysiological basis of the particular disease state. Protein expression profiling in cell or tissue extracts enables one to elucidate pathways and to identify mechanisms involved in gene regulation. Antibody arrays are available from various companies (e. g. *Sigma-Aldrich, Invitrogen, Genetix, Clontech Laboratories, Hypromatrix, Chemicon, Panomics*).

To identify splicing variants of mRNA by exon-level expression profiling, exon microarrays are offered by, for example, *Affymetrix, ExonHit Therapeutics* together with *Agilent Technologies*. This approach takes into account that one gene encodes for multiple different proteins by alternative splicing, i. e. small blocks of transcribed mRNA can be rearranged in multiple various combinations to form different transcripts from the same gene. Splicing variants of proteins cannot be detected on the DNA level and are supposed to be involved in several diseases.

Cell Arrays for Interaction Studies in Life Processes

In similar fashion to DNA and protein microarrays the ability to create arrays of cells and even tissues at high-density offers the potential for the development of cell-based sensors with extremely high throughput and multiplex capability. Research on biomolecular interactions on the genomic, the proteomic and the cellular level paves the way for advanced understanding of the function of the human genome and to unravel the complexity of biological pathways and cellular networks that control life processes.

Progress in Microarray Fabrication Techniques

These advances in life science research using the highly parallel microarray technology would not have been possible without enormous progress in bioprinting on chips. For microarray fabrication the on-chip approach to synthesise capture molecules on chips is well established and highly reproducible. But it is only applicable to oligonucleotide arrays. The deposition of cDNA by contact and non-contact printing is also highly developed, and integrated quality control mechanisms guarantee high-quality microarray fabrication. The higher complexity of protein microarrays compared to nucleic acid microarrays leads to greater demands regarding bioprinting on chip. This implies correct folding of the capture molecules on the microarray surface to achieve reproducible results. Binding sites of bound proteins need to be accessible and in native conformation to act as functional capture molecules to deliver valid results. Additionally, posttranslational modifications, e. g. phosphorylation, methylation or farnesylation, might play an important role for reliable molecular interactions with other proteins as well as with nucleic acids.

Cell microarray printing implies the exclusion of shear forces during the printing process to keep the cells on the chip alive. Additional specific supplements within the printing buffer can prevent cells from breaking during the printing process. There are different approaches to couple living cells on a substrate surface. First of all – for adherent cells – the cellular adhesion can be used to keep the cells at the spot positions. This could be aided or mediated by binding of discrete areas of *poly-l-lysine* or *extracellular matrix protein* acting as kind of adhesive agent within the spot areas. An application of recent cell microarray studies is the parallel investigation of cell adhesion forces of different permanent cell lines on different polymer substrates. To couple non-adherent cells to generate a microarray containing living cells could be mediated by specific anchor molecules that are located within spots on the surface. One end of these anchor molecules binds to the substrate surface and the other end is a transmembranal region that incorporates into the cell membrane, connected by a spacer in between.

Future Directions for Research

Clinical Diagnosis and Treatment Prediction

With the progressive development of the capabilities that microarrays provide, comprehensive investigations lead to new insights into regulatory processes within cells to elucidate cellular processes like transcription and replication as well as protein expression. With the complete sets of genes of organisms available, studies of gene regulation and interactions are available for scientists. Using this technology, coherences of cellular processes and health can be discovered and used to develop new drugs and to improve healthcare by advanced diagnostics and treatment prediction by assessing related gene signatures. The first steps towards diagnostic microarrays and treatment prediction are being taken with the ISO accreditation of *MammaPrint* and *CupPrint* arrays by *Agendia*. Another

step forward into the clinic was the approval of *AmpliChip (Roche Diagnostics)* by the *FDA (US Food and Drug Administration)* in 2005. The pharmacogenetic *AmpliChip* helps physicians to tailor patient dosages of drugs that are metabolised differentially by cytochrome P450 enzyme variants. These real medical applications of microarrays will lead to a gathering of momentum towards the wide field of medical applications that was anticipated years ago. Commercialisation towards real medical application beyond pure research breaks into new markets.

Reliability of Microarray Data, Standardisation and Terminology

Currently the progress to utilise microarray studies for clinical practice is further supported by the *FDA*. Under the auspices of *FDA* scientists, combined community-wide efforts are ongoing within the *MAQC project (MicroArray Quality Control)* dealing with the objective assessment of seven microarray platforms to experimentally address the key issues surrounding the reliability of DNA microarray data. The project aims at the set-up of guidelines for using microarrays in clinical practice and regulatory decision-making. Studies aiming at intraplatform reproducibility and analytical consistency across microarray platforms that are indispensable to translate the technology from pure research to clinical application are the main subject.

An important starting point to perform reliable microarray experiments and to gain meaningful information is the biological question and with it choosing the optimal microarray type (nucleic acid vs. protein vs. cell vs. any other kind) and information content (low-, mid-, high-density array) together with an adequate platform for each experiment. Furthermore a range of quality control for all successive processes and protocols is required.

In the very beginning of making sense out of microarray experiments enormous discrepancies between microarray results appeared. Furthermore standard formats for microarray data to share data and results were missing. One effort towards standard generation in microarray data handling started in 2001. Brazma et al. published in 2001 the *Minimum Information About a Microarray Experiment (MIAME)* that describes the minimum information that is needed to enable the interpretation of the results of the experiment unambiguously and potentially to reproduce the experiment and is aimed at facilitating the dissemination of those data [12]. The *Microarray Gene Expression Data Society* (MGED) further refined those efforts in 2002 with a publication of Spellmann et al. [13] with the design and implementation of *MicroArray Gene Expression Markup Language* (MAGE-ML), followed by the set-up of standards and ontologies for microarray databases and for high-throughput data sharing. Those efforts towards standardisation and community-wide usability of generated data and results lead to the accord that with careful experimental design and appropriate data transformation and analysis, microarray data can indeed be reproducible and comparable among different formats and laboratories. One major outcome is that statistical analysis in regulatory submissions and clinical diagnostics is likely to be different from that used in basic research and discovery. This study can be used as a solid foundation for combining other microarray studies to realise the comprehensive potential by accumulating microarray results to enlarge understanding of biological processes and with it pave the way for new healthcare uses.

Microarray Evolution

DNA sequencing is another challenge to unravel coherences between DNA sequence and DNA function. Deciphering the whole genome of organisms leads to new possibilities by comparison of sequence differences interacting with their resulting phenotypes. The differences between human beings are small and the unique DNA sequences differ by only about 0.1%, regardless of ethic origin. These genetic differences encode for how humans look and to what diseases they are susceptible. Furthermore they can be used for evolution studies as well as for historical migration patterns of humans across the world.

The numerous different types of microarrays in combination with the widespread fields of applications claim for advanced microarray fabrication technologies that are adapted to the specific needs regarding speed and flexibility. For all technologies reproducibility and robust processing as well as accuracy and printing precision should be taken for granted. With the ongoing and shifting usage of this tool further innovative platforms will appear.

Taken together these various capabilities that microarrays provide make high demands on bioprinting on chip technologies and therewith coupling chemistries. The important conclusion is that the microarray technology will continue to dramatically change over time as our picture of regulatory processes becomes more sophisticated and complete. With it the relevant microarray fabrication technologies and microarray platforms have to develop further associated with the increasing requirements.

Biorecognition

Definition

Biorecognition is the ability of a biologically derived entity (molecule or pathway) to reproducibly identify an analyte target and to generate a predictable response commensurate with that recognition reaction.

Definition

Sample preparation is usually defined as a series of molecular separation/fractionation steps required or recommended in order to obtain higher sensitivity and selectivity of downstream biosensing or bioanalysis.

Overview

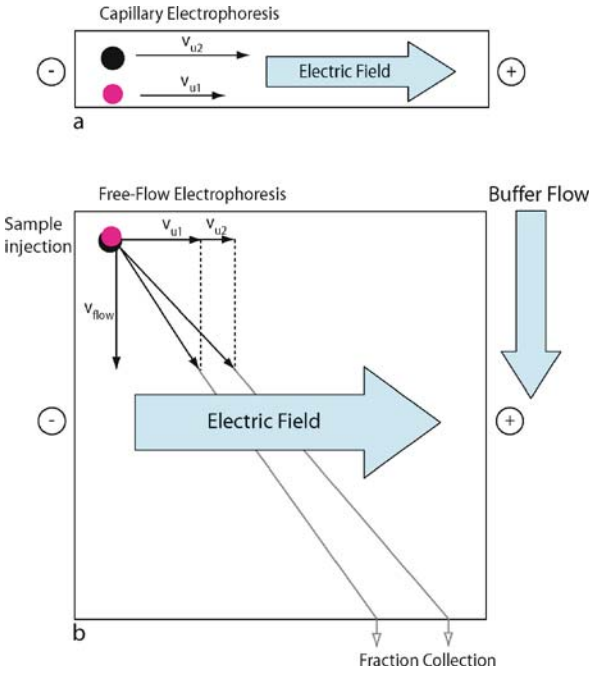
Given the complexity of most biological samples, sample preparation has been, and will be, one of the critical challenges in bioanalysis. Typically, most biosensing involves detection of low-concentration target molecules over molecular backgrounds with much higher concentrations. In genomic biosensing, this problem is largely

resolved by polymerase chain reaction (PCR), which can be used to increase the number of nucleotides with a specific sequence by several orders of magnitudes. However, in proteomic biosensing and bioanalysis, the issue of sample preparation still remains as a serious technical bottleneck, since there is no PCR equivalent for proteins and other biomolecules. For example, blood plasma or serum from any source is valuable for proteomics-based discovery of biomarkers for diseases or for discovery of novel drug targets. Detection of these proteins has potential diagnostic values; however, the major challenge is the complexity of common biomolecule samples. It is estimated that there are more than 10 000 protein species present in a serum sample. Moreover, most biomarker proteins are generally present at very low concentrations ($\ll$ pg/ml), while others, such as albumin and immunoglobulins, are present in very large amounts ($\gg$ mg/ml). This large concentration variation poses a formidable challenge to currently existing biomolecule detection techniques, most of which do not have low enough detection sensitivity and large enough dynamic range. It is expected, therefore, that the detection of low-abundance protein species or biomarkers would be possible only by better sample preparation and sorting. Conventionally, two dimensional (2D) protein gel electrophoresis, coupled with mass spectrometry (MS) has been the norm of proteomics research for decades, while multidimensional liquid chromatography coupled with MS is getting wider use due to ease of automation. Both techniques demonstrate similar separation peak capacity (up to ~ 3000) and dynamic range of detection ($\sim 10^4$) when coupled with MS.

Microfluidic engineering has the potential to improve the proteomic sample preparation processes significantly, by the automation and integration of many, laborious fractionation steps on a chip. While microfluidic devices for 2D protein separation [1] have already been demonstrated, the following technical issues still need to be addressed before the wider application of microfluidic 2D protein separation devices.

1. Preparatory separation should be able to process large sample volume. While small sample consumption is beneficial for some applications (such as single-cell analysis), most proteomic samples (blood, for example) are available in the volume larger than $\sim 1\,\mu L$. Most microfluidic separation systems are based on miniaturized capillary electrophoresis, which is essentially an analytic (not preparatory) technique. Therefore, the overall sample throughput and the detection sensitivity in such separation are limited.
2. Any preparatory separation device should be designed with the downstream sensing in mind. Many capillary electrophoresis separations utilize polymeric sieving media or reagents like carrier ampholytes, which are detrimental to most downstream detection systems (such as MS) by causing huge background and nonspecific binding.
3. Since there is no *PCR-like signal amplification* process for proteins or peptides, there must be efficient sample pre-concentration steps in the overall process. The low-abundance molecules could be efficiently separated, but in order to cover several-order-of-magnitude concentration ranges, one needs to concentrate these purified dilute, low-abundance species into higher concentration.
4. Usually, more than one separation strategy would be needed to deal with the complexity of proteome. However, there is a need for developing separation techniques by pI (isoelectric point) or size (kD), rather than other properties such as hydrophobicity. One reason is that size-based separation would be an ideal method to eliminate most abundant proteins (albumin/globulin) from a given sample, which are typically larger than signaling molecules. Also, fractionation based on size (kD) or pI values will significantly reduce database searching time at the end of MS (or tandem MS)-based proteomic analysis.

The above issues come from the fact that technical requirements for preparatory separation are quite different from those of analytic separation. For the last decade, many microchip-based separation processes have been developed, demonstrating high resolution and speed. However, the requirement for preparatory separation/fractionation is different from that of analytical separation. Generally speaking, resolution is less stressed while sample throughput becomes more important. Accordingly, to meet the demand for high throughput, continuous-phase separation (free-flow electrophoresis, transverse electrophoresis) has been gaining increasing popularity. In this continuous-flow mode separation, molecules are fractionated continuously into different streams, based on different molecular properties (size, charge, electrophoretic mobility, etc.). As a result, the biomolecules are separated and flow to different output channels at the end of the main separation chamber, where the fractionated samples can be collected continuously, as shown in Fig. 1. This eliminates the need for careful sample loading and ensures higher throughput. Typical biosample analysis could involve many (up to ~ 10) steps, which are currently of manual operation. Therefore, integration of different separation and fractionation steps is highly important, in order to build meaningful sample preparation microsystems. Two main challenges are buffer exchange and flow rate (volume) matching between each component. Some of the techniques that are very useful for analytical separation are



Biosample Preparation by Lab-on-a-Chip Devices, Figure 1 Comparison between (**a**) batch-mode capillary electrophoresis and (**b**) continuous-mode free-flow electrophoresis

not adequate for preparatory separation, because of specific buffer requirements or reagents to be used. Efficient buffer exchange methods in a microfluidic system have not been fully explored yet, as well as desalting of the sample (required for MS-based biosensing).

Basic Methodology

Filtration and Size-Based Separation

Gel filtration chromatography and gel electrophoresis are the two most commonly used techniques for separation of biologically relevant macromolecules (such as nucleic acids and proteins) based on size. Both techniques use gelatinous materials consisting of cross-linked three-dimensional pore networks, where the sieving interactions with the migrating biomolecules determine the separation efficiency. Depending on the relative size of the macromolecule compared with the gel mean pore size (e.g., the ratio of the radius of gyration R_g of the molecule to the gel mean pore size a), three basic separation mechanisms [2] have emerged to explain how flexible macromolecules migrate though a constraining gel medium – Ogston sieving ($R_g/a < 1$), entropic trapping ($R_g/a \sim 1$), and reptation ($R_g/a > 1$). In Ogston sieving, the macromolecule is smaller than the gel pores or constrictions, and the molecular sieving occurs because of steric interactions of the macromolecules with the gel pore network. Since $R_g/a < 1$, the molecules move rather freely through the gel matrix, assuming their unperturbed conformations. Entropic trapping applies when $R_g/a \sim 1$, and the conformation of the flexible macromolecule must deform or fluctuate to pass through the gel medium's spatial constrains. At each point, the number of accessible conformations defines the molecule's local entropy. Entropy differences derived from the gel medium's spatial heterogeneity drive molecules to partition or localize preferentially in less constrictive spaces, where their enhanced conformational freedom raises entropy. Reptation can be envisioned as a long flexible macromolecule occupying multiple pores threading its way through the gel in a snake-like fashion, which is very similar to the *reptation in a tube* process proposed by deGennes for entangled synthetic polymers. In reptation, only the end segments can escape as the molecule undergoes random curvilinear motion along the tube axis.

Both gel filtration chromatography and gel electrophoresis represent the current standard for size-based separation of biomolecules in laboratories. However, poor separation resolution in gel filtration chromatography and difficult sample recovery with gel electrophoresis make neither method optimal in separating complex mixtures for downstream analysis. Various microchip-based separation systems have been developed by using liquid or solid polymeric materials as sieving media contained in microchannels, and such systems have demonstrated fast separation of various biomolecules (e.g., DNA, proteins and carbohydrates) with rather high resolution [3, 4]. However, the foreign sieving matrices pose intrinsic difficulties for the integration of automated multistep bioanalysis microsystems. Furthermore, these microchip-based systems are limited to analytical separation of biomolecules, due to the difficulty of harvesting purified biomolecules for downstream analysis.

Recently, there has been great interest in switching from disordered porous gel media to patterned regular sieving structures, in the hope of achieving more efficient separation than gels in terms of separation speed and resolution [5]. While there are many different techniques to fabricate micrometer- or nanometer-sized sieving pores, it is sometimes more important to consider and understand the detailed molecular interaction with micro- or nanopore sieves before designing a molecular filter. Biomolecule interaction with molecular filters or sieves can be quite complicated, especially for the case of biopolymers such as long DNA. Intuitions based on filtration process of macroscopic objects can be quite misleading for the interaction between nanosized molecular sieves and nanometer-sized biomolecules in liquid environments.

Charge-Based (pI-Based) Separation

The charge density of biomolecules is related to their electrophoretic mobility; therefore electrophoresis in a free solution (*capillary zone electrophoresis (CZE)*) can be a method to separate biomolecules based on the charge density. The free solution electrophoretic mobility μ_e is a characteristic feature of each analyte, which is determined by the complicated balance among the electrical driving force on the analyte, electrical driving force on the counterions within the Debye layer on the analyte backbone and the frictional force from the surrounding fluid. Therefore, it is not a trivial matter to determine or calculate the electrophoretic mobility of a given protein/peptide *a priori* from the sequence information. Also, electrophoretic mobilities of many proteins among a given proteome can be similar. Therefore, the CZE is not an ideal technique for separating a very complex protein mixture for sample preparation purposes.

The most powerful variant for charge-based separation is *isoelectric focusing (IEF)*. To perform this separation technique, a linear pH gradient has to be established first either in the gel or in the microchannel. Once the pH gradient has been established, the biomolecules such as proteins and peptides migrate to the position where the pH equals their specific isoelectric point (pI). At this specific position, the net charge of the molecules becomes zero and they stop migrating. Molecules with different pI values focus at different positions with the pH gradient, thus allowing an effective charge-based separation of the molecules. This is a powerful fractionation technique because pI of a given target protein can be easily and accurately estimated from amino acid sequences; therefore one can collect and analyze only the pI region of interest. This could significantly cut down database searching time after MS detection, which can be quite time-consuming.

Because of its utility, IEF has been employed in many different forms even at macroscopic scales. Miniaturization of IEF would have benefits of employing small potentials. In IEF, the separation resolution does not depend of the length of the channel. The focused peak width σ can be given as the following equation:

$$\sigma = \sqrt{\frac{D\left(dx/d(\mathrm{pH})\right)}{E\left(d\mu/d(\mathrm{pH})\right)}} \sim \frac{L}{\sqrt{V}} \qquad (1)$$

Here, D is the diffusion constant of the protein, E $(= V/L$, L is the channel length) is the electric field and μ is the mobility of the protein. While $\mathrm{d}\mu/\mathrm{d(pH)}$ is an inherent property of the protein, $\mathrm{d}x/\mathrm{d(pH)}$ (pH gradient in length) scales as $\sim L$ for a given pH range determined by the ampholyte used in the experiment. The separation resolution R_S is given as $\sim d/\sigma$, where d is the separation distance in the microchannel between the two peaks of interest. Since d also scales as $\sim L$, R_S is only proportional to $V^{1/2}$, independent of the length of the channel L. In other words, for a given applied potential, the separation resolution does not change as the channel length is decreased, because of increased field strength in the channel makes the focused peak narrower. However, the time it takes to achieve IEF in the channel is decreased, because of shorter channel length as well as higher electric field strength.

One important consideration for the miniaturization would be the ways to achieve a pH gradient. The best resolution can be achieved by immobiline gel, where ampholyte chemical groups are polymerized into a gel. The other method to obtain a pH gradient is to use carrier ampholytes in solution form. The ampholytes are small buffer molecules with a wide range of isoelectric points that form a pH gradient when an electric field is applied. Typically, the electric field is generated between a basic solution (catholyte) such as ammonium hydroxide at the cathode and an acidic solution (anolyte), e.g. phosphoric acid, at the anode. It is possible to establish a natural pH gradient, relying on reduction–oxidation process near the electrode [6]. However, such a natural pH gradient is not stable enough for practical applications. Instead, adding carrier is preferred, in order to obtain more stable pH gradient. This is true even when immobiline gel is used. More stable separation is achieved by adding carrier ampholytes to the gel solution. Therefore, the use of carrier ampholytes has been the method of choice for microfluidic IEF devices. This, however, can interfere with subsequent analysis such as MS.

Isotachophoresis utilizes two different buffer systems, one as the leading electrolyte and the other as the trailing electrolyte. The leading electrolyte has a higher mobility than that of the analytes while the trailing electrolyte has a lower mobility. When an electric field is applied, the ions of the leading electrolyte migrate fastest and those of the trailing electrolyte slowest. Then, the ions of the analytes spread into the gradient of the electrical strength set by the mobilities of the terminating electrolytes. However, for practical applications, it is often difficult to find the appropriate terminating electrolytes with the required mobilities. The other limiting factor for this separation technique is that the ions have to be of the same polarity in order to be separated.

Affinity-Based Separation

The affinity-based sample preparation method on microchips is another powerful tool for separation of biomolecules. Conventional affinity-based separation

B

methods such as liquid chromatography or affinity chromatography have been successfully implemented in microfluidic chip format. The way the chromatography works in the microchannel is essentially the same as in the conventional method. In capillary electrochromatography (CEC), which combines the separation power of both liquid chromatography and capillary electrophoresis, the analyte is forced through a column of the stationary phase by electroosmosis instead of pressure. After this step, the gradient elution with a varying solvent composition, for instance 5% to 50% methanol, flows across the column and separates the analyte mixture depending on how well it mobilizes the analyte. The more hydrophobic component will elute first if the methanol content is high. However, when the methanol concentration is low, the hydrophilic analyte will elute more readily. The affinity chromatography is based on the specific interaction between an immobilized ligand and the target protein to be separated.

The last two variants of affinity-based separation are *micellar electrokinetic chromatography (MEKC)* and *electrochromatography (EC)*. MEKC uses surfactants which form micelles as pseudo-stationary phase in the microchannel. During electrophoresis, the analytes partition into the micelles depending on their hydrophobicity. Through the interaction with the micelles, the retention time of the molecules can be increased. In this way, even neural molecules can be separated. Electrochromatography utilizes an electrokinetic flow instead of pressure-driven flow to bring the mobile phase through a packed bed consisting of silica with a large negative surface charge. This induces an electro-osmotic flow (EOF) which drives the separation. A plug-like velocity profile brings a higher efficiency than HPLC.

Signal Amplification and Preconcentration

Several research groups have reported ways to preconcentrate samples in "Lab-on-a-Chip" devices. While most on-chip preconcentration approaches evolve from conventional capillary electrophoresis and chromatographic column techniques, these preconcentration techniques play an increasingly important role in chip-based system. The basic preconcentration strategies applied on microfluidic devices can be classified into three large categories: electrokinetic preconcentration, chromatographic preconcentration and membrane preconcentration.

Electrokinetic Preconcentration

Field-amplified stacking (FAS) (Fig. 2a) is a technique with a long history, first introduced by Mikkers et al. in the late 1970s [7].

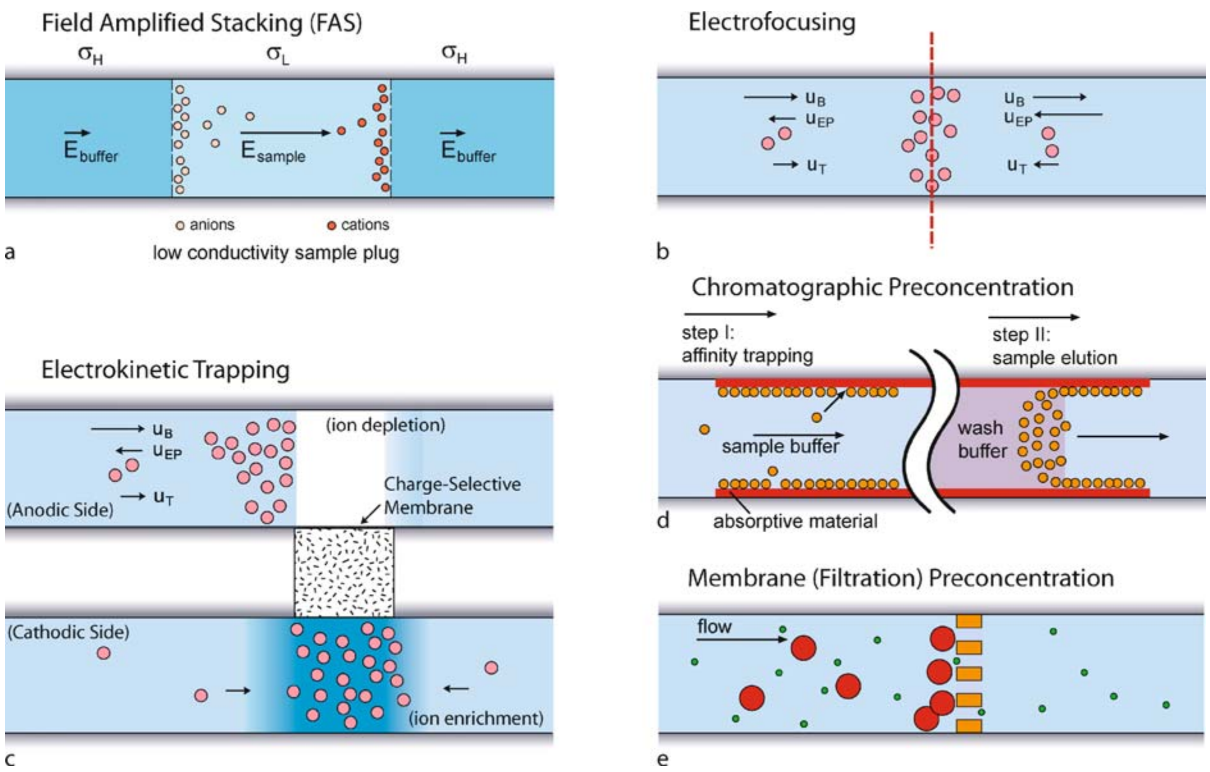
The mechanism relies on manipulating buffer concentration to achieve local field amplification. The relation between the electrical field (E) and buffer concentration (C) can be defined by the relative conductive (γ) as:

$$\gamma = \frac{c_L}{c_H} = \frac{\sigma_L}{\sigma_H} = \frac{E_{\text{buffer}}}{E_{\text{sample}}} \tag{2}$$

As a result, when we introduce low conductivity (σ_L) sample plug into capillaries or microfluidic channels with high conductivity running buffer, most of the potential drop will be applied onto the injected sample. This locally amplified field will therefore drive/stack sample to the ends of the plug by electrophoretic force. With a given plug size, one can increase the enhancement factor by increasing the relative conductivity. Even though FAS is one of the simplest preconcentration schemes to implement on microchips, the band broadening at the stacking boundary caused by hydrodynamic mixing from both flow injection and mismatched EOF makes it difficult to have highly focused peak.

Transient isotachophoresis and *micellar electrokinetic sweeping* can be viewed as extensions of the stacking concept of FAS. In the case of isotachophoresis, with the understanding of a sample's electrophoretic mobilities, the sample plug is sandwiched by leading electrolyte (LE) and terminating electrolyte (TE) instead of the same high conductivity buffer. Based on the order of descending mobilities, the constituents will separate into distinct zones between high mobility LE and low mobility TE (relative to sample constituents) upon the application of the separation voltage. Moreover, once the steady-state gradient is achieved, the boundaries between samples can be maintained by a self-focusing mechanism which alleviates the dispersion problem from which FAS suffers. Both FAS and isotachophoresis use buffer manipulation to achieve local field enhancement that helps sample stacking. Micellar electrokinetic sweeping, on the other hand, works on changing the electrophoretic mobilities of samples by labeling them with micelle compounds (surfactants). Once the correct compound is chosen, one can use a small plug of fast moving micelle compounds to sweep samples rapidly out of the sample zone by hydrophobic interaction. The enhancement factor of micellar electrokinetic sweeping can be further improved by coupling with FAS, however, it is still limited by analytes' affinity to the micellar compounds.

While FAS and its related techniques are well-established, their merit for sample preparation device is limited since these techniques usually require special buffer arrangements or reagents in the system. *Electrofocusing* (Fig.2b) is another class of techniques used to collect and concen-



Biosample Preparation by Lab-on-a-Chip Devices, Figure 2 Various types of preconcentration strategies. (**a**) Field amplified stacking, (**b**) electrofocusing (various types), (**c**) electrokinetic trapping (both anodic and cathodic side), (**d**) chromatographic preconcentration and (**e**) membrane preconcentration

trate analytes by manipulating both hydraulic and electrophoretic driving forces in the microchannel. Electrofocusing can occur whenever the net molecular velocity profile is converging, as shown in Fig.2b, by either controlling the flow and/or electric field of the two zones. Such a condition can be obtained by changing channel geometry, electric field of each zone or temperature of each zone. Electrofocusing can be achieved in a continuous fashion (collection of molecules until enough concentration is reached), and does not require any special buffers or ionic strength arrangements. However, the collection would be critically dependent on the specific electrophoretic mobility of the target.

Another novel electrokinetic preconcentration technique is *electrokinetic trapping* (Fig.2c), utilizing unique electrokinetic properties of perm-selective membranes. As a perm-selective membrane, one can use traditional membranes (such as Nafion®), nanochannels or charged polymer monoliths. When a current is applied through such a perm-selective membrane/nanochannel, concentration polarization of ions can occur (even at moderate buffer concentrations), causing the ion concentration of anodic side to decrease (ion depletion) and that of cathodic side to increase (ion enrichment). Both phenomena can be (and have been) utilized for concentrating biomolecules. In the cathodic side, biomolecules and ions can be enriched due to the ion enrichment process. In the anodic side, ion depletion region can be used in a similar manner as a *stacking boundary*, although the physical mechanism in this case is different from FAS. Unlike FAS, both cations and anions are collected at the same boundary. This is because both ionic species are *repelled* by concentration polarization process from the membrane/nanochannel. The advantage of electrokinetic trapping is that the preconcentration can be less sensitive to specific molecular electrokinetic properties (such as electrophoretic mobility), therefore providing a generic way for various types of molecules. However, concentration polarization and related phenomena are generally poorly understood, and the linearity and stability of the trapping is sometimes an issue.

Chromatographic Preconcentration

Chromatographic preconcentration (Fig.2d) is also called solid-phase extraction. It usually involves two steps. First, analytes are retained by affinity binding force onto an

appropriate stationary subject. Then, with the application of elution buffer, the analytes can be eluted into a more concentrated form. Non-microfluidic examples of this strategy are widely used, such as commercially available trap column for mass spectrometry and SELDI (surface-enhanced laser desorption and ionization)-MS. Affinity reagents and bead systems are well-developed for trapping proteins and peptides and commercially available, which makes its implementation to microfluidic format rather straightforward. Also, chromatographic preconcentration techniques can also desalt biosamples, which is another important benefit especially for MS. One of the drawbacks of chromatographic preconcentrations, however, is that the preconcentration can be biased (hydrophobic vs. hydrophilic), and the washing (elution) step could potentially re-dilute the concentrated plugs. In addition, chromatographic preconcentration can be limited by the number of binding sites (binding surface area) in the systems.

Membrane Preconcentration

In membrane preconcentration (Fig.2e), gel or porous membranes are used to concentrate molecules bigger than the size of the pores. By adjusting the pore size, one can allow the passage of buffer ions and small molecules but exclude larger molecules of interest. With the formation of nanofilters or nanoporous membranes within the microfluidic systems, this strategy can be implemented easily. Membrane (filtration)-based preconcentration will not have any chemical bias (mainly dependent on the size of the molecule), but continuous membrane filtration could generate eventual clogging of the system, which is one of the main problems in this technique.

Key Research Findings

Filtration and Size-Based Separation

For size-separation of biomolecules, it is imperative to have a molecular sieving structure incorporated in the system. Formation of polyacrylamide gel in a microchannel is one viable option, but solid-state, artificial sieving systems are much preferred due to their mechanical and chemical stability. Artificial molecular sieving systems can be fabricated using a variety of techniques [8–13], such as colloidal templating, anodized alumina pore fabrication, packed nanospheres, superparamagnetic particle arraying, standard photolithography and e-beam lithography.

Regular arrays of micrometer- or nanometer-sized pillars have been fabricated by different groups with either photolithography (with pillar diameter and spacing down to 1 μm) or e-beam lithography (with pillar diameter and spacing down to 100 nm) on silicon substrates. The advantages of such microlithographically fabricated devices include the precise control over the sieving matrix geometry and the design flexibility. By applying two alternating electric fields of different directions and different magnitudes, Huang et al. recently devised a *DNA prism* device that can continuously separate long DNA molecules with high speed [14]. In this design, the longer DNA molecules only follow the strong electric field component while the shorter ones migrate in the direction of the sum electric field vector. However, their application was largely limited to rather large biomolecules (long DNA).

The concept of Brownian ratchets has been applied to construct asymmetric obstacle courses that provide a spatially asymmetric steric potential for biomolecule separation [15, 16]. The basic idea is to use such asymmetric obstacles to rectify the Brownian motion laterally and thereby to deflect diffusing biomolecules based on their sizes. So far, the Brownian ratchet systems have been successfully demonstrated for long DNA and phospholipids [15, 16], even though the separation resolution reported so far was not ideal.

More recently, a microfabricated nanofilter array system was developed, which can be used for separating various biomolecules such DNA molecules and proteins [17, 18]. The unique feature of this class of molecular filters is that only standard photolithography is needed to create ∼ 10 nm sized molecular filters. Using the same system, one can employ different sieving mechanism. For long DNA molecules, entropic trapping mechanism is used, while small DNA and proteins can be separated by Ogston sieving mechanism. These devices demonstrated speed and resolution comparable to or better than the conventional techniques (i. e. pulsed field gel electrophoresis for long DNA, and capillary gel electrophoresis for proteins). One important advantage of a nanofilter array system is that the separation efficiency could be further improved by increasing the nanofilter density, by using advanced high-resolution (photo or e-beam) lithography techniques.

In terms of sample preparation, continuous-flow separation is also highly desirable for micro-/nanofluidic devices because of the low sample throughput. We choose two recent developments here that we believe represent the current advance of this particular exciting area: the *Tango* device (or the bump array) (by Huang et al. [19]) that separates long DNA molecules by asymmetric bifurcation of laminar flow [19], and the anisotropic nanofilter array (ANA) (by Fu et al.) that separates DNA and proteins based on the different sieving characteristics along two orthogonal directions within the ANA structure [18]. The Tango device employed arrays of micrometer-sized pillars and spacing, with each pillar column slightly shifted with respect to the previous one in a direction perpendicular to

the flow direction. Longer DNA molecules are displaced as they flow through the pillar array while shorter DNA molecules remain in the feeding streamlines (i. e. the deterministic lateral displacement), leading to efficient separation. It is believed that as the gap size of pillar array is reduced using nanofabrication, the Tango device can be used to fractionate biologically relevant molecules. The design of the ANA consists of a 2D periodic nanofilter array, and the designed structural anisotropy in the ANA causes different sized biomolecules to follow radically different trajectories leading to separation. So far, continuous-flow Ogston sieving-based separation of short DNA and proteins as well as entropic trapping-based separation of long DNA molecules have been demonstrated with the ANA structure. The design of the structural anisotropy is the key for the continuous-flow biomolecule separation, and it can be applied to any sieving mechanism across the nanofluidic sieving structure along the orthogonal direction (size-, charge- or hydrophobicity-based) that can lead to differential transport across the nanofilters. Highly efficient, continuous-flow molecular separation would be possible as long as one can create a separation system that is *anisotropic* in nature.

Charge-Based Separation

IEF-based sample fractionation devices have been developed and commercialized, but miniaturizing them into a microfluidic format is being studied actively. Especially, there have been tremendous efforts to increase the throughput of charge-based separation by operating the microfluidic device in a continuous mode. The Yager group from the University of Washington fabricated a multi-stacked Mylar continuous-flow separation device with palladium electrodes in direct contact with the solution. Since the electrodes were in direct contact with the solution, only a small voltage, 2.3 V, could be applied over a 1.27 mm wide channel [6]. Because of the small distance, however, it generated sufficient electric field, ~ 18 V/cm, for the separation of a binary mixture of proteins. The same group used the electrolysis of the buffer, H^+ at the anode and OH^- at the cathode, to generate a natural pH gradient across the microchannel without using any carrier ampholytes [6]. This low-voltage approach, however, requires a significant amount of time for separation at around 4 minutes. To reduce the separation time, Zhang et al. developed a high-voltage μ-FFE (free flow electrophoresis) device by isolating the separation channel from the electrode reservoirs using narrow (4 μm wide) microchannels [20]. Their FFE microchip with 10 μm deep channels in a polydimethylsiloxane (PDMS) substrate allowed an electric field up to 270 V/cm and they could successfully separate two fluorescent dyes, rhodamine 110 and fluorescein, as well as two amino acids in 2 s. However, the high voltage induced a strong EOF which deteriorated the separation result. The μ-FFE device developed by Kohlheyer incorporates two new improvements compared to the previous ones [21]. First, it is a multifunctional μ-FFE device which can perform free-flow zone electrophoresis and free-flow IEF. Depending on the separation method to be used, the only parameter to be changed is the width of the sample by hydrodynamic focusing. This can be performed easily on the run by changing the flow rates in the two side channels. Second, they implemented a polymerized acrylamide as the salt bridge between the main separation channel and the electrode reservoirs. This proved to be more effective in suppressing the EOF than the microchannel as the salt bridge. Isotachophoresis (ITP) has been also realized in microchip format for the free-flow electrophoresis [22]. A sample mixture of fluorescein, eosin G and acetylsalicylic was separated in less than a minute. Song et al. developed a novel ampholyte- and gel-free pI-based continuous-flow sorting technique [23]. Their method differs from previous approaches in that this continuous sorting process involves no external power supply and no special ampholytes. Instead, they utilized the diffusion potential generated by the diffusion of different ionic species in situ at the laminar flow junction.

Free-flow electrophoresis has also been successfully applied to separate subcellular particles such as organelles (mitochondria) [24]. This is facilitated by the fact that these particles contain many different proteins and amphoretic molecules. The sorting in microscale devices offers obvious advantages compared to the conventional ones. Less heat is generated by using only ~ 2 V compared to 2000 V of conventional devices and this causes less damage of organelles. The result shows that free-flow electrophoresis can be applied to various organelles, even for organelles that are larger and do not have uniform pI values.

Affinity-Based Separation

While the technology for affinity-based separation is very well developed for capillary-based separation, chromatography in microchips has not been as popular as electrophoresis, mainly due to the difficulty in packing microchannels with beads. In particular, if the channels are not straight but are curved into serpentine configurations, it is quite a challenge to achieve a uniform packing of the channels. Instead of packing affinity beads, creating a polymer monolith [25, 26] is much preferred, with controlled, relatively uniform pore sizes, variety of chemical groups one can incorporate into the system, and covalent

linkage to the channel wall (therefore no need of frits to hold the monolith stationary).

Often, fittings for microfluidic systems cannot handle the high pressure required for chromatographic separation, and electrokinetic flow can be used in lieu of pressure-driven flow. Using the microchip chromatography, driven either by elecroosmosis or pressure, a separation of low-molecular-weight neutral and basic compounds and acidic proteins has been demonstrated. He et al. demonstrated CEC of peptides in a microfabricated system [27]. They mimicked the packed bed by etching an array of support structures into a quartz substrate, the so-called collocate monolith support structures. These columns were prepared with polystyrene sulfate for stationary phase. A mixture of tryptic peptides from ovalbumin was separated in the CEC isocratically as opposed to the gradient elution mode.

In capillary-based separations, technologies based on microbeads with specific chemistry are well-developed and mature, and utilizing such bead systems in microfluidic channels would be of tremendous value. Oleschuk et al. developed a design that allows exchange of packing materials [28]. This can be utilized for solid-phase extraction (SPE) and CEC. Using CEC, a separation of BODIPY and fluorescein could be achieved with a mobile-phase composition of 30% acetonitrile / 70% aqueous 50 mM ammonium acetate. The BODIPY is hydrophobic and has a higher affinity for the column than the fluorescein, causing slower elution of BODIPY. In addition to affinity-based separations, microchannels with packed beads could provide other functionalities for microfluidic sample preparation systems, such as peptide digestions [29, 30], removal of majority proteins and extraction of DNA from cells [31]. It was shown that peptide digestion reaction can be significantly expedited ($\sim$ 10 min) compared with solution-phase digestion process.

Signal Amplification and Preconcentration

Given the importance of sample preconcentration in many biosensing applications, several sample preconcentration techniques, including field-amplified sample stacking (FAS), isotachophoresis (ITP), electrokinetic trapping, micellar electrokinetic sweeping, chromatographic preconcentration, electrofocusing (various types) and membrane filtration preconcentration have been developed. Each technique has its own advantages and disadvantages.

Field-Amplified Stacking and Other Related Techniques

FAS can be implemented on microchips in a very similar manner as capillary electrophoresis. However, the requirement of low ionic strength sample buffer for FAS puts limitation on its use as general preconcentration technique. Variations of the technique, such as transient isotachophoresis and micellar electrokinetic sweeping, have been more successfully used. Jung et al. reported on-chip transient isotachophoresis by introducing TE and LE into a T-junction simultaneously to achieve fast sample loading, preconcentration and separation [32]. Micellar electrokinetic sweeping, pioneered by the Terabe group, combines field-amplified stacking with affinity concentration using micelles [33], and provides very high concentration factors. These techniques were originally developed for capillary electrophoresis; therefore they are well suited for enhancing the sensitivity of microchip-based separation and detection. However, they require special arrangements of buffers with different ionic concentrations, which makes the coupling to the downstream biosensing challenging, limiting their use as sample preparation devices. For example, micellar electrokinetic sweeping relies on a detergent additive (sodium dodecyl sulfate), which has a negative impact on the downstream analysis.

Electrofocusing and Electrokinetic Trapping

Newer techniques such as electrofocusing and electrokinetic trapping could be ideal alternatives for proteomic sample preconcentration. One of the benefits electrofocusing offers is that the collection can be run continuously, and therefore, concentration can be arbitrarily increased (with a limitation imposed by crystallization and other technical issues). Electrofocusing can continuously collect molecules by applying two different (electrophoretic and hydraulic, typically) driving forces in the opposite direction in a microchannel or capillary to trap molecules. Various types of electrofocusing [34–37], which differ in the method to generate a gradient in electrophoretic mobility (temperature, electric field, etc.), have been demonstrated in microfluidic and capillary systems. Depending on the focusing time, these techniques can achieve typically up to $\sim 10^5$-fold concentration enhancement.

Electrokinetic trapping techniques [38–41] have been recently demonstrated as an efficient way of concentrating protein samples. Different membrane materials can be used, such as polymer monolith (Singh and coworkers), Nafion® (Swerdlow and coworkers), nanochannels (Han and coworkers) and even PDMS (Kim et al.). These techniques demonstrate impressive concentration factors (up to $\sim 10^6$) as well as the flexibility to be coupled to downstream analysis. These techniques are dependent on the ion depletion and concentration polarization, which as a generic process are quite common to most nanoporous membrane systems. Therefore, there is no specific buffer

requirement, as long as the ionic strength is moderate (∼ 10 mM or less).

Chromatographic Preconcentration/Membrane Preconcentration

Several groups [42, 43] have demonstrated affinity-based molecular preconcentration systems in a microfluidic format. Affinity chemical groups can be directly coated to the surface of the glass microchannel, although techniques using microbeads (Harrison and coworkers) and polymer monoliths (Frechet and coworkers) provide better functionality, larger binding surface area and flexibility in fabrication and integration. The concentration factor in these systems is eventually determined by the surface binding area. For efficient capturing from larger sample volume (∼ 1 μL or more), a larger microchannel is required.
Membrane preconcentration [44, 45] is a microscale version of membrane filtration and dialysis, which is well established. Typically gel or other polymeric materials (Singh and coworkers) as well as nanofluidic channels/solid membranes (Ramsey and coworkers) are used as a molecular filter. An advantage of this technique is that one can combine preconcentration with filtration/separation in a single step. A disadvantage of this technique would be that it becomes progressively more difficult for smaller proteins and peptides, and it is also limited by the ambiguity of the molecular weight cut-off of the nanoporous filter membrane materials. Even in the case of regular nanofilters, molecular size filtration of biomolecules can be quite complicated due to conformation changes of biomolecules.

Future Directions for Research

The importance of sample preparation in bioanalysis is expected to draw more attention in the future, since this is currently one of the major bottlenecks in biosensing. For preparatory separation, continuous-flow fractionation is much preferred over elution-type separation, due to the flexibility of integration and higher sample processing rates. More and more fractionation techniques would be made into a continuous-flow format, possibly by adopting anisotropic sieving system designs. Since typical sample preparation could easily involve many (up to ∼ 10) different separation/reaction/preconcentration processes, integration of these individual steps on a single device would be highly desirable for practical application. Recent developments in sample preconcentration devices have the potential to enhance any new and existing biosensors in terms of sensitivity and selectivity, if properly integrated with preparatory separation steps.

Biosensor

Definition

A *biosensor* is a device for the detection of an analyte that combines a biological component with a physicochemical detector component.

It consists of 3 parts:

- the *sensitive biological element* , including biological material (eg. tissue, microorganisms, organelles, cell receptors, enzymes, antibodies, nucleic acids etc) and a biologically derived material or biomimic).
- the *transducer* in between (associates both components)
- the *detector element* (works in a physicochemical way; optical, piezoelectric electrochemical, thermometric, or magnetic.)

Definition

Biosensors using ►atomic force microscopes (AFMs) are devices which employ an atomic force microscope for biological recognition events. The principle of biosensors

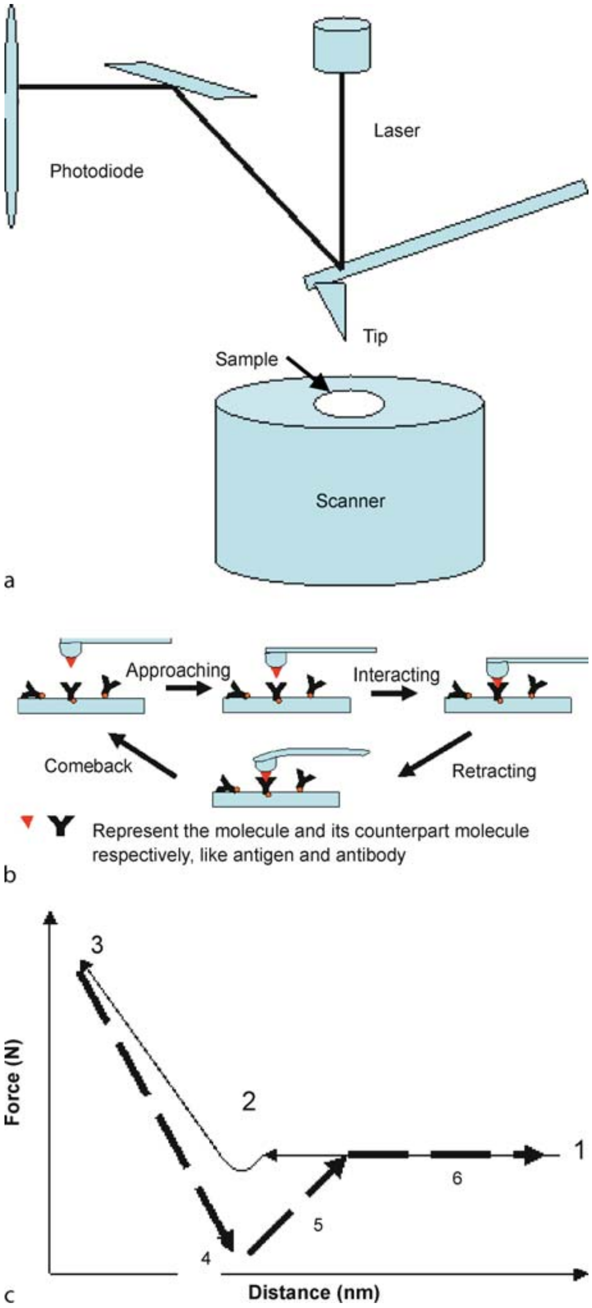
using atomic force microscopy is mainly based on the mass-sensitive detection of binding events that change the deflection of a ►cantilever whose surface is modified with immobilized bioreceptors.

Overview

A ►biosensor, which exploits a biological detection or recognition system for target molecules, typically consists of three components: the transducer, the detector and the signal output. The core of a biosensor is the physico-chemical transducer which converts the biological recognition event into a useable output signal. There are numerous studies that integrate various detection schemes with biosensors, which can be categorized into optical detectors (for example, UV-Vis absorption, fluorescence, and chemiluminescence), electrochemical detectors (for example, amperometry, potentiometry, and conductometry) and mass spectrometric (MS) detectors according to the different detection principles. Recently, state-of-the-art AFMs have also entered into the biosensing area as highly sensitive detectors.

AFM is a type of scanning probe microscope with very high resolution, and is one of the foremost tools for imaging, measuring and manipulating matter at nanoscale level. An AFM mainly consists of a microscale cantilever (with a sharp tip), an optical deflection system and a sample stage (Fig. 1a). AFM has basically been used as a high-resolution imaging tool to "feel" the topography of a sample and it has the ability to visualize the atomic and molecular structure of sample surfaces. In the imaging mode of AFM, the sharp tip at the end of the cantilever is raster-scanned over the surface of a sample. As the tip approaches the surface, the cantilever deflects as a result of the interaction forces between the tip and the surface of the sample, and its deflections are monitored by a laser and a photodiode and then used to reconstruct the topography of the sample [1, 2]. Besides its imaging mode, AFM is also a powerful tool for measuring the force between a single bio-molecule pair interaction with nanometer resolution, as AFM is able to measure intermolecular forces as small as a few piconewtons (as weak as a single hydrogen bond interaction). As a biosensor AFM is able to directly probe the adhesion or rupture (unbinding) force interactions between molecules, such as ligands and receptors, antibody and antigen pairs; and strength of chemical bonds, such as hydrogen bonds [3].

When AFM operates as a force sensor, the interaction force between the tip and the substrate surface can be measured by moving the tip perpendicular to the surface while measuring the force on the tip. The working principle is as follows: one type of molecule, i. e., an



Biosensors Using Atomic Force Microscopes, Figure 1 (**a**) Basic components and working principle of AFM. A sharp tip fixed at the end of a flexible cantilever is raster-scanned over the surface of a sample. As the tip interacts with the surface, the cantilever deflects and its deflections are monitored by a laser and a photodiode and then used to reconstruct the topography of the sample. (**b**) A schematic diagram of AFM as a biosensor in detecting the force interaction between biological molecules. (**c**) Force–distance curve. During the tip (immobilized with one type of molecule, i. e., antigen) of the cantilever approaches to the substrate (immobilized with the counterpart of molecule, i. e., antibody), the *line* 1–3 is followed. By retracting the tip back, the cantilever bends downward as a function of the unbinding force between the two molecules, the line 4–6 (*dash*) is followed

antibody is attached to the tip of the cantilever and its counterpart molecule, i. e., an antigen is attached on the substrate surface. When the tip and substrate approach to each other, the two molecules interact and bonds are formed. Thus, their adhesion force can be measured. By retracting the tip back, the cantilever bends downward as a function of the unbinding force between the two molecules. Thus, the unbinding force, defined as the maximum force at the point of separation of the samples, can be recorded and measured. The force is monitored by the deflection of the cantilever and the deflection is directly proportional to the force. The schematic diagram of such an experiment and the force–distance curve are illustrated in Fig. 1b and 1c.

There have been several other powerful techniques for probing the molecular interaction between biosurfaces, including the use of shear flow detachment, surface force apparatus, biomembrane force probe, and optical tweezers [4]. The main advantages of using AFM are its high resolution, easy sample preparation, and its ability to manipulate in aqueous medium. AFM is currently the only force technique that makes mapping and analyzing single receptors with nanoscale lateral resolution possible [4]. Up to now, researchers have successfully used this system to measure interaction force between biotin and streptavidin, avidin and biotin, antibodies and their antigens, and single pairs of DNA nucleotides.

Basic Methodology

The first studies using AFM as a detection tool for intra- or intermolecular force can only measure discrete force. As the techniques for tip and sample preparation improve, single molecular interaction force detection will become the focus of AFM biosensors.

Major Factors for Single Molecular Interaction Force Detection

For real measurements of interactions between single molecules, very strict conditions are needed. Several important factors should be considered. First, the density of molecules distributed on both tip and sample should be sufficiently low to allow the formation of single molecular interactions. Second, to prevent unwanted detachment, covalent bonding of the molecules to the tip and the sample is critical. Generally, the binding between the surfaces and the molecules should be much stronger than the intermolecular force being studied. Third, a suitable molecular crosslinker (spacer) is a good choice to attach the molecules to the surfaces so that the molecules can interact with their counterparts with sufficient mobility. Forth, unspecific adsorption on the modified surfaces should be blocked to minimize the contribution of unspecific adhesion to the measured forces. Fifth, for oriented systems, site-directed coupling in which the molecule has a defined orientation may be desired [4]. Moreover, the rupture forces measured in an interaction force experiment are highly dependent on the conditions of the experiment, i. e., the spring constant of the cantilevers and the retraction rate of the cantilevers, and these factors will affect the result of the measurement.

Basic Procedures for Preparing AFM Tips and Samples

The coupling of biomolecules to the tip and to the surface has proved to be essential in the measurement of single molecular interaction force. The quality and reproducibility of the functionalization steps are the key factors leading to the success and reliability of a single-molecule experiment.

Preparing AFM Tips

Two types of surface chemistries have been developed for the functionalization of tips, they are based either on the strong chemisorption of thiols on gold surfaces or on the covalent attachment of silanes or alcohol on silicon oxide surfaces [4].

Strong Chemisorption of Thiols on Gold Surfaces The gold coating techniques can be used to functionalize the tip. When the tip has been coated by a thin adhesive layer of gold (gold tip), proteins, oligonucleotides or carbohydrates that bear thiol groups can be attached directly onto the gold surfaces. We can also functionalize the gold tip with alkanethiols which can attach biomolecules by self-assembled monolayers (SAMs). SAMs are easily obtained by immersing gold surfaces in dilute (typically 1 mM) ethanol solutions of the interested alkanethiols. The alkanethiols may be terminated by carboxyl group or amino group. The former can be reacted with amino groups of proteins using 1-ethyl-3-(3-dimethylaminopropyl) carbodiimide (EDC) and N-hydroxysuccinimide (NHS) in aqueous solution. This method can provide both firm attachment and molecular mobility, but is restricted by the multiple attachment points which lead to broad unbinding force distributions. The latter can also be used to attach proteins [4].

When the gold tip is functionalized with alkanethiols terminated with nitrilotriacetate (NTA) group, recombinant histidine-tagged proteins can attach to it via their carboxy or amino group. This method allows the optimal exposure of the C-terminal or N-terminal domains. Moreover, it can orient the attached molecules in the same way and minimize nonspecific protein adsorption and allows low density coupling to ensure single molecule recognition. But

the binding strength between NTA and histidine-tagged protein is ten times lower than that of the covalent bond. Therefore this method is not suitable for studying strong receptor–ligand bonds [4].

Covalent Attachment of Silanes or Alcohol on Silicon Oxide Surfaces The method does not require a gold coating tip, and can be applied directly to silicon tips. Proteins can be linked to the silicon tip through a crosslinker which carries heterobifunctional group, for example, a polyethylene glycol (PEG) crosslinker with an amine-reactive NHS group on one end and 2-pyridyldithiopropionyl (PDP) on the other end. The NHS group reacts with amines on the silicon tip forming a stable amide bond while the PDP group reacts with free thiols presented by cysteines in the protein forming a stable disulfide bond.

Preparing Samples

The receptors or ligands recognized by the functionalized tip need to be firmly attached to a solid support using appropriate, nondestructive approaches. Mica, glass and silicon have proved to be excellent supports for immobilizing purified receptors. The surface of mica is negatively charged at neutral pH, positively charged proteins can adsorb to it forming a strong enough binding to withstand the pulling force during the force detection experiments. The surface chemistries that are often used to prepare the samples are the same as those for preparing the tips, including strong chemisorption of thiols on gold surfaces and covalent attachment of silanes or alcohol on silicon oxide surfaces [4].
Besides molecules and biomolecules, cells can also be attached to the tips or sample supports. It makes the detection of cell–cell, cell–support interactions possible. The most important factor when attaching cells is that the attaching methods should retain the integrity and viability of the cells while at the same the binding between the cell and tip, cell and support should firm enough. Chemical fixation using crosslinking or attaching through adhesive coating proteins (collagen, fibronectin) can be applied to the cell attachment.

Other Features for the Single Molecular Interaction Force Detection

When the tips and samples have been functionalized, the quality of the tip and sample modifications should be evaluated. A control experiment is necessary to ensure that the bonds being formed during the tip or sample preparation processes will not break during the force experiment. A block experiment is important to address the specificity of the interaction force being detected. A block experiment can be performed by masking the receptor sites with free ligands.

Key Research Findings

Detection of the Forces of Discrete Bonds

Several investigations have demonstrated the measurement of inter- or intra-molecular interactions using AFM. Lee and co-workers were the first to use AFM to measure discrete and biologically specific rupture forces between biotin and streptavidin which are one of the strongest ►noncovalent interactions in nature. The schematic diagram was similar to Fig. 1b. First, the force probe (a glass microsphere glued to a cantilever) and the surface were coated with bovine serum albumin (BSA) by nonspecific adsorption; then, biotin was covalently coupled to BAS-coated force probe and surface; subsequently, the biotin-functionalized surface was incubated with the counterpart molecule, streptavidin, resulting in a monolayer of streptavidin bound to the biotinylated BSA on the glass surface. When the force probe and surface approached each other, the biotin on the probe could interact with the streptavidin and bonds were formed. When retracting the cantilever, the bonds formed could be disrupted. This rupture occurs when the gradient of the cantilever potential exceeds the highest gradient in the unbinding pathway of the ligand–receptor interaction potential. By registering the deflection of the cantilever at rupture, the rupture force could be measured. After blocking the streptavidin by free biotin, no rupture force was measured, which showed the specificity of the interactions.

Detection of Single Molecular Interaction Force

Lee's work was very useful for measuring the unbinding forces of discrete bonds, but not for measuring the single molecular interaction force. To successfully detect the single molecular interaction force, several techniques have been developed to modify the tips and the samples, e. g., crosslinker system, intrilotriacetate (NTA)-Ni^{2+}-His system. Whatever technique is used, the key point is to make the density of the molecules distributed on both the tip and the sample sufficiently low to allow the formation of single molecular interactions. Kienberger et al. [5] have successfully detected the single molecular interaction force between abotin and avidin.

Detection of the Force Interactions of DNA in the Aqueous Medium

The most significant point of AFM is that it can be applied to detect the force interactions in aqueous medium. The

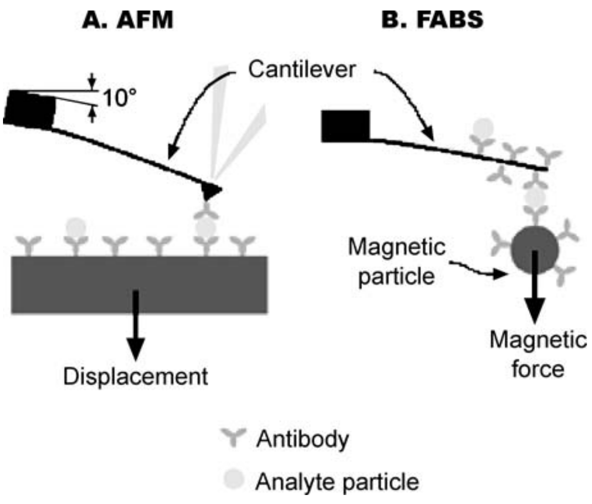
measurements are not as straightforward as those between the tips and the solid surfaces. Cengiz and co-workers [6] have constructed a biosensor for quantitative measurements of molecular nucleic acid in aqueous medium. Only an AFM head with a cantilever, a sensitive approaching unit (to control the approach of the target solution to the AFM tips) and a CCD camera were needed in such a system. The sensitive approaching unit was in fact an inchworm motor that provides precise approach positioning in the Z-direction with high stiffness and holds position even with the power turned off. This type of motor has a resolution of 1 nm and a speed range of 1 nm/s to 0.5 mm/s when used as its own controller. When using this system, a model single strand DNA (ssDNA) molecule was covalently attached onto the tips (cantilevers) of the AFM as a specific ligand. Buffer solutions with and without free ssDNA molecules were approaching to the tip ($+Z$-direction) by the inchworm motor until the tip touched to the solution. The tips interacted with the target ssDNAs in the buffer solution for about 10 min to complete hybridization and then the buffer solution was driven at the opposite direction ($-Z$-direction) and meanwhile the *separation distance* (L, in nm) that the tip got rid of the solution was measured to follow the interaction between the ligand molecules attached on the cantilever (the tip) and the target molecules in the buffer solution. The percentage separation distance (PSD) was calculated from the following equation and used as the main variable:

$$(\mathrm{PSD})(\%) = \left\{(L_2 - L_1)\right\} \times 100 \qquad (1)$$

Where L_1 is the separation distance for the buffer solution without ssDNA (nm), and L_2 is the separation distance for the same buffer solution containing the target ssDNA (nm). Note that the negative value shows the decrease in the interaction between the AFM tip and the liquid phase. And in order to show the specificity of these AFM sensors, buffer solutions with the non-complementary ssDNA were also measured. The results showed that after hybridization with its complementary ssDNA, the PSD values were significantly increased when compared with the PSD values for the buffer solutions, while the PSD values for the non-complementary ssDNA increased slightly (specificity of the method). The PSD values also decreased with the concentration of the target ssDNA in the medium. It seemed that there was a correlation between the concentration of the complementary target ssDNA in the medium and the PSD value, although it was not linear.

Force Amplified Biological Sensor (FABS)

AFM biosensors have been used by researchers to measure binding or rupture forces between biological molecules.



Biosensors Using Atomic Force Microscopes, Figure 2 Detection of antibody–antigen interaction forces with AFM and with FABS. (**a**) In AFM, a piezoceramic translator moves an antibody-derivitized surface away from a cantilever until a single antibody–antigen bond breaks. (**b**) In FABS, a magnetic field pulls on antibody-derivitized magnetic particles. The cantilever can bear thousands of particles, although the figure only shows one. (reproduced from [7])

However, they have a few drawbacks, for example, the nonideal geometry of AFM can produce artifacts, the result of measurement is affected by many factors and in order to obtain good results, very strict experimental conditions are required. Improvements of the AFM biosensors are being studied.

A FABS, whose working principle was very similar to that of the AFM biosensor, was a cantilever-based immunosensor [7]. However, its configuration was much simpler than that of the AFM. Rather than using a piezoceramic translator to pull on intermolecular bonds, it used magnetic particles, which eliminated the need to manually position a tip and sample next to each other with picometer precision and stability. The cantilever-beam force transducer was the only element of the AFM retained by the FABS.

Here, the measurement of antibody–antigen interactions was used to illustrate the working mechanism of a FABS (Fig. 2): one or more cantilevers with attached antibodies will capture antigen from a sample solution; 2 μm magnetic particles that also have attached antibodies will then bind to the captured antigen (at this stage the particles are not magnetized); after they have bound to the cantilever, a large magnetic field will magnetize the particles while a modulated field gradient exerts force on them. This force will cause particles bound via antibody–antigen bonds to pull on and bend the cantilever, while dislodging nonspecifically bound particles (*force discrimination*). The amount that the cantilever bends will indicate the

number of particles bound to the cantilever and, therefore, the concentration of analyte (antigen) in the sample. The FABS is capable of detecting a single bound particle, potentially corresponding to a single antigen molecule. A second detection mode might involve gradually increasing the force on the magnetic particles and determining the number of particles that detach at the expected antibody–antigen interaction force.

As can be seen from above, the magnetic particles, the Helmholtz coils, and cantilevers are the critical components of the FABS. The force generated by each magnetic particle is

$$F = 0.524Md^3(\mathrm{d}B/\mathrm{d}Z) \quad (2)$$

Where M is the volume magnetization of the magnetic material, d is the particle diameter, and $\mathrm{d}B/\mathrm{d}Z$ is the field gradient generated by the Helmholtz coils.

With its ability to detect a single bound molecule and to distinguish specific from nonspecific interactions, FABS could potentially have 6 – 8 orders of magnitude more sensitivity than commonly used immunoassays. This ability would be of value for environmental monitoring. Testing for airborne bacteria or viruses, for example, can presently require several days of air collection to accumulate detectable amounts of analyte. The high sensitivity of FABS could dramatically reduce sampling times and speed the detection of dangerous microorganisms or chemicals.

Combination of AFM and Other Techniques: AFM-Tip-Integrated Biosensors

Kueng et al. [8] have developed an AFM-tip-integrated biosensor to map molecular transport across membranes. Actually, this biosensor was a combined AFM-SECM (scanning electrochemical microscopy) probe which retained the integrity of both techniques and could be applied in dynamic-mode operation on soft biological samples. The combined AFM-SECM probe was fabricated as shown in Fig. 3a. An electroactive area with defined geometry, which was recessed from the apex of the AFM tip, allowed integration of the SECM functionality into AFM by correlating the current measured at the integrated electrode with the topographical information obtained by the AFM tip. Biological recognition elements, such as enzymes were then immobilized to the combined AFM-SECM probe as shown in Fig. 3b. In this integrated biosensor, AFM worked in its imaging dynamic mode, which was different from the above described biosensors which used AFM in a nonimaging mode.

To demonstrate the ability of this AFM-tip-integrated biosensor to study glucose membrane transport, a porous polycarbonate membrane (200 nm pore size) was mounted in a vertical diffusion cell that separated aqueous solutions in the donor and receptor compartments to mimic glucose transport through cellular membranes (Fig. 3c) and the glucose oxidase containing polymer layer was immobilized onto the probe (Fig. 3b). The combined AFM-SECM glucose oxidase electrode acted as a sensor that established concentration profiles of individual species near the sample surface. When the AFM tip was scanning in the X-direction above a synthetic membrane with 200 nm pores, the expected qualitative height and current signals were recorded (Fig. 3c). At the position of the pores, the height signal decreased, and glucose diffused through the pores toward the immobilized glucose oxidase layer, which catalyzed the conversion of glucose into gluconolactone (Fig. 4a). The current recorded at this glucose biosensor during the imaging of the pores increased as a result of the localized production of H_2O_2 when glucose diffused from the donor into the receptor compartment. Fig. 4c and 4d show AFM topography, SECM current images in the presence and absence of glucose in the donor compartment and exemplary line scans of the height and current response, respectively. The glucose signal response in the electrochemical image corresponded to the topography measured simultaneously with the AFM tip. The SECM current image of the porous membrane represented a contour map of the glucose concentration after emergence of the aqueous solution of glucose from the membrane pore and free diffusion into the receptor-compartment solution. While in the control experiment without glucose in the donor compartment, the measured current was negligible (Fig. 4f).

The glucose transport rate could be obtained by using Fick's law at appropriate boundary conditions, assuming that the pore opening was hemispherical. The concentration profile $C(r)$ at a radius r above the hemispherical pore opening could be described by Eqs. (3) and (4).

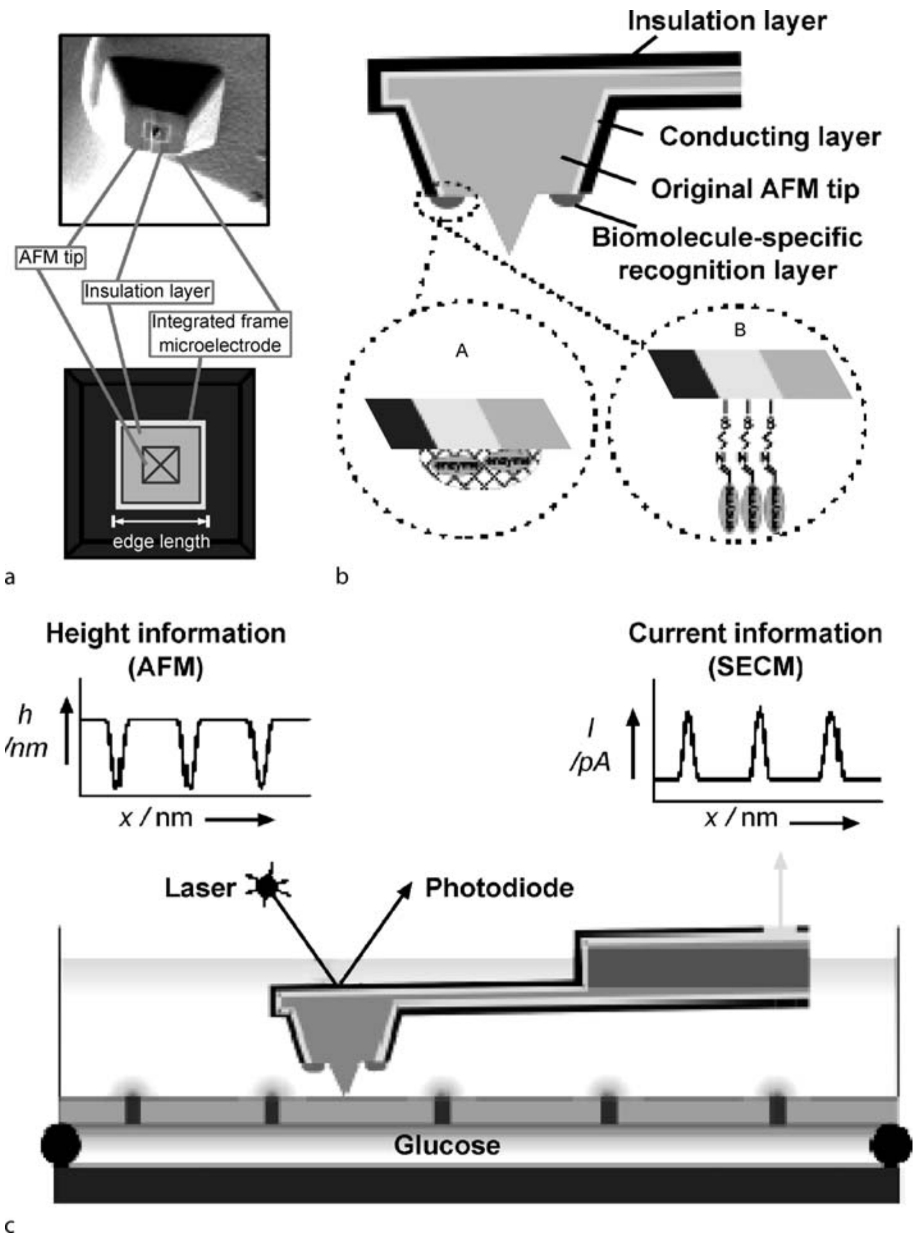
$$C(r) = (r_0/r)C_S \quad (3)$$

$$r_0 = 2a/\pi \quad (4)$$

Where C_S was the molecule concentration at the surface of the pore opening.

Earlier results showed that the radial divergence of the diffusive flux from a microscopic pore, regardless of its real shape, results in the pore appearing as if it were hemispherical in shape. For a disk-shaped pore with radius a, the radius of the corresponding hemispherical pore r_0 could be described by Eq. (4) [8].

Based on this approach, the theoretical glucose concentration at a distance (r) of 310 nm, which corresponds to



Biosensors Using Atomic Force Microscopes, Figure 3 (**a**) SEM image and schematic top view of an AFM-tip-integrated frame electrode; (**b**) schematic cross-section of an AFM-tip integrated biosensor. Enzymes can be immobilized at the surface of the scanning-probe tip-integrated electrode through self-assembled thiol monolayers with functionalized headgroups (A) or through electrochemical deposition of enzyme-containing polymer films (B). (**c**) Schematic cross-section of the experimental setup for imaging glucose transport through a porous membrane during simultaneous AFM mapping. (reproduced from [8])

the reshaped AFM tip height, above a pore opening with a radius (a) of 100 nm was estimated to be 0.62 mM for a 3 mM glucose solution. The evaluation of the current response in the SECM image (Fig. 4d) resulted in an average peak current of 1.5 ± 0.3 pA. According to the linear regression of the glucose calibration obtained at the integrated electrode (Fig. 4b), the measured glucose concentration was estimated to be 0.66 ± 0.13 mM. This semi-quantitative value corresponded well to the theoretically estimated concentration of 0.62 mM.

Glucose biosensors fabricated with this technology exhibit excellent sensitivity, response time, reproducibility, and long-term stability. This technology has a wide range of applications for biological specimens and processes.

(**e**) Exemplary corresponding line scans of height and current. (**f**) Current image recorded without glucose in the donor compartment. (reproduced from [8])

Future Directions for Research

The development of AFM and its use in detecting molecular interactions has led to the understanding of molecular recognition on a variety of biological surfaces. Researchers will continue to find more suitable surface chemistries to functionalize the AFM tip for the more precise measurement of single molecule interaction force and individual bond strength, and eventually use the AFM as a biosensor in the medical profession to screen samples for a particular chemical or biological agent. Second, the ability of the AFM to acquire movies (sequential images) under aqueous environments can be used to follow biological processes, dynamics and macromolecular assembly occurring in real time. Finally, the combination of AFM and other techniques to develop multifunctional, highly sensitive, easy operating devices for the purpose of molecular interactions study will be among future research interests.

Laser-based biosensors

Definition

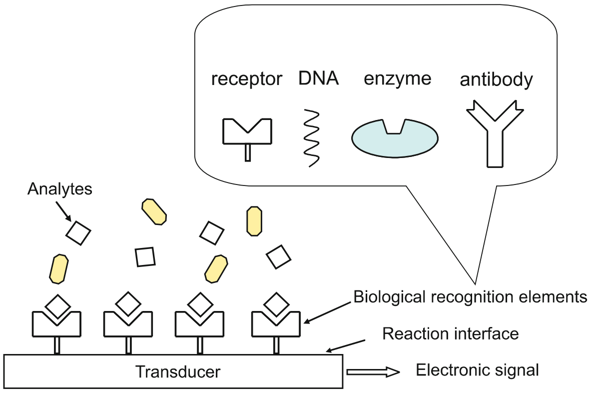
Biosensors using lasers are defined as sensors for biological applications which are based on laser technology. There is a series of biosensors which use laser-based detection methods such as: surface plasmon resonance, fiber optics, waveguides, microcantilevers, and so on. Due to their high sensitivity and precision, laser-based biosensors have been widely used in many fields, including immunoassays and drug screening.

Overview

Biological sensing is a process which obtains selected information about biological macromolecular interactions in real time. Biosensors are miniaturized analytical devices based on biological sensing technology, which commonly comprise a biorecognition molecular layer immobilized on the interface between the analyte solution and a signal transducer (Fig. 1) [1]. The main part of a typical biosensor is this biologically sensitive layer that converts the biological change into a detectable signal, which is subsequently translated into a digital electronic result. The sensitive substances on the interface, which can include enzymes, antibodies, DNA segments, peptides or even a microorganism, provide the biosensor with its selectivity for the target analyte so that the molecule that is of interest can be picked out by the biosensor from a mixture of many different molecules. The extent of the biorecognition event is determined by the signal transducer and converted into an electronic signal for the end user. Popular transducers in biosensors include electrical, optical, or piezoelectric devices.

Optical biosensors are the most popular because of their high sensitivity, fast response time, in situ monitoring, and the absence of electrical interference. Due to its outstanding advantages in monochromaticity, coherence, low beam divergence, and strong irradiance, the laser is widely used as the light source in optical biosensors. For a wide range of biological systems, biosensors using lasers can be used to provide qualitative information, such as whether or not two molecules interact, and quantitative information, such as kinetic and equilibrium constants for macromolecular interactions. In a typical experiment, one molecule is attached to a surface and the other molecule, which is in solution, flows over the surface. Their interaction is transferred to a recognizable optical signal under the laser irradiation and converted to an electronic signal by optoelectronic components such as the charge coupled device (CCD) and the photomultiplier tube.

Many laser-based biosensors are derived from traditional detection methods. For example, traditional enzyme-based biological sensing analyses use the photometric detection



Biosensors Using Lasers, Figure 1 The biosensor comprises a biorecognition molecular layer immobilized on the interface of a signal transducer. Biological change on this interface is converted into a detectable signal and subsequently translated into a digital electronic result. Many types of sensitive molecules including enzymes, antibodies, a DNA segment, peptides or even a microorganism can be immobilized on the interface

method, where the enzyme reaction is linked to a colorimetric or fluorescent indicator. Some of these assay methods can be miniaturized and converted to solid-state systems, which were the early laser-based biosensors. This concept is now being applied to absorbance measurements by using evanescent wave detection, where the optical fiber, or in more general terms, the waveguide, itself forms the sensor surface. The binding of the immobilized biorecognition molecule and the analyte has an impact on the light propagating through the waveguide. The evanescent wave decays exponentially away from the surface of the waveguide, so that recognizable molecular interaction is limited to the layer immediately adjacent to the sensor surface, which is not affected by changes in the bulk solution.

Direct reading unlabeled immunoassay has also been sought through laser-based optoelectronics. In order to monitor the physico-chemical change produced by the interaction between an antibody and an antigen, without the secondary labels which are used in traditional biochemical assay methods, exploration of new detection techniques is required. Surface plasmon resonance (SPR) is the most outstanding of these techniques, with a sensitivity as high as 10^{-8} g/l [2]. The SPR biosensor is now the most popular optical biosensor. The microcantilever is another laser-based biological sensing method for the detection of analyte without labeling, where biological changes are monitored by using a laser optical beam deflection technique which detects the reflection of a microcantilever induced by biological interaction.

Several popular laser-based biosensors, SPR, optic fibers, waveguides, and microcantilever biosensors, will be summarized below.

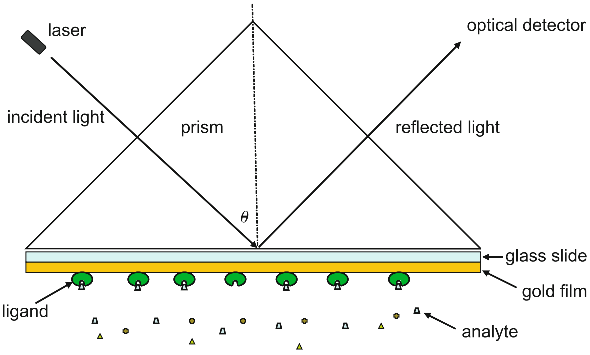
Basic Methodology

Surface Plasmon Resonance

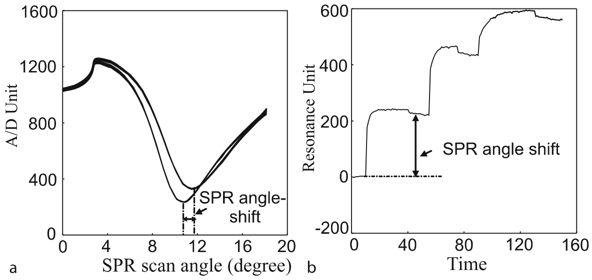
As a laser-based optical biosensor technique, SPR can measure molecular binding events at a metal surface by detecting changes in the local refractive index. The depth probed at the metal–aqueous interface is typically 200 nm, making SPR a surface-sensitive technique ideal for studying interactions between immobilized biological molecules and a solution-phase analyte.

SPR is an optical phenomenon that arises under conditions of total internal reflection of p-polarized light at an interface between a metal film and a liquid/gas phase, where a prism or grating is used as a coupling component (Fig. 2) [2]. Total internal reflection of light occurs when light traversing a medium of high refractive index (commonly a glass prism) encounters an interface with a medium of lower refractive index (usually an aqueous or gaseous environment). During total internal reflection, the energy and momentum of incident light can be transferred into the surface of the metal to create a surface plasmon. This excitation of plasmons generates an evanescent wave which propagates along the glass–metal surface, but decays exponentially over about one wavelength from the interface. For a fixed excitation wavelength, variation of the incident angle (θ) allows detection of the optimal angle associated with SPR, where most incident light is absorbed by the surface plasmon wave. This unique angle for minimal reflected light intensity is called the SPR angle (θ_{SPR}). Measurement of the intensity of reflected light as a function of the incident angle generates a SPR spectrum (Fig. 3a), which depends upon the refractive index and the thickness of the dielectric medium in the immediate vicinity of the interface. Although the evanescent field extends some 300 nm into the medium of low refractive index, the exponential decay of its amplitude gives rise to a rapidly decreasing sensitivity of response with increasing distance from the metal surface. As the detection method based on SPR angle, for a fixed incident angle, variation of the excitation wavelength allows the wavelength associated with optimal conditions for SPR to be detected. The incident angle and excitation wavelength scan are commonly used as detection methods in SPR biosensors.

The incident angle (or wavelength) where the resonance occurs strongly depends on the refractive index close to the metal surface. In a SPR biosensor, the interaction between immobilized biomolecules on the surface and analytes in solution changes the local refractive index, which results



Biosensors Using Lasers, Figure 2 Schematic representation of a SPR biosensor. Laser and prism are used as the emitted light source and coupling component, respectively. Receptor molecules immobilized on the gold surface interact with analytes in solution, which induce the change in the refractive index in the immediate vicinity of the interface. This change can be detected by the SPR signal monitoring on the gold surface



Biosensors Using Lasers, Figure 3 (a), SPR curve of a detection method based on incident angle scan. SPR angle shifts with the change in refractive index. (b), monitoring the shift of SPR angle in real time

in a shift in the SPR angle. By monitoring changes in the shift process of the SPR angle, it is possible to measure the interaction on the surface in real time (Fig. 3b). Here no label is needed. Typical biological systems examined using these instruments include antibody–antigen, ligand–receptor, and protein–nucleic acid interactions.

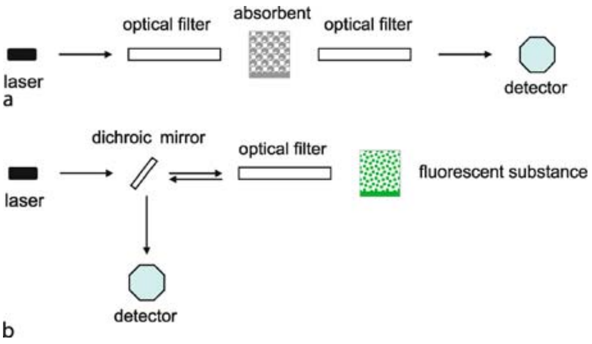
Traditional SPR spectroscopy biosensors, which measure the entire SPR curve as a function of the angle or wavelength, have been widely used, but offer limited throughput. The development of SPR imaging (microscopy (SPM)) allows for the simultaneous measurement of thousands of biomolecular interactions [3]. Typically, a SPM consists of a highly coherent p-polarized light source expanded by a beam expander and consequently reflected from an SPR active medium (sensing surface) to a detector. The CCD camera is frequently used as the detector in this system, which collects the reflected light intensity in an image. SPM imaging measurements are performed at a fixed incident angle that falls within a linear region of the SPR curve, so that changes in light intensity are proportional to the changes in refractive index caused by the biomolecular interaction on the surface. Thus, the gray-level intensity of the SPM image correlates with the amount of material bound to the sensing region. When combined with protein arrays, SPM imaging technology has the potential to become an invaluable tool for a broad range of applications that require high-throughput analysis of biomolecular interactions, such as proteomic analysis, drug screening, and immunoassay.

SPR offers several advantages over conventional techniques such as fluorescence or enzyme-linked immunosorbent assay. Here the analyte does not require any special characteristics or labels and can be detected directly; the measurements can be performed in real time to collect kinetic data; it is a versatile technique, capable of detecting analytes over a wide range of molecular weights and binding affinities. Because of its unique features, SPR has become a powerful tool for studying biomolecular interactions.

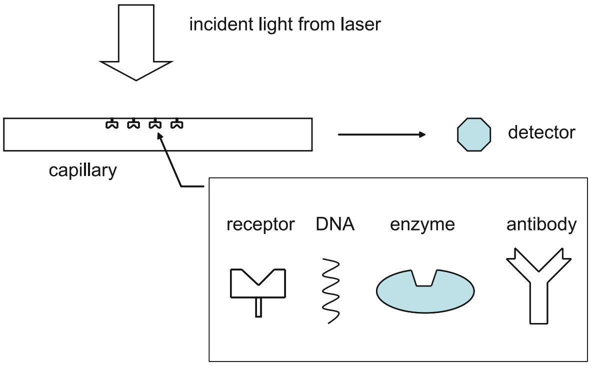
Fiber Optics

Fiber optic biosensors, which often use a laser as the light source are based on several different detection principles. Most existing laser-based detection methods used in large-scale instruments can be miniaturized by using optical fibers. For example, fluorescence and absorbance detection have been miniaturized by this way. In the case of absorption, the detector measures the reduction in the intensity of light from the source. This reduction is caused by an absorbent product arising from the reaction between the immobilized substance and the analyte. Absorption measurements are generally made using monochromatic wavelength light, and both the incidence and emitted beams have the same wavelength. At least two fibers are necessary in this system, one for the inward beam and one for the outward beam, because the intensities of these two beams cannot be separated at the same wavelength (Fig. 4a). The use of white light, however, can yield a complete absorption spectrum with the help of photodiode matrices or arrays. The wavelength of the rescence emission is different from its excitation wavelength, and a single fiber is sufficient to transport both the excitation and the emission radiation (Fig. 4b). A single fiber can also be used to measure fluorescence quenching, which occurs when a compound that absorbs in the same spectral region as the emission is present.

Some optical phenomena (e. g., evanescent waves) within the microscale optical environment are used to construct fiber optic biosensors [4]. In fiber optic biosensors for photometric detection, the light between the sample and the source or detector is transported along the interior of



Biosensors Using Lasers, Figure 4 Fiber optic biosensors based on (a) absorbance, and (b) fluorescence detection methods



Biosensors Using Lasers, Figure 5 A capillary is used as an optical waveguide for evanescent wave-based biological sensing detection. The waveguide is perpendicularly illuminated by laser light, and the detection signal is subsequently collected from one end of the waveguide

the fibers following the principle of total reflection. The total reflection in a fiber is not perfect and some electromagnetic radiation penetrates the sheath covering the fiber. This is called the evanescent wave, and its intensity diminishes exponentially with the perpendicular distance from the interface as the surface wave in SPR. It can be used to detect the variations in optical properties of chemical and biological films placed around the fiber [5]. The laser optical detection method based on evanescent waves is widely used in biosensors. For example, a tapered optical fiber is used to analyze the total internal reflectance fluorescence. As light is propagated down the fiber, an evanescent wave excites fluorescent tracers bound to the fiber surface. Because the evanescent wave decays exponentially with the distance from the fiber surface, the excitation radius only extends about 100 nm into the buffer medium. A portion of the emission is captured and propagated back through the fiber to the detector.

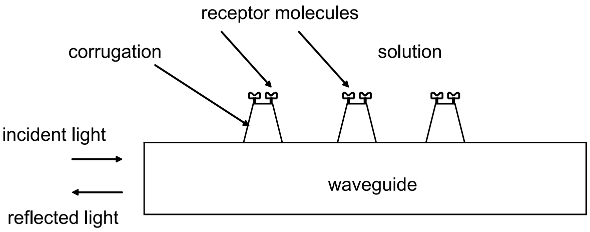
Waveguides

A waveguide works on a similar principle to optical fibers, so most fiber optic detection methods can be transplanted to waveguide-based biosensors [6]. Compared with optical fibers, the waveguide is more easily integrated with other optical components (e. g., grating, interferometer) and can be integrated into miniaturized detection devices such as microfluidic chips.

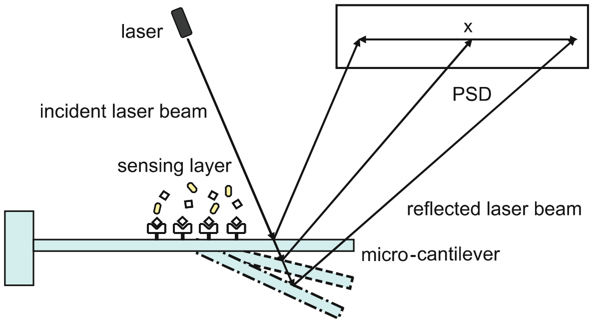
The fiber optic biosensor, based on an evanescent wave, is the most popular of the biosensors using waveguides. In the early stage, a capillary is used as the waveguide to collect free propagating fluorescence [7]. For biosensor applications, probe molecules can be covalently bonded to the interior surface of the capillary to detect target molecules flowing through the capillary. Placing the probe coating on the interior surface also facilitates handling and protects against accidental damage. One detection method is achieved by illuminating the capillary (waveguide) at a 90° angle relative to the length of the waveguide and subsequently collecting the emitted fluorescence from the end of the waveguide (Fig. 5).

A waveguide can be integrated with a ating to form an optical waveguide grating coupler sensor, which responds to the change in optical refractive index of the liquid or gas cover medium. As in SPR detection, the optical refractive index in the immediate vicinity of the interface is directly related to the adsorption or binding of molecules on the surface. The optical waveguide grating coupler sensor chip is based on a fine optical grating prepared on a thin waveguide layer on a glass substrate. The optical grating couples the light of a laser at a given resonance angle into the waveguide layer. This resonance angle is very sensitive to the presence of adsorbed molecules and to any change in the refractive index of the medium covering the surface of the chip.

A planar waveguide with a corrugated surface, which can be tuned to be a resonant Bragg reflector, is also a laser-based biosensor (Fig. 6) [8]. The reflection coefficient of the light propagating through the waveguide depends on the depth of the corrugation as well as on the length of the corrugated region. A specially prepared layer, which selectively adsorbs the target biomolecules, is only covered on the surface of higher parts of the corrugation. When solution flows over this corrugation, some target biomolecules bind with the cover layer, the corrugation depth rises and the reflection coefficient changes. This change is proportional to the difference between the dielectric permittivities of the analyte and solution, and can be used to monitor the dynamics of the surface reaction. The presence and concentration of the target biomolecules in the solution can also be inferred by this method.



Biosensors Using Lasers, Figure 6 Schematic of a laser-based biosensor using the resonant Bragg reflector principle. A receptor molecular layer covers the surface of some corrugation that is used as sensing materials. After some target molecules bind with the receptor molecular layer, the corrugation amplitude rises and coupling coefficient changes

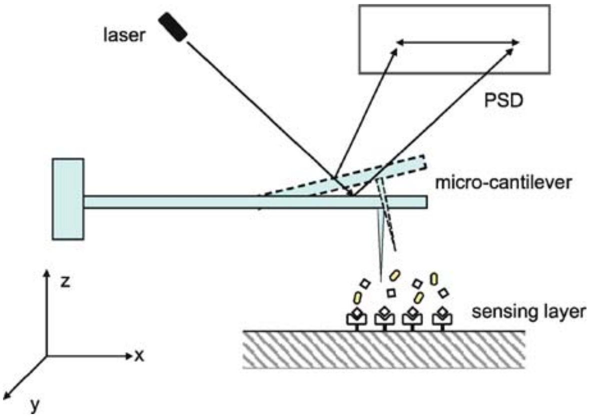


Biosensors Using Lasers, Figure 7 Scheme of the optical read-out method for a microcantilever bending evaluation. The displacement of the free end of the cantilever is measured by monitoring the optical deflection of an incident laser beam on a position-sensitive detector

Microcantilevers

Biosensors using microcantilevers have attracted considerable interest in the last few years [9, 10]. The microcantilevers transduce the recognition event from their receptor-coated surface into a mechanical deflection. As the ligands interact with the receptors, the adsorption stress leads the bending of the cantilever toward or away from the receptor side depending on the nature of the chemical bonding of the molecules. The deflection of the microcantilever can be measured using the optical beam deflection technique, which is highly sensitive and widely used in atomic force microscopy. The displacement of the free end of the cantilever is measured by detecting the optical deflection of an incident laser beam on a position-sensitive detector (PSD), which allows the absolute value of the cantilever displacement to be calculated (Fig. 7). This method provides sub-angstrom resolution and can easily be implemented. High sensitivity biological sensing thus becomes possible.

The defection (δ) of a microcantilever, which is caused by the surface stress difference of the top (receptor-coated) and the bottom surfaces, can be estimated according to



Biosensors Using Lasers, Figure 8 Working principle of the microcantilever atomic force biosensor

Stoney's formula:

$$\delta = \frac{3\,(1-v)\,(\sigma_1-\sigma_2)\,L^2}{Ed^2}$$

where v is the Poisson ratio of the cantilever material; σ_1 and σ_2 represent the surface stress of the top and bottom surfaces, respectively. L and d are the length and the thickness of the cantilever, respectively, and E is Young's modulus of the cantilever material.

The microcantilever atomic force biosensor is another type of microcantilever-based biosensor. Its working principle is similar to that of the microcantilever biosensor. However, receptor molecules are covered on a planar other than the surface of cantilever. Biological changes are also monitored using an optical beam deflection technique. The laser illuminates the end of the microcantilever and changes in position are detected using a matching PSD. This sensor works like a profilometer by moving a microfabricated tip held at the end of a microcantilever across the sample while recording the x-, y-, and z-coordinates of the preparation being scanned (Fig. 8). The z-coordinate is calculated by detecting the laser beam reflected off the surface of the cantilever. These microcantilever biosensors are able to detect many biological systems such as single-strand DNA hybridization, and protein–protein/DNA binding, pH variations.

Future Directions for Research

In recent years, laser-based biosensors have become important tools in many fields such as analytical biochemistry, pharmaceutical research and development, and food/environmental monitoring. However, the volumes of the optic components in these biosensors limit their application in portable microdevices. In order to obtain

more powerful, miniaturized, and cheaper biosensors using lasers, novel biological sensing principles, detection means and fabrication methods need to be sought. The integration of biosensors and microfluidic chips will be an important direction for developments in laser-based biosensors. Biosensors can be used as microscale detection tools in lab-on-a-chip for the research and development of miniaturized detection devices, i. e., micro-total analysis systems.

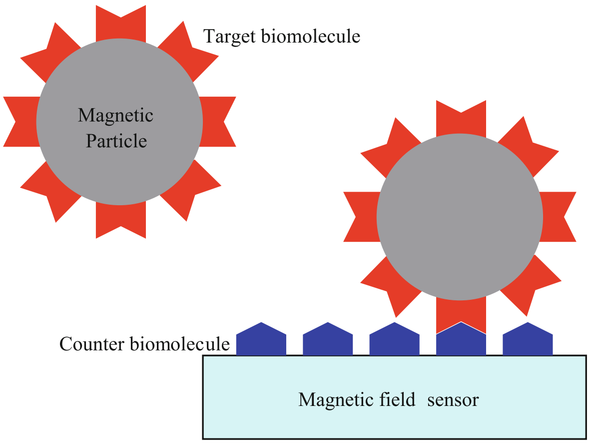
Definition

Biosensors are analytical devices incorporating biological or biologically derived sensing elements with physicochemical transducers to produce digital electronic signals [1]. These biosensors determine the concentration of substances and other parameters of biological interest. The detecting elements of biosensors work in different physicochemical ways: optical, piezoelectric, electrochemical, thermometric, and magnetic. Biosensors using magnetics utilize the magnetic field created by magnetic particles that bind to target molecules in a biological assay (Fig. 1).

Overview

There is an increasing need for higher sensitivity and specificity of detection for biosensors. Magnetic particles, by the use of the magnetoresistive (MR) effect, have been developed as labels for biosensing. These magnetic biosensors have several advantages compared to optical and electrical biosensors. The properties of magnetic particles are not affected by reagent chemistry so that they are very stable over time. Magnetic fields are also not screened by aqueous reagents or biomaterials. In addition, magnetism may be used to remotely manipulate the magnetic particles [2]. Therefore, magnetic biosensors using MR materials have been proposed as a new technology to detect low concentrations of targets in biofluids [3].

The target biomolecules in a biofluid are attached on magnetic particles. When these magnetically labeled



Biosensors Using Magnetics, Figure 1 Schematic of magnetically labeled biomolecule detection in a biosensor. Target biomolecules bound with a magnetic particle interact with magnetoresistive sensor-bound counter biomolecules to be detected

target biomolecules pass over the magnetic biosensor with counter biomolecules bound on its surface, these biomolecules interact with each other and the biosensor generates detecting electronic signals (Fig. 1).

A number of sensitive magnetic field detection devices have been developed as biosensors: giant magnetoresistive (GMR) sensors [4], piezoresistive cantilevers [5], inductive sensors [6], superconducting quantum interference devices (SQUIDs) [7, 8], anisotropic magnetoresistive (AMR) rings [9], and miniature Hall crosses [10].

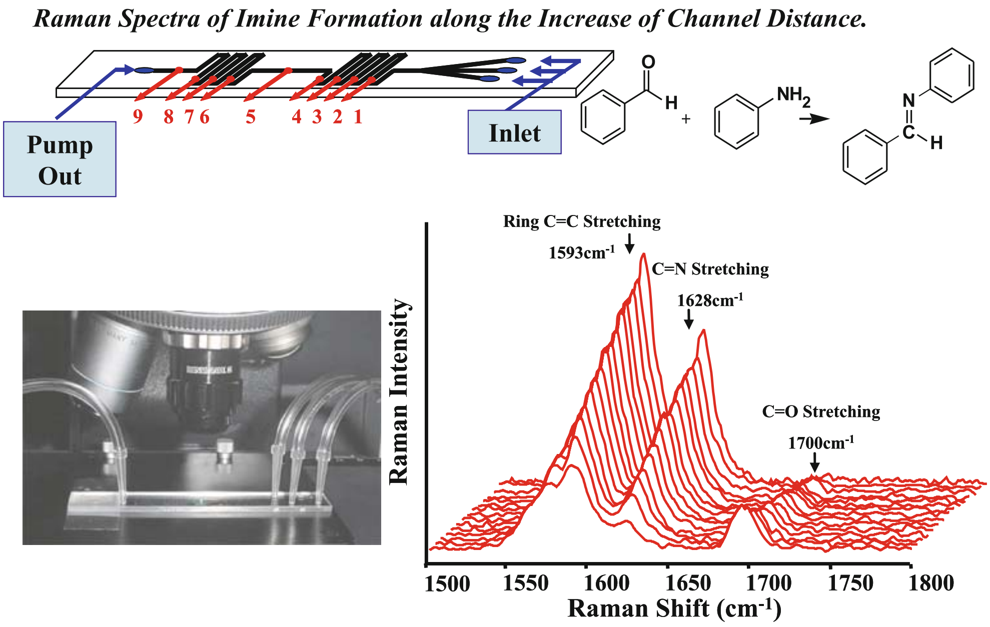
SERS-based biosensors

Definition

Devices for the highly sensitive detection of biological analytes using surface enhanced Raman scattering (SERS) spectroscopy. SERS is a highly sensitive optical detection technique in which lasers are used to excite vibrational transitions in molecule adsorbed on a metal nanoparticle surface. As a result of large optical fields, the Raman cross section for a molecule on a surface is enhanced by factors of $10^6 – 10^{10}$.

Overview

Microfluidic technology has recently been developed to perform a variety of biological or environmental trace analyses. These devices have several advantages compared with conventional techniques, such as minimal sample requirement, reduced reaction time, ease-of-use, improved product conversion, and reduced waste generation. It has long been realized that the system used for detection of the progress of the reaction is a key issue in determining the applicability of the microfluidic system. Because of the extremely small volume in a microfluidic channel, a highly sensitive detection method is essential in order to monitor the progress of the reaction. At the early development stage of a microfluidic detection, off-chip detection methods, such as high performance liquid chromatography or mass spectrometry, have been widely used to detect the small volumes of chemical species in a microfluidic channel. However, off-chip detection is very inconvenient for continuous monitoring of reactions since the sample must be removed from the reservoir of a chip on each detection occasion.



Biosensors Using Surface-Enhanced Raman Scattering, Figure 1 In situ Raman monitoring of imine formation reaction in a glass microfluidic sensor. The change in Raman spectra corresponds to the peak changes caused by the imine formation at various points along the channel

On the other hand, spectroscopic detection methods, such as laser induced fluorescence (LIF), UV/Vis absorption, chemiluminescence and thermal lens microscopy (TLM), have been used for on-chip detection. Among these methods, the fluorescence detection method has been most widely used because of its high sensitivity and low detection limits for biologically relevant species. However, the fluorescence detection technique has some disadvantages. Many chemical species do not fluoresce and so need to be treated with fluorescence tags to allow on-chip detection. Furthermore, it may have drawbacks such as a photobleaching and overlapping peaks caused by broad fluorescence emission profiles in multiplexed biological detection. Raman spectroscopy is another well-known analytical method, which offers great advantages for probing the biological and structural properties of a compound on a microscopic scale. The detection and identification of non-fluorescent samples is possible using this technique. Photodecomposition is reduced compared with fluorescent samples since the excited states are rapidly quenched and the excitation energy does not have to be in resonance with electronic transitions.

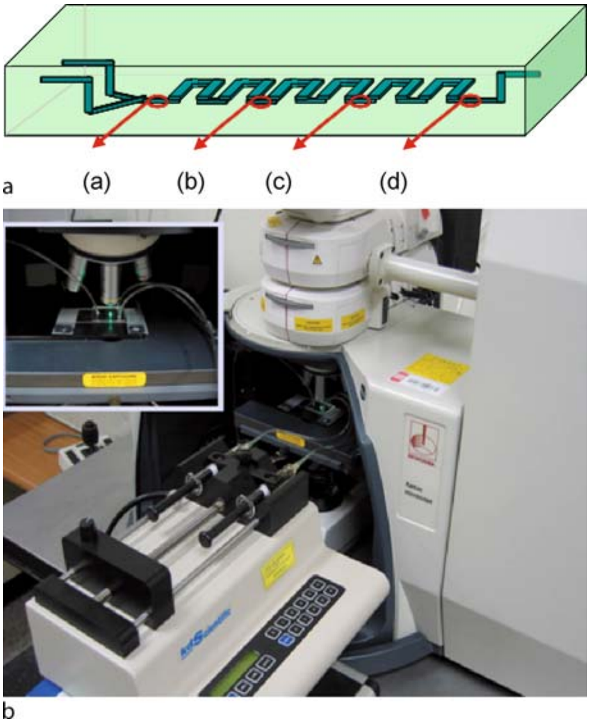
However, Raman scattering is an extremely inefficient process with low scattering cross-sections that are approximately fourteen orders of magnitude smaller than the absorption cross sections of fluorescent dye molecules. In order to achieve a high sensitivity of a biological sample, the scattering intensity should be greatly increased. Surface enhanced Raman scattering (SERS) spectroscopy, using silver nanoparticles, has shown promise in overcoming the low sensitivity problems inherent in Raman spectroscopy. Using the SERS technique, the detection sensitivity is enhanced up to 6 – 10 orders of magnitude over conventional Raman spectroscopy. As a result, the SERS technique provides a comparable sensitivity with fluorescence detection. In order to understand the enhancement mechanisms, it is instructive to refer to the following equation:

$$P = \alpha E \tag{1}$$

where P is the induced dipole moment, α is the molecular polarizability, and E is the incident electric field. The Raman scattering intensity (I) is proportional to the square of the induced dipole moment (P).

$$I = P^2 \tag{2}$$

Raman enhancement can take place by either increasing the electric field (E) experienced by the molecule (electromagnetic enhancement) or by changing the molecular polarizability of the adsorbate (chemical enhancement). The electromagnetic enhancement mechanism is explained by a phenomenon known as surface plasmon resonance. Surface plasmons are oscillations of conduction band electrons at a metal surface. At the surface



Biosensors Using Surface-Enhanced Raman Scattering, Figure 2 Schematic diagram of the experimental set-ups comprising a PDMS microfluidic channel and a microstage: (**a**) A schematic view of a 3D serpentine PDMS channel and four measurement spots along the channel distance: (a) at 0.15 mm, (b) at 28.5 mm, (c) at 68.4 mm, and (d) at 105.7 mm. (**b**) the optical arrangements for focusing the laser on the PDMS channel on the stage of confocal Raman microscope

plasmon resonance frequency, conduction band electrons move easily producing a large oscillation in the local electric field intensity. The surface plasmon frequency strongly depends on surface morphology (size and shape of particles), the dielectric properties of the metal, and the wavelength of the incident light. Electromagnetic effects are known to be decreased as a function of $1/r^3$ distance from the surface. Chemical enhancement involves the bond formation between the analyte and the metal surface. This bond makes it possible to transfer charge from the metal surface to the adsorbate molecule and this effect increases the molecular polarizability of the molecule. There have been many experimental evidences that both effects play a key role on the SERS effects. However, it is generally believed that electromagnetic enhancement may have a greater part to play than chemical enhancement. The main analytical advantages of SERS are enhanced sensitivity, surface specificity, and fluorescence noise reduction. Furthermore, it is possible to simultaneously detect multiplex analytes using SERS since its signals are much narrower than fluorescence bands.

However, the quantitative application of SERS is known to be very difficult because it is very hard to control the experimental conditions such as the degree of aggregation, the particle sizes of metal colloids, and the inhomogeneous distributions of molecules on the metal surface. As a result, under ordinary sampling conditions, the precision expected from a SERS experiment is very poor. On the other hand, a highly precise quantitative measurement can be obtained if continuous flow and homogeneous mixing conditions between analytes and silver nanoparticles are maintained. For this purpose, a functional microfluidic channel for the efficient mixing of analytes and aggregated silver colloids. Under the optimum conditions of using an an efficiently designed mixing channel and flow velocity, the quantitative SERS detection of analytes can be achieved under flowing conditions. This analytical method provides fast and reproducible results for the quantitative measurement of analytes at low detection levels. For example, the GC/MS or HPLC analysis requires longer than ten minutes for the sample pretreatments and measurements. On the other hand, only thirty seconds are needed when the SERS detection technique is applied. The SERS detection, in combination with microfluidic technology, can applied to the highly sensitive biological/environmental trace analyses.

Basic Methodology

Fabrication of an Alligator Teeth-Shaped PDMS Channel

Microfluidic channels are fabricated by stacking two PDMS layers that have upper and lower teeth patterns. These layers are produced by the pattern replication from mould masters. Two epoxy-based photoresist (EPON) mould masters, including upper and lower teeth patterns, were fabricated. By pouring the mixture of PDMS prepolymer and curing agent in a 10 : 1 ratio onto the lower mould master and by curing for 2 h on the hot plate at 80 °C, the patterned thick layer (thickness: 1.0 cm) with a lower pattern is constructed. The layer with upper teeth pattern is fabricated by the compression micro-moulding of PDMS elastomer. The PDMS pre-polymer is poured onto the mould master and compressed with transparent film and an aluminum disk. Then it is cured for 2 h. The thin upper layer (thickness: 200 μm) is produced by separating it from the mould master. For the bonding of upper and lower layers, the surfaces of both layers are activated in the oxygen plasma. Then it is aligned using the house-made aligner. Methanol is used as a surfactant between both layers. Finally, the cover glass is stacked onto the upper layer.

Preparation of Silver Nanocolloids

Silver colloids are prepared by the method, as is recently reported by Leopold and Lendl. Here silver nitrate is reduced by hydroxylamine hydrochloride. The advantages of the hydroxylamine hydrochloride-reduced silver colloid are in its fast preparation at room temperature and its immediate applicability for SERS. First, 5 mL of hydroxylamine hydrochloride (3.0×10^{-2} M) is dissolved in 84 mL of triply distilled water and then 1 mL of sodium hydroxide (1.7×10^{-3} M) is added to maintain an alkaline pH condition. Next, 10 mL of silver nitrate solution (1.0×10^{-3} M) is added dropwise to the solution with continuous stirring. The solution is continuously stirred for additional 20 min. UV/Vis spectroscopy and TEM were used to characterize the particle size of produced colloids. Figure 1 shows the TEM, AFM images and UV/Vis absorption and Raman spectra of SERS-active colloidal nanoparticles.

SERS Detection

SERS measurements are performed using a Raman microscope system. An argon ion laser operating at $\lambda = 514.5$ nm is generally used as the excitation source. The Rayleigh line is removed from the collected Raman scattering by a holographic notch filter located in the collection path. Raman scattering signal is detected using a charge-coupled device (CCD) camera or photomultiplier tube (PMT). In Raman microscope, an additional CCD camera is fitted to an optical microscope to obtain optical images. A two-slit confocal arrangement is used to reduce the background Raman scattering from the unfocused laser beams. Although the laser beam is focused on the middle of the micro channel, i. e., the section between the top and the bottom in the z direction, the Raman signal from a small volume of chemicals in the micro channel cannot be completely separated from the signals originating from the surrounding PDMS material. To resolve this problem, all the Raman spectra are measured in the confocal mode. In the Raman system, the function of the pinhole is replaced by the cooperation of the entrance slit and the pixels in the CCD detector. Using the confocal technique, the background stray light, due to any out-of-focus regions of the PDMS, is effectively removed. The silver colloids and biological analytes are introduced into the channel from microsyringes connected by tubes to the inlet pipettes. The flow rate is controlled by using a microsyringe pump. The confocal SERS is measured after the analytes are effectively adsorbed on the silver nanoparticles by traveling the upper and lower alligator teeth-shaped microfluidic channel. Confocal SERS microscopy can be used as a highly sensitive sensing technique for the detection of non-fluorescent biological samples in a PDMS microfluidic channel.

Key Research Findings

In situ Monitoring of Chemical Reaction Using Raman Microscopy

Laser-induced Raman microscopy can be used to monitor a chemical reaction in a microfluidic channel. In situ monitoring of imine formation reaction in a glass microfluidic chip was previously performed. In order to monitor the diffusion process in a microfluidic channel, the Raman spectra are measured at various points along the channel with a constant flow rate. Time-dependent Raman spectra are also measured without flow in order to monitor the variation of Raman peaks to a complete conversion. The disappearance of the $C=O$ stretching peak at 1700 cm^{-1} of the reactant, benzaldehyde, and the appearance of the Raman peak for the product, an imine, at

The molar ratio between Cy3-labeled SRY and TAMRA-labelled SPGY1 is (a) 1 : 3, (b) 1 : 2, (c) 1 : 1, (d) 2 : 1, and (e) 3 : 1, respectively. The flow velocity was 74.08 mm/sec. The insert shows the variation of peak area ratio (I_{1469}/I_{1650}) as a function of SRY/SPYG1 molar ratio

1628 cm^{-1} have been successfully monitored. In addition, the intensity increases of three phenyl-stretching modes in the 1550–1630 cm^{-1} region have also been observed. The increase of Raman intensity for this vibrational mode is caused by an effective π electron conjugation between two phenyl rings through the $-C=N-$ bridging group of the product. Laser-induced Raman microscopy enables us to monitor in situ product formation as well as to get detailed structural information in a microfluidic channel. Laser-induced Raman microscopy is considered as a very sensitive detection technique with a high spatial resolution for the in situ monitoring of organic reaction in a microfluidic channel system. Figure 1 shows in situ Raman monitoring of imine formation reaction in a microfluidic sensor and the optical arrangement for laser focusing on the microfluidic channel of the channel.

Analysis of Passive Mixing Behavior in a PDMS Microfluidic Channel Using Confocal Raman Microscopy

A rapid mixing of the fluids flowing through a microfluidic channel is very important for various applications of microfluidic systems, and a number of devices have been designed to enhance the mixing on the microscale. To use this channel as a microchemical reactor, it is very important to continuously monitor the chemical changes of reaction mixtures in the channel. Confocal Raman Microscopy (CRM) offers a promising route to achieve this goal, since it provides a direct measurement of the conversion process from reactant to product. The applicability of CRM for effective evaluation of the mixing efficiency in a recently developed 3D serpentine channel has been studied. Figure 2a shows a schematic view of a 3D serpentine PDMS channel and four measurement spots along the channel distance. Figure 2b shows the experimental set-up for the confocal Raman measurements on the confluent streams in the microfluidic channels. These two streams were introduced into the PDMS channel from micro syringes connected by tubes to the inlet pipettes. The flow rates were controlled simultaneously using a KD Science micro syringe pump. For the confocal Raman spectroscopic measurements, no fluorescence dye was used during the signal measurements. Figure 3 shows the changes of profiling Raman spectra along the channel distance in the 3D serpentine channel. Ethanol and isopropanol were used for the test of mixing process in the Raman spectroscopy. The results show that the fast mixing behavior of the confluent laminar streams in the 3D serpentine channel that are driven by chaotic advection can be successfully evaluated using the confocal Raman profiling technique.

Ultra-Sensitive Trace Analysis of Cyanide Ion Water Pollutant in a PDMS Microfluidic Channel Using SERS Microscopy

Cyanide ion is one of the most hazardous toxic pollutants in ground waters. It is mainly discharged from the industries such as gold mining, electroplating, printing, tex-

tiles and leather manufacturing. Thus, it is very important to develop a highly sensitive detection system for monitoring trace amounts of cyanide ion in ground waters. SERS spectroscopic technique for a rapid and sensitive trace analysis if cyanide ion water pollutant in an alligator-teeth shaped PDMS microfluidic channel. The confluent streams of silver colloids and trace analytes were effectively mixed in the channel through the triangular structures, which are located on the upper and lower surfaces of the channel in a zigzag manner. The flow rate was controlled using a microsyringe pump. In this work, an alligator teeth-shaped PDMS channel has been fabricated and the SERS detection method has been used to achieve highly sensitive analyte detection. SERS detection, in combination with Lab-on-a-Chip technology, has been applied to the trace analysis of cyanide ion water pollutant. Compared with other methods for the trace analysis of cyanide ions, the detection sensitivity was enhanced by several orders of magnitude. Figure 4 shows the adsorption process of cyanide ions on the silver nanoparticles in a PDMS microfluidic channel. The limit of detection (LOD) is determined to be in the 0.5 – 1.0 ppb range from three standard deviations above the backgrounds.

Quantitative Analysis of Methyl Parathion Pesticides Using Confocal SERS

A quantitative analysis of the methyl parathion pesticides is performed based on the measured SERS peak height at 1246 cm^{-1}. This method has a detection limit of 0.1 ppm. This value satisfies the requirement recommended by the Collaborative International Pesticides Analytical Council (CIPAC) for the determination of methyl parathion in pesticide formulations. This study demonstrates the feasibility of using confocal SERS for the highly sensitive detection of methyl parathion pesticides in a PDMS microfluidic channel. Raman peak, centered at 1246 cm^{-1}, is used as a quantitative evaluation of methyl parathion pesticides. A very good linear response is found in the concentration range 0.1 – 1 ppm. The limit of detection (LOD) is determined to be 0.1 ppm assessed from five standard deviations above background. Compared to other methods for the trace analysis of methyl parathion pesticides, the LOD is enhanced by several orders of magnitude. We expect this analytical technique can be successfully applied to highly sensitive bioanalysis as well as to other trace analysis.

Quantitative Analysis of Duplex Dye-labelled DNA Oligonucleotides in a PDMS Microfluidic Sensor Using Confocal SERS

Rapid and highly sensitive detection of duplex dye-labelled DNA sequences in a PDMS microfluidic channel is investigated using confocal SERS microscopy. This method does not need either an immobilization procedure or a PCR amplification procedure, which are essential for a DNA microarray chip. Furthermore, Raman peaks of each dye-labelled DNA can be easily resolved since they are much narrower than the corresponding broad fluorescence bands. To find the potential applicability of confocal SERS for sensitive bio-detection in a microfluidic channel, the mixture of two different dye-labelled (TAMRA and Cy3) sex determining Y genes, SRY and SPGY1, is adsorbed on silver colloids in the alligator-teeth shaped PDMS microfluidic channel and its SERS signals are measured under flowing conditions. Its major SERS peaks were observable down to the concentration of 10^{-11} M. In the present study, we explore the feasibility of confocal SERS for the highly sensitive detection of duplex dye-labelled DNA oligonucleotides in a PDMS microfluidic channel. Figure 5a shows the confocal SERS spectra of 1 : 1 DNA oligomer mixture adsorbed on colloidal silver at the constant flow velocity. According to our spectral data, the LOD of duplex oligomer mixture is estimated to be 10^{-11} M. Figure 5b also illustrates the confocal SERS spectra for different molar ratios of two oligonucleotides in a microfluidic channel. Different amounts of Cy3-labeled SRY (from 1.65×10^{-10} to 1.5×10^{-9} M) are added to the constant concentration of TAMRA-labelled SPGY1 (5.0×10^{-10} M) to control the molar ratio between SRY and SPGY1 to be 1 : 3, 1 : 2, 1 : 1, 2 : 1, and 3 : 1, respectively. The TAMRA peak at 1650 cm^{-1} is used as an internal standard and the variations of Cy-3 Raman peaks at 1588, 1469 and 1393 cm^{-1} are monitored for their different molar ratios. The intensities of those Raman peaks increase concomitantly with the increase in the concentration of Cy3-labeled SRY. In particular, the Raman peak at 1469 cm^{-1} can be used for the quantitative evaluation of SRY since it does not overlap with any Raman peaks of SPGY1. The insert in Fig. 5b shows the linear response of peak area ratio (I_{1469}/I_{1560}) with the changes in the molar ratio of duplex DNA oligonucleotides. This means that the highly sensitive quantitative detection of duplex DNA oligonucleotide mixtures in a microfluidic channel is possible using the confocal SERS microscopic technique.

Future Directions for Research

In order to apply the SERS sensor to biological analysis, the problem for high throughput screening (HTS) should be solved. In the case of DNA microarray, the throughput is around 16 h for 1 mill oligonucleotide hybridizations. There are two possible ways to apply the microfluidic system to a high-throughput screening (HTS) of biological analysis. First, a multi-parallelization microfluidic channel

can be used for this purpose. Second, a biological assay can be performed in series by rapidly injecting the sample solutions one after the other. In this case, several thousand assays are possible within a period of a few hours if the injection time is less than 1 s.

Biotransducer

Definition

The biotransducer is the functional heart of a biosensor system. The biotransducer comprises the molecular biospecificity of the biorecognition membrane layer and the signal generating capability of the physicochemical transducer. The reproducible, intimate linking of these two parts across an interface is a key distinguishing quality of biotransducers.

Bipolar Membrane

Definition

An ion-exchange membrane that consists of a layered ion structure. This typically consists of a cation exchange layer and an anion exchange layer. The use of a bipolar membrane enables many functionalities to be used such as antifouling, water dissociation, and the separation of ions. Bipolar membranes are typically unstable in high current environments.

Bistability

Definition

Capability to remain, without an external control action, in either one of two different stable states.

Bistability is a useful property in diverter valves with two outlets when operating in two alternative regimes, the supplied fluid leaving in each regime mainly through one of them. If the microfluidic valve operates at Reynolds numbers – related to the conditions in the inlet – higher than ~ 1000, the bistability may be obtained without use of any movable components in the valve, using the Coanda effect of alternative attachment of a fluid jet to one of two mutually opposed attachment walls. The bistable valves may be

a very useful part of sampling units used in microfluidic systems for combinatorial chemistry testing.

Boiling and Evaporation in Microchannels

Satish G. Kandlikar
Rochester Institute of Technology, Rochester, NY, USA
sgkeme@rit.edu

Synonyms

Flow boiling in microchannels; Flow boiling in narrow channels

Definition

Flow boiling in a microchannel refers to the boiling of a liquid, caused by the addition of heat through the channel walls, as it flows through a microchannel resulting in a net vapor generation at the exit.

Overview

► Microchannels are defined on the basis of the following definition by Kandlikar and Grande [1]:

Conventional channels:	$D > 3$ mm
Minichannels:	$3\text{ mm} \geqslant D > 200\,\mu\text{m}$
Microchannels:	$200\,\mu\text{m} \geqslant D > 10\,\mu\text{m}$
Transitional channels:	$10\,\mu\text{m} \geqslant D > 0.1\,\mu\text{m}$
Transitional microchannels:	$10\,\mu\text{m} \geqslant D > 1\,\mu\text{m}$
Transitional nanochannels:	$1\,\mu\text{m} \geqslant D > 0.1\,\mu\text{m}$
Nanochannels:	$0.1\,\mu\text{m} \geqslant D$

where D is the minimum channel dimension. This article deals with the change of phase of a liquid due to heat transfer from the channels walls while it flows through a microchannel.

The boiling process refers to nucleation of vapor bubbles and their growth resulting from heat transfer from a heated wall. Evaporation refers to change of phase from liquid to vapor at the liquid–vapor interface. Boiling is further classified as pool boiling, which refers to boiling in a pool of liquid, and flow boiling, which refers to boiling with an impressed flow.

Flow boiling in microchannels is essentially similar to the flow boiling process in ► conventional sized channels. Some differences are noted due to the effect of small channel dimensions on the flow boiling process resulting in a large surface area to flow volume ratio [2]. The surface tension forces become important at these scales as compared to the gravitational forces. This makes the boiling process in microchannels less dependent on gravity and orientation. Flow boiling in microchannels is therefore seen as a desirable heat transfer mode in ► microgravity environments.

Applications of microchannel boiling process using low-pressure water [3] or a dielectric hold great promise for chip cooling applications. The high heat transfer coefficients coupled with large heat-carrying capacity due to latent heat removal present an attractive cooling option.

The smaller channel dimensions also shift the flow towards lower Reynolds number. In general, there is a lack of available experimental data for heat transfer in microchannels and a need exists to generate new experimental data to cover the overall shift in the Reynolds numbers, heat flux and mass flux in practical applications.

Basic Methodology

Flow boiling in microchannels is currently at the research stage. The experimental methods employed are evolving as temperature and pressure measurements in the microchannels require deployment of sensors that are microfabricated. For this reason, silicon microchannels with embedded pressure and temperature sensors are being pursued. This is an area where further research is needed to establish the measurement techniques. Metal and ceramic heat exchanger devices are also being fabricated using advanced micromachining and chemical/laser etching and machining processes.

Key Research Findings

Heat Transfer During Flow Boiling in Microchannels

A limited number of experimental studies are available on flow boiling in microchannels using copper and silicon as the substrate over a limited range of heat and mass fluxes for a few fluids (water being the most widely used working fluid), e. g. Pokharna et al. [3], Lee and Mudawar [4], Kosar et al.[5], Hetsroni, et al.[6]. Early studies indicated that the heat transfer at lower mass flux and lower quality conditions is dominated by the nucleate boiling process as in the case of pool boiling. As more data become available, it is seen that the heat transfer exhibits the nucleate boiling dominant mode under low mass flux, low quality conditions, while it appears to be dependent on mass flux and independent of heat flux at higher mass fluxes and higher qualities, as in the case of the convective boiling dominant mode. However, the experimental data are seen to have a larger uncertainty band as compared to the flow boiling data in conventional sized channels due to difficulties in measuring local temperature, pressure and channel dimensions accurately. As the instrumentation, measuring techniques and experimental procedures are refined, more reliable data are expected to become available in the coming years. Further information on the research needs in this area is given by Kandlikar [2].

Heat Transfer Correlations for Flow Boiling in Minichannels and Microchannels

The flow boiling process in microchannels and minichannels has been studied over a limited range of heat and mass fluxes (mostly at the lower ends of their respective ranges employed in macroscale channels). In this range, some authors have found pool boiling type correlations to work well, while others have found the influence of convective effects. The following correlation is an extension of the Kandlikar correlation for large-diameter tubes that is derived from the low mass flux data available in the literature. In the higher mass flux regions, corresponding to the higher all-liquid Reynolds number, the correlation is expected to follow the trends in larger diameter tubes. The overall correlations for microchannels in different regions are given below [7].

Terminology

h_{TP} – two-phase heat transfer coefficient, x – quality, q – heat flux, G – mass flux, h_{LV} – latent heat of vaporization, ρ – density, k – thermal conductivity, D_h – hydraulic diameter, and $\mathrm{Co} = [(1-x)/x]^{0.8}[\rho_V/\rho_L]^{0.5}$, $\mathrm{Bo} = q''/(Gh_{LV})$, $\mathrm{Re}_{LO} = G(1-x)D_h/\mu_L$, $\mathrm{Fr}_{LO} = G^2/(\rho_L^2 g D_h)$ and $\mathrm{Nu}_{LO} = (h_{LO}D_h/k)$. Subscripts CBD and NBD refer to nucleate boiling dominant and convective boiling dominant regions respectively, and L and V refer to liquid and vapor, respectively.

For flow boiling in microchannels and minichannels, heat transfer correlations in the NBD and CBD regions are given below:

$$h_{TP,NBD} = 0.6683\,\mathrm{Co}^{-0.2}(1-x)^{0.8} f_2(\mathrm{Fr}_{LO})\,h_{LO} + 1058\,\mathrm{Bo}^{0.7}(1-x)^{0.8}\,h_{LO}F_{FL} \quad (1)$$

$$h_{TP,CBD} = 1.136\,\mathrm{Co}^{-0.9}(1-x)^{0.8} f_2(\mathrm{Fr}_{LO})\,h_{LO} + 667.2\,\mathrm{Bo}^{0.7}(1-x)^{0.8} h_{LO}F_{FL} \quad (2)$$

The flow boiling heat transfer coefficient h_{TP} is then related to $h_{TP,NBD}$ and $h_{TP,CBD}$ depending on the flow regions under all-liquid flow conditions as described below.

Region I

Turbulent flow region: $\mathrm{Re}_{LO} \geqslant 3000$

$$h_{TP} = \text{larger of } \left(h_{TP,NBD}, h_{TP,CBD}\right) \quad (3)$$

h_{LO} is given by:

For $10^4 \leqslant \mathrm{Re}_{LO} \leqslant 5\times10^6$, Petukhov and Popov correlation:

$$h_{LO} = \frac{\mathrm{Re}_{LO}\,\mathrm{Pr}_L(f/2)(k_L/D)}{1+12.7\left(\mathrm{Pr}_L^{2/3}-1\right)(f/2)^{0.5}} \quad (4)$$

For $3000 \leqslant \mathrm{Re_{LO}} < 10^4$, Gnielinski correlation:

$$h_{\mathrm{LO}} = \frac{(\mathrm{Re_{LO}} - 1000)\,\mathrm{Pr_L}(f/2)(k_\mathrm{L}/D)}{1 + 12.7\left(\mathrm{Pr_L^{2/3}} - 1\right)(f/2)^{0.5}} \qquad (5)$$

The friction factor f in the above equations is given by

$$f = \left[1.58\ln(\mathrm{Re_{LO}}) - 3.28\right]^{-2} \qquad (6)$$

Region II

Transition region: $1600 \leqslant \mathrm{Re_{LO}} < 3000$

$$h_{\mathrm{TP}} = \text{larger of } (h_{\mathrm{TP,NBD}}, h_{\mathrm{TP,CBD}}) \qquad (7)$$

With h_{LO} taken from linear interpolation between the turbulent value using the Gnielinski correlation (given under Region I above) and the appropriate laminar value (for $q'' = C$ or $T = C$) using $h_{\mathrm{LO}} = (\mathrm{Nu_{LO}}k/D_\mathrm{h})$.

Region III

Laminar flow region: $100 \leqslant \mathrm{Re_{LO}} < 1600$

$$h_{\mathrm{TP}} = \text{larger of } (h_{\mathrm{TP,NBD}}, h_{\mathrm{TP,CBD}}) \qquad (8)$$

With h_{LO} taken from the appropriate laminar value (for $q'' = C$ or $T = C$) using $h_{\mathrm{LO}} = (\mathrm{Nu_{LO}}k/D_\mathrm{h})$.

Region IV

Deep laminar flow region: $\mathrm{Re_{LO}} < 100$

$$h_{\mathrm{TP}} = h_{\mathrm{TP,NBD}} \qquad (9)$$

Fluid-Surface Parameter, F_{FL}

The fluid surface parameters in Eqs. (1) and (2) are given in Table 1, with h_{LO} taken from the appropriate laminar value (for $q'' = C$ or $T = C$) using $h_{\mathrm{LO}} = (\mathrm{Nu_{LO}}k/D_\mathrm{h})$.

Boiling and Evaporation in Microchannels, Table 1 Values of F_{Fl} (fluid-surface parameter) in the flow boiling correlations (Eqs. (1) and (2))

Fluid	F_{Fl}
Water	1.00
R-11	1.30
R-12	1.50
R-13B1	1.31
R-22	2.20
R-113	1.30
R-114	1.24
R-134a	1.63
R-152a	1.10
R-32/R-132	3.30
R-141b	1.80
R-124	1.00
Kerosene	0.488

Critical Heat Flux

During the flow boiling process, the walls of the channel are generally covered with liquid or a liquid film, occasionally exposing the walls to the vapor phase followed by rewetting with the liquid. At certain conditions, the liquid fails to rewet the walls leading to the condition of *dryout*. Since the vapor is unable to cool the wall as effectively as a liquid-covered wall, the local wall temperature may rise uncontrollably with further addition of heat.

The heat flux at this condition is referred to as the ►critical heat flux, or ►CHF. It depends on the flow conditions, channel geometry, local quality, fluid properties, channel material and flow history. Bergles and Kandlikar [8] discuss the CHF in microchannels from a systems perspective. It is important to establish CHF condition as a function of the mass flux and quality for a given system to ensure its safe operation. Qu and Mudawar [9] presented CHF data with water in 21 parallel minichannels of $215\,\mu\mathrm{m} \times 821\,\mu\mathrm{m}$ cross-section over a range of $G = 86 - 268\,\mathrm{kg/(m^2 s)}$ and $q'' = 264 - 542\,\mathrm{kW/m^2}$, $x = 0.0 - 0.56$, and $P_{\mathrm{in}} = 121.3 - 139.8\,\mathrm{kPa}$. Kosar et al. [5] present low-pressure water data in microchannels enhanced with reentrant cavities. Also, the correlation by Katto [10] developed for large channels may be applied for approximate CHF estimation in the absence of an established CHF correlation for microchannels.

Future Directions for Research

Flow boiling in microchannels is currently in the research phase. Its applications include high heat flux removal in advanced computer chips and high-power electronics and electrical systems, pulsed power weapons systems, solid-state lasers and phased-array radars and sensor arrays. Microchannel heat exchangers for phase change applications offer the advantages of very compact design with large volumetric energy transfer densities. It is especially suited for the future 3D computer chip architecture by incorporating the microchannels in multiple parallel configurations. Other cooling arrangements which rely on the surface cooling techniques, such as spray or jet cooling, may not be suitable to the 3D configuration. Hot spot cooling and integration with the device architecture is also a possible application.

Another area that is expected to benefit by incorporation of microchannels is the refrigeration industry where

the potential benefits resulting from material and space savings will be quite significant. The high heat transfer coefficients and compact design makes flow boiling in microchannels very attractive in air liquefaction and cryogenic industries as well. It is expected that significant innovations and new developments will occur in this field in the near future.

One of the challenges faced in microchannel flow boiling systems is the limit posed by the critical heat flux (CHF). Establishing the CHF limits of the plain microchannels and developing new enhanced geometries with higher CHF limits is a priority that needs to be addressed in the future before widespread application of microchannel flow boiling systems can be considered.

Boundary element method; Boundary integral approaches

Definition

The boundary element method is a numerical method for solving integral equations. These integral equations are the integral representations of the governing equations of the underlying physical problems, often formulated based on the fundamental solutions of the problems.

Overview

The boundary element method (BEM) has been established as a powerful numerical method for solving engineering problems. Applications include, but are not limit to, electromagnetics, elasticity, acoustics, potential and viscous flow. In contrast to other numerical techniques, the governing equations are cast into a set of integral equations that are solved by collocation or Galerkin discretization. A detailed description of this method can be found in [1]. One major advantage of the BEM is that it reduces the dimensionality of the problem by one. Thus for the majority of practical cases the simple boundary discretization leads to a much smaller system of algebraic equations than any domain method. Another advantage of the BEM is that it can handle rapid transitions and steep gradients of fields since the formulation only involves unknowns on surfaces. Given the reduced complexity of data preprocessing (meshing) and smaller size of the resulting systems, the BEM is an efficient method for solving many engineering problems, especially for exterior problems and problems with free surfaces or moving boundaries.

One disadvantage of the conventional BEM is that it generates a fully populated system matrix. Also, the computation of matrix entries involves singular and nearly singular surface integrals, which are difficult to compute. This offsets some of the computer time saved by the much reduced matrix size. The recently developed accelerated BEM approaches have overcome this difficulty by combining matrix sparsification techniques, such as the fast multipole method (FMM) [2] and the precorrected-FFT technique [3], with iterative solvers. A central idea in acceleration techniques is to approximate the matrix-vector product by some computationally efficient means. In the FMM, multipole and local expansion is used to calculate the long-range interactions. In the precorrected-FFT method, a uniform grid is used to represent the long-range interactions. This grid representation allows the fast Fourier transform to be used to efficiently perform the computation. With these accelerated techniques, the BEM has emerged as one of the most efficient numerical methods for large-scale problems particularly those with complex 3D geometry. Fast BEM codes have been developed and applied successfully in a variety of applications including the modeling of complex MEMS devices, for example, the prediction of air damping in micro-resonators [4].

Basic Methodology

Boundary Integral Formulation

The BEM starts with an integral formulation of the governing equation. As an illustration, consider the potential problem governed by the Laplace equation:

$$\nabla^2 u = 0 \tag{1}$$

An integral formulation of the Laplace equation reads

$$c(\boldsymbol{x})u(\boldsymbol{x}) = -\int_{\partial\Omega} G(\boldsymbol{x},\boldsymbol{y})\frac{\partial u(\boldsymbol{y})}{\partial n(\boldsymbol{y})}\,\mathrm{d}S(\boldsymbol{y}) + \int_{\partial\Omega} \frac{\partial G(\boldsymbol{x},\boldsymbol{y})}{\partial n(\boldsymbol{y})}u(\boldsymbol{y})\,\mathrm{d}S(\boldsymbol{y}) \tag{2}$$

where

$$c(\boldsymbol{x}) = \begin{cases} 1, \boldsymbol{x} \in \Omega \\ 0, \boldsymbol{x} \notin (\Omega \cup \partial\Omega) \\ \alpha, \boldsymbol{x} \in \partial\Omega \end{cases}$$

In Eq. (2), Ω is the domain of the problem with boundary $\partial\Omega$, $n(\boldsymbol{y})$ is the outward normal vector at the field point $\boldsymbol{y}$, $\boldsymbol{x}$ is the evaluation point and α is the solid angle at $\boldsymbol{x}$ (it equals $1/2$ when $\boldsymbol{x}$ is a smooth surface point). $G(\boldsymbol{x},\boldsymbol{y})$ is the Green's function of the Laplace operator which, in a 3D space, is given by

$$G(\boldsymbol{x},\boldsymbol{y}) = \frac{1}{4\pi r}\,,\ \text{where } r = |\boldsymbol{x}-\boldsymbol{y}|\ .$$

Note that all integrals in Eq. (2) are boundary integrals, i. e., they involve only the boundary values of the dependent variable and its derivatives. As such, this integral

equation can be employed to obtain the unknown boundary quantities based on the given boundary conditions. For example, for Dirichlet problems, the unknown boundary values are the normal derivatives of the potential, which can be calculated by solving Eq. (2) with evaluation points being on the boundary. Once all the boundary quantities are obtained, the potential at any point inside the domain is calculated again using Eq. (2) but with $c(\boldsymbol{x}) = 1$.

Discretization

To numerically solve Eq. (2), one can employ either the Galerkin scheme or the collocation scheme. In the Galerkin scheme, Eq. (2) is satisfies in a weighted integral sense while in the collocation scheme, the integral equation is satisfied at the chosen collocation points. For simplicity, the collocation scheme is used to illustrate the numerical implementation of the BEM.

First, the boundary of the problem domain is discretized into a collection of elements. On each element, quantities are assumed to be simple functions, often polynomials, which are fully determined by their nodal values. For example, a constant element has only one node located at its centroid. Over this element, quantities are assumed to be constant determined by their values at the centroid. For a general case at the i-th element

$$u = \sum_{j=1}^{p} N_j u_j^{(i)} \tag{3}$$

$$q = \frac{\partial u}{\partial n} = \sum_{j=1}^{p} N_j q_j^{(i)} \tag{4}$$

where N_j is the interpolation function, p is the number of nodes of this element and $u_j^{(i)}$ and $q_j^{(i)}$ are the nodal values at the j-th node of the i-th element. Substituting Eqs. (3) and (4) into the integral formulation (2) and enforcing Eq. (2) is satisfied at each node, a set of discretized equations in the form of Eq. (5) can be obtained:

$$\begin{aligned} c(\boldsymbol{x}_k)u(\boldsymbol{x}_k) = &-\sum_{i=1}^{n}\int_{\Gamma_i} G(\boldsymbol{x}_k,\boldsymbol{y})\sum_{j=1}^{p} N_j(\boldsymbol{y})q_j^{(i)}\,\mathrm{d}S(\boldsymbol{y}) \\ &+\sum_{i=1}^{n}\int_{\Gamma_i}\frac{\partial G(\boldsymbol{x}_k,\boldsymbol{y})}{\partial n(\boldsymbol{y})}\sum_{j=1}^{p} N_j(\boldsymbol{y})u_j^{(i)}\,\mathrm{d}S(\boldsymbol{y}), \\ k = 1, 2, \cdots m \end{aligned} \tag{5}$$

In Eq. (5), n is the number of elements, Γ_i denotes the i-th element and m is the total number of nodes. This set of equations can be rearranged into a matrix form:

$$[\mathbf{G}]\{\boldsymbol{q}\} - [\mathbf{H}]\{\boldsymbol{u}\} = \mathbf{0} \tag{6}$$

where $\mathbf{G}$, $\mathbf{H}$ are matrices with entries being the element-wise integrals of the product of the kernel function (G and $\partial G/\partial n$) and the interpolation functions, and $\boldsymbol{u}$ and $\boldsymbol{q}$ are vectors comprised of nodal values of the potential and its normal derivative respectively. Equation (6) is a linear system that can be solved to obtain the unknown boundary values at each node. These values together with the given boundary conditions can be substituted into Eq. (2) to obtain potentials at interior points.

Key Research Findings

Air Damping of Laterally Oscillating Micro-Resonators

Air-packaged micro-resonators are widely used in a variety of low-frequency applications such as accelerometers, gyroscopes and sensors. In many of these applications, the quality factor of the resonator, defined as the ratio of total energy to energy dissipated per cycle, is a key performance variable but is very difficult to predict. The problem is that the dominant loss mechanism for many air-packaged resonators is viscous drag, and to predict drag it is necessary to accurately determine the detailed air flow in these typically very complicated three-dimensional resonators.

A number of approximate analytic models for drag have been developed, typically based on one-dimensional Couette or Stokes flow [5]. Such models give a good rough estimate of the drag force but they can be insufficiently accurate to correctly predict geometrical sensitivities. In particular, these one-dimensional models do not account for important finite size and edge effects. To account for these effects accurately, a detailed 3D analysis of air flow surrounding the resonators is necessary. This leads to a problem with a domain which is bounded by the complex resonator at one end and extends to infinity at the other end. For such a problem, domain methods such as the finite element method and the finite volume method, etc., could be very inefficient and are not suitable. The accelerated BEM, on the other hand, is a perfect method for handling this problem.

Micro-Resonator

The comb drive micro-resonator used for this study is shown in top and side view in Fig. 1. The main components of the resonator are a shuttle structure comprised of the connected back-to-back combs, two suspended folder beams with one end anchored to the substrate, and fixed

comb drives. Table 1 lists some key dimensions of the resonator.

The shuttle structure can be moved to the left or right using electrostatic forces generated by creating a potential difference between the shuttle and either the left or the right fixed combs (shown in dark blue in Fig. 1). Once the shuttle moves away, the folded beams, acting as springs, bring it back to its equilibrium position. This results in an oscillating motion.

Macro Model

Based on its operation principle, the resonator can be modeled as a simple spring–mass–dashpot system, as shown in Fig. 2, with the shuttle being the proof mass, folder beams being the spring and the surrounding air being the dashport damper. The displacement of the proof mass can then be obtained by solving the second-order differential equation

$$m_{\text{eff}}\ddot{x} + c\dot{x} + kx = F_{\text{applied}} \tag{7}$$

where x is the mass displacement measured from the equilibrium position, m_{eff} is the effective mass, c is the damping coefficient, k is the stiffness of the spring and F_{applied} is the externally applied electrostatic force.

The frequency and the quality factor of the resonator are related to the parameters as

$$f_0 = \frac{1}{2\pi}\sqrt{\frac{k}{m_{\text{eff}}}} \tag{8}$$

and

$$Q = \frac{\sqrt{km_{eff}}}{c} \tag{9}$$

The effective mass for the micro-resonator is easily determined from the geometry, given fabrication process information and the density of the structure material which is polysilicon in this case. Uncertainties in polysilicon's elastic material properties and manufacturing-induced residual stress make it difficult to predict the spring constant, though the measured resonant frequency data can be

combined with the computed effective mass to determine a spring constant. What has been most difficult to determine from geometry and process information is the loss in an air-packaged micromachined device, or equivalently the dashpot constant for the spring–mass–dashpot model. The difficulty is that loss in air-packaged microresonators is primarily due to viscous drag, which in turn depends on a very complicated air flow pattern. These issues will be considered in more detail in subsequent sections, with particular emphasis given to the issue of loss prediction.

Determination of Parameters

The effective mass for a spring–mass–dashpot model of the resonator is related to geometry and the density of the polysilicon. In particular, energy considerations and an application of beam theory lead to a resonator effective mass given by

$$m_{\text{eff}} = m_{\text{p}} + m_{\text{f}} + \frac{12}{35} m_{\text{b}} + \frac{1}{4} m_{\text{t}} \qquad (10)$$

where m_{p}, m_{f} are the masses of the shuttle and the moving fingers respectively, m_{b} is the mass of the beams and m_{t} is the mass of the connecting truss. With the dimensions shown in Table 1 and the density of $\rho = 2300\,\text{kg/m}^3$ for polysilicon, the effective mass of the system is 5.61×10^{-11} kg.

A simple approach to computing the spring constant for the resonator is to assume that the trusses joining the folded beam segments (shown in light blue in Fig. 2) are rigid. If there is no residual stress, beam theory predicts a spring constant of

$$k = 4Eh \left(\frac{w}{L}\right)^3 \qquad (11)$$

where E is the Young's modulus of polysilicon, and h, w and L are the thickness, the width and the length of the beam respectively. If E is chosen to be 150 GPa, the calculated stiffness of the beam in our resonator is $0.454\,\text{N/m}$. This value, together with the effective mass, would predict a natural resonant frequency of 14,321 Hz which is far from the measured value of 19,200 Hz. This indicates that either the stiffness or the mass was predicted wrong. Because stiffness is more sensitive to measurement error than mass (mass is linearly proportional to the beam width, but stiffness is proportional to the cube of width) and it also depends on residual stress and Young's modulus of polysilicon that are difficult to predict, it is reasonable to assume that mass is more accurate than the prediction of the stiffness. In addition, since the focus is on the issue of modeling damping, the semi-empirically determined value of $0.816\,\text{N/m}$, obtained from Eq. (8) using the effective mass from Eq. (10) and the measured resonant frequency, was used as the stiffness in this work.

The damping coefficient, c, caused by the drag force exerted on the resonator by the air, can only be determined if the air flow velocities are known. This requires the modeling of the fluid field surrounding the resonator. In the following section several of the flow models that have been used to compute resonator drag are discussed.

Flow Models

The frequency of operation is so slow that the open air surrounding the resonator can be regarded as an incompressible fluid. In addition, the characteristic length (micrometers) and oscillation amplitude (35 nm) are both small, resulting in a small Reynolds number (8×10^{-5}, $\text{Re} = \rho UL/\mu$, where ρ and μ are the density and viscosity of the fluid, U is a characteristic velocity and L is a characteristic length, 2 μm in the resonator under study), so the nonlinear inertial force will be negligible compared to the viscous force. Finally, rarefaction effects are unlikely to be significant, as the Knudsen number (Kn) for this resonator is small (0.03, $\text{Kn} = \lambda/L$; λ is the mean free path of the gas molecules, 0.065 μm). Thus, the fluid behavior is expected to be accurately described by solutions of the incompressible Stokes equations with no-slip boundary conditions.

For the oscillating resonator, the velocity is in sinusoidal steady state and therefore the velocity $\boldsymbol{u}$ and the pressure P of the fluid satisfy the frequency domain Stokes equation. The Stokes equation consists of the continuity equation and the linear momentum equation

$$\mathrm{i}2\pi f \rho \boldsymbol{u}(f) = -\nabla P(f) + \mu \nabla^2 \boldsymbol{u}(f) \qquad (12)$$

$$\nabla \cdot \boldsymbol{u}(f) = 0 \qquad (13)$$

where $\boldsymbol{u}(f)$ and $P(f)$ are complex amplitudes. For notational convenience, in the following the dependence on frequency will be assumed, and not stated explicitly. Note that in the case of steady flow, the only frequency-dependent term, the inertial term on the left side of Eq. (8), is zero.

To solve Eqs. (12) and (13) with oscillating velocity boundary conditions, simple models such as the Couette flow model and 1D Stokes model have been used. These models ignore the finite size and edge effects, as both of them model the device as two infinitely large parallel plates with one (the proof mass) oscillating on the top of the other (substrate). The Couette model further assumes a steady flow, resulting in a linear velocity profile between the plates. As shown later, the quality factor obtained by these two models is over-predicted by a factor of two, indicating the importance of 3D effects.

To account properly for all the edge and finite size effects and possible pressure gradients created by the motion of plates, a full 3D analysis is required. With the infinite domain and rather complicated resonator geometry, the BEM accelerated with the precorrected-FFT technique is chosen to numerically solve the 3D Stokes problem. To do so, an integral formulation must be introduced first:

$$u_j(\boldsymbol{x}) = -\frac{1}{8\pi\mu}\int_{\partial\Omega} G_{ij}(\boldsymbol{x},\boldsymbol{y}) f_j(\boldsymbol{y})\,\mathrm{d}S(\boldsymbol{y}) \tag{14}$$

where $\partial\Omega$ is the surface of the resonator, and the Greens function is given by

$$G_{ij}(\boldsymbol{x},\boldsymbol{y}) = \frac{\delta_{ij}}{r}A(R) + \frac{\hat{x}_i\hat{x}_j}{r^3}B(R) \tag{15}$$

$$A(R) = 2\,\mathrm{e}^{-R}\left(1+\frac{1}{R}+\frac{1}{R^2}\right) - \frac{2}{R^2}$$

$$B(R) = -2\,\mathrm{e}^{-R}\left(1+\frac{3}{R}+\frac{3}{R^2}\right) + \frac{6}{R^2}$$

$$R = \lambda r\,.$$

In Eq. (14), $u_j(\boldsymbol{x})$ is the j-th component of the velocity vector at the evaluation point $\boldsymbol{x}$, $\boldsymbol{f}$ is the Stokeslet density function, and the real part of $\boldsymbol{f}$ corresponds to the real part of the surface traction if there is a single moving object that rigidly moves in the fluid, $\hat{x}_i$ is the i-th component of the relative position vector between the evaluation point and the field point, i.e., $\hat{x}_i = y_i - x_i$, and λ is the frequency parameter which is defined as

$$\lambda^2 = i\frac{2\pi f\rho}{\mu}$$

Numerical Solution of 3D Stokes Model

The surface of the resonator is discretized into n small elements. A collocation scheme and constant elements were employed. A system of equations for the unknowns is derived by insisting that the integral Eq. (4) is satisfied exactly at each element centroid. The result is a linear system which relates the known quantities (velocity $\boldsymbol{u}$) to the unknown quantities (traction force $\boldsymbol{f}$), as in

$$\begin{Bmatrix} \boldsymbol{u}^1 \\ \boldsymbol{u}^2 \\ \vdots \\ \boldsymbol{u}^n \end{Bmatrix} = P(\omega) \begin{Bmatrix} \boldsymbol{f}^1 \\ \boldsymbol{f}^2 \\ \vdots \\ \boldsymbol{f}^n \end{Bmatrix} \tag{16}$$

where $\boldsymbol{u}^i$ and $\boldsymbol{f}^i$ are the velocity and traction force for the i-th element, and P is a $3n \times 3n$ dense matrix whose elements are given by

$$P^{ij}_{kl} = \int_{\Gamma_j}\left[\frac{\delta_{kl}A(R)}{r} + \frac{(x^i_k - y_k)(x^i_l - y_l)B(R)}{r^3}\right]\mathrm{d}s$$

$$k,l = 1,2,3\,. \tag{17}$$

Here, $\boldsymbol{x}^i$ denotes the centroid of the i-th element and Γ_j denotes the surface of the j-th element.

The dense linear system in Eq. (16), without any sparsification, could be very expensive to solve for large-scale systems. The computational time of a direct solver, for example, the Gaussian elimination, grows as the cube of the number of unknowns. For the resonator example, there are near 60,000 unknowns in the discretization shown in Fig. 3. Gaussian elimination would require more than 300,000 gigaflops to solve. In addition, the memory required to store the matrix grows as the square of the number of unknowns, and for the resonator example it would require more than 40 gigabytes.

Even with an iterative method which does not use the entries of the matrix P explicitly, but only requires matrix-vector products, the cost of computing dense matrix-vector products grows with the square of the number of unknowns. So just using an iterative method still results in a computationally expensive algorithm. However, there are a number of techniques for quickly computing approximate matrix-vector products for matrices associated with discretized integral equations.

The FastStokes program [6, 7] was used to compute the drag forces on the micro-resonator shown schematically in Fig. 2. FastStokes combines the iterative method GMRES [8] with the precorrected-FFT [3] technique for computing fast matrix-vector products. The discretized, or meshed, structure is shown in Fig. 3. Note that both the

FastStokes	510.72	294.50	142.80

polysilicon structures and the substrate are discretized, for a total of 20,148 panels.

The viscous drag forces on the resonator oscillating at $f = 19{,}200$ Hz were computed using progressively finer discretizations, to ensure that the discretization error was sufficiently small. Figure 4 is a plot of how the drag force converges with discretization refinement. As is clear from the plot, the results have converged to within 1% with as few as 10,000 panels. For these simulations, the kinematic viscosity and the density of air were assumed to be $0.157\ \text{cm}^2/\text{s}$ and $1.177\ \text{kg/m}^3$ respectively.

Table 2 shows the distribution of drag forces obtained from FastStokes (with a total of 36,700 panels) together with results obtained from the Couette model and the 1D Stokes model.

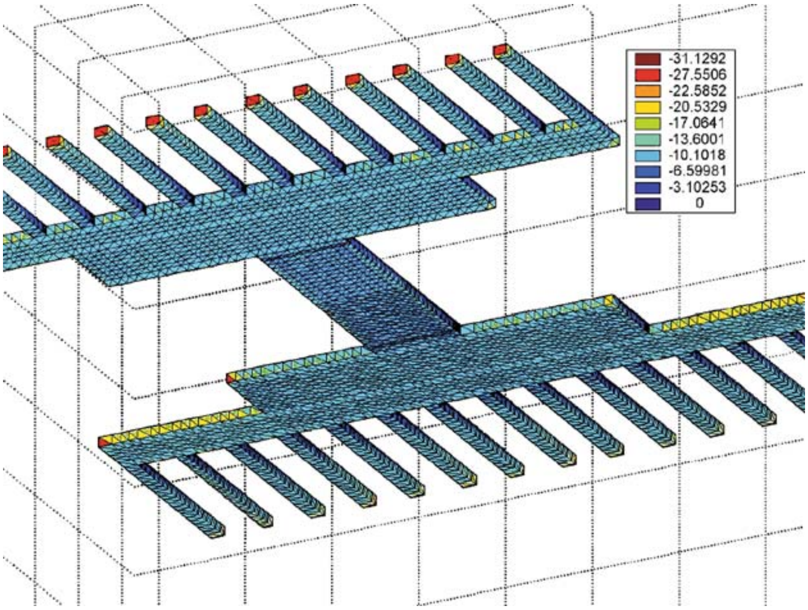
The contribution to the drag from the fluid between the resonator and the substrate (denoted as the bottom force) is predicted reasonably well by two simple 1D models. It is not surprising that the two 1D models are in such close agreement. The small gap ($g = 2\ \mu\text{m}$) and slow motion imply that the penetration depth, defined as the distance over which the motion amplitude has dropped to 1% of its maximum value, is 37 times larger than the gap. This indicates that the flow between the resonator and the substrate is fully developed and the velocity profile will be reasonably predicted by the Couette model. That the two 1D models are so close also suggests that the difference between the drag forces obtained from the 1D and 3D models is mostly due to the finite size effects.

Both 1D models seriously underestimate the drag force coming from the side. Due to the infinite-long plate assumption, only drag coming from the fluid between fingers is included in the 1D models. Result from the 3D calculation indicates that side forces are a significant contributor to resonator drag.

In the Couette model, in order to satisfy zero velocity at infinity, the velocity gradient at the top plate is zero. Thus there is no drag force from the top flow. By including the inertial term, the 1D Stokes model predicted about 52.67 pN of drag due to the fluid on the top. However, this value is much smaller than the drag predicted from the 3D Stokes model. This fact, again, indicates the significance of the finite size effects on the drag force.

Results

Quality Factor The quality factor, Q, of the resonator was calculated based on the computed drag force, the



Boundary Element Method and its Applications to the Modeling of MEMS Devices, Figure 5 Drag force distribution on the resonator, bottom view

effective mass and the spring stiffness (9). Results are shown in Table 3 together with the measurement data.

It is clear that both the Couette model and the 1D Stokes model fail to predict the quality factor correctly. They overestimated the value of the quality factor by a factor of two. On the other hand, results from the 3D analysis agree well with the experimental result, with an error of 10%. This indicates that 3D effects are profound in this resonator. Figure 5 shows the detailed drag force distribution for the resonator. The drag force from the ambient air on the top of the resonator contributes 15.7% to the total drag, and the drag force from the air between the resonator and the substrate contributes 55% to the total drag. Side forces contribute almost 29.3%.

Impact of Frequency on Drag Force It is of interest to find out if the unsteady Stokes solver is necessary for computing drag forces on resonators because the unsteady Stokes solver is more expensive than a steady Stokes solver. The integrals in the matrix elements in a unsteady Stokes solver are more expensive to evaluate and both the matrix and vectors are complex. To study the impact of frequency on the drag force, a plot of drag force versus the frequency is shown in Fig. 6. The number of elements used in this simulation is 20,148. At $f = 19{,}200$ Hz, the difference in drag force obtained from the steady Stokes solver and the unsteady Stokes solver is under 6% (see Table 4). As an examination of Table 4 indicates, ignoring the inertial term results in under-predicting top force by nearly one third. Therefore, even at these low frequencies, it is necessary to include the inertial term.

Sensitivity of Drag Force on the Film Thickness A sensitivity test has been performed by varying the film thickness and simulating the drag force on the resonator. Results (obtained by using 20,148 panels) are shown in Table 5.

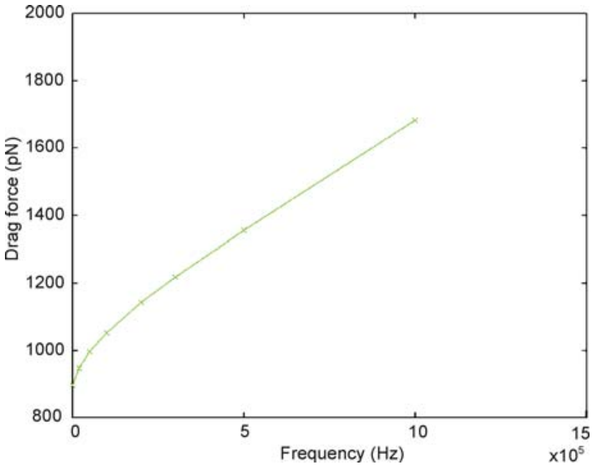
2.06 μm (3%)	932.59 (1.6%)
2.2 μm (10%)	900.10 (5.1%)



Boundary Element Method and its Applications to the Modeling of MEMS Devices, Figure 6 Drag force as a function of frequency

It has been found from the simulations that the perturbation of the drag force is roughly proportional to the perturbation of the film thickness times a factor of 0.55 for small perturbations. This can be explained using the Couette model because

- the bottom force (drag force coming from air between the resonator and the substrate) is affected the most by changes in gap and
- the Couette model predicts the bottom force pretty well for small gaps (as indicated in Table 2).

In the Couette model, the bottom force is inversely proportional to the gap. Thus, the relative change in bottom force is the same as the relative change in gap. However, the bottom force contributes only 55% of the total drag force. Therefore the relative change in total drag force is 0.55 times the relative change in gap.

Future Directions for Research

To date, most successful applications of the BEM are limited to linear and homogeneous problems. The extension to nonlinear problems is hindered by the existence of the volume integrals in the integral formulations of nonlinear problems. The evaluation of these volume integrals requires a volume discretization of the nonlinear region if standard methods are employed. As such, the boundary-only nature of the method is lost and the BEM loses its advantage in mesh generation as compared to domain methods. An efficient treatment of volume integrals would greatly expand the application scope of the BEM as many practical problems such as those encountered in MEMS devices and systems are inherently nonlinear. Research efforts have been made [9, 10] in this direction, but need to be continued and expanded.

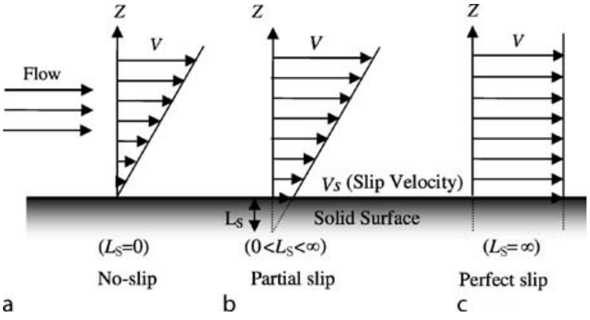
Definition

The Navier–Stokes equation is one of the basic governing equations for study of fluid flow related to various disciplines of engineering and sciences. It is a partial differential equation whose integration leads to the appearance of some constants. These constants need to be evaluated for exact solutions of the flow field, which are obtained by imposing suitable boundary conditions. These boundary conditions have been proposed based on physical observation or theoretical analysis. One of the important boundary conditions is the no-slip condition, which states that the velocity of the fluid at the boundary is the same as that of the boundary. Accordingly, the velocity of the fluid adjacent to the wall is zero if the boundary surface is stationary and it is equal to the velocity of the surface if the surface is moving. This boundary condition is successful in representing a wide range of fluid flow problems. However, it has been observed that the no-slip boundary condition is not valid for all situations and there is a difference between velocity of the surface and the fluid particles near the boundary. This boundary condition is termed as slip condition.



Boundary Slip of Liquids, Figure 1 Schematic representation of the no-slip, partial slip and perfect slip boundary conditions. Under no-slip boundary condition the relative velocity, V_S, between the fluid and the solid wall is zero at the wall. When slip occurs at the wall V_S is finite. The extent of slip is characterized by the slip length L_S (see text)

Overview

Three possible velocity profiles near a solid boundary are shown in Fig. 1. Figure 1a shows that the velocity of fluid particles near the stationary solid wall is equal to zero and represents the no-slip boundary condition. Figure 1b shows that the velocity near the stationary solid wall is non-zero with a relative velocity between the two and represents the slip boundary condition. Figure 1c shows the perfect slip condition, for which there is no influence of the boundary surface on the velocity profile. The velocity when extrapolated towards the wall matches that of the wall at some distance L_s away from it (Fig. 1b), which is known as the slip length and is used as a measure of the slip. The slip length is a fictitious distance below the surface at which the velocity would be equal to zero if extrapolated linearly. The velocity difference between the boundary surface and the adjacent fluid particles is known as the slip velocity, V_s, and is related to the velocity gradient $(\delta V/\delta y)$ near the solid boundary as [1]

$$V_s = \frac{\mu}{C_s}\frac{\delta V(y)}{\delta y} \tag{1}$$

where C_s is the coefficient of slip and μ is the coefficient of viscosity of the fluid. The slip length L_s is the ratio of coefficient of viscosity (μ) to the coefficient of slip (C_s). The no-slip boundary condition is equivalent to $C_s = \infty$ and the perfect slip condition is equivalent to $C_s = 0$.

The slip flow near the boundary surface can be analysed based on the type of fluid, i. e. gas, Newtonian and non-Newtonian liquids. The slip flow in gases has been derived based on Maxwell's kinetic theory. In gases, the concept of mean free path is well defined. Slip flow is observed when characteristic flow length scale is of the order of the mean free path of the gas molecules. An estimate of the mean free path of ideal gas is $l_{\mathrm{m}} \approx 1/(\sqrt{2}\pi\sigma^2\rho)$, where ρ is the gas density (here taken as the number of molecules per unit volume) and σ is the molecular diameter. The mean free path l_{m} depends strongly on pressure and temperature due to density variation. The Knudsen number is defined as the ratio of the mean free path to the characteristic length scale, i. e. $\mathrm{Kn} = l_{\mathrm{m}}/L$. The characteristic length scale (L) can be the overall dimension of the flow or scale of a macroscopic quantity ($L = \rho\ /\ |\delta\rho/\delta y|$). The slip velocity is expressed as a function of the Knudsen number and the velocity gradient at the wall as

$$V_{\mathrm{s}} = \frac{2-\sigma_{\mathrm{v}}}{\sigma_{\mathrm{v}}}\left(\mathrm{Kn}\left(\frac{\delta V}{\delta n}\right)_{\mathrm{s}} + \mathrm{Kn}^2\left(\frac{\delta^2 V}{\delta n^2}\right)_{\mathrm{s}} + \ldots\right) \quad (2)$$

where σ_{v} is the momentum accommodation coefficient, which is a function of the wall and gas interaction. The slip velocity is zero when the Knudsen number is small, i. e. the no-slip boundary condition is valid. The slip condition is valid for large Knudsen number, i. e. when $\mathrm{Kn} \geqslant 0.1$.

Liquid slip has implications to various macroscopic applications, i. e. flow through porous media, particle aggregation, liquid coating and lubrication, etc., in addition to small-scale, i. e. MEMS and bio-MEMS, applications. The movement of a three-phase contact line between two immiscible fluids and solid on a substrate during the advancing or receding film motion indicates the importance of the slip flow boundary condition. The visible contact angle from measurement differs from that predicted using the Young–Laplace equation. The buoyancy and Marangoni effect due to temperature and composition distribution is attributed to the slip flow nature of contact line movement. The conventional hydrodynamics with classical no-slip condition on the substrate generates multi-valued velocity and infinite drag force near the contact line. The imposition of slip condition eliminates this viscous stress singularity at the contact line. Molecular dynamics simulation has also confirmed the local slip near the contact line. Similarly, flows of polymer solutions also show significant apparent slip. Therefore, for liquids, the slip flow characteristics are different from those of gases and need a different explanation.

The liquid slip phenomenon is presented in the following sections. The experimental investigation quantifying the liquid slip is discussed to begin with followed by the results from molecular dynamics simulation. Subsequently, the factors responsible for liquid slip and possible mechanism responsible for liquid slip are discussed.

Basic Methodology

The applicability of slip flow is not well accepted to date by the academic community. One of the problems is the small length scale of the slip flow regime (if present) in comparison to the length scale of the flow or system. The hydrodynamic boundary condition appears to be one of no-slip, unless the flow is examined on a length scale comparable to the slip length. Hence, very accurate techniques with high spatial resolution capable of interfacial flow measurements are required to detect the effects of slip. Some of the experimental techniques for quantification of liquid slip are presented in the following sections.

Flow Rate

Macroscopic quantities, i. e. flow rate and pressure drop measurement, can be used for indirect determination of liquid slip. In this approach, a known pressure gradient ΔP is applied between the two ends of a capillary or a microchannel and the flow rate Q is measured. The flow rate for the slip flow condition is higher than that predicted from the no-slip boundary condition. For Poiseuille flow of fluid with viscosity μ through a narrow cylindrical channel of radius R and length L, the flow rate assuming no-slip boundary condition is

$$Q_{\mathrm{th}} = \left(\frac{\Delta P \pi R^4}{8\mu L}\right) \quad (3)$$

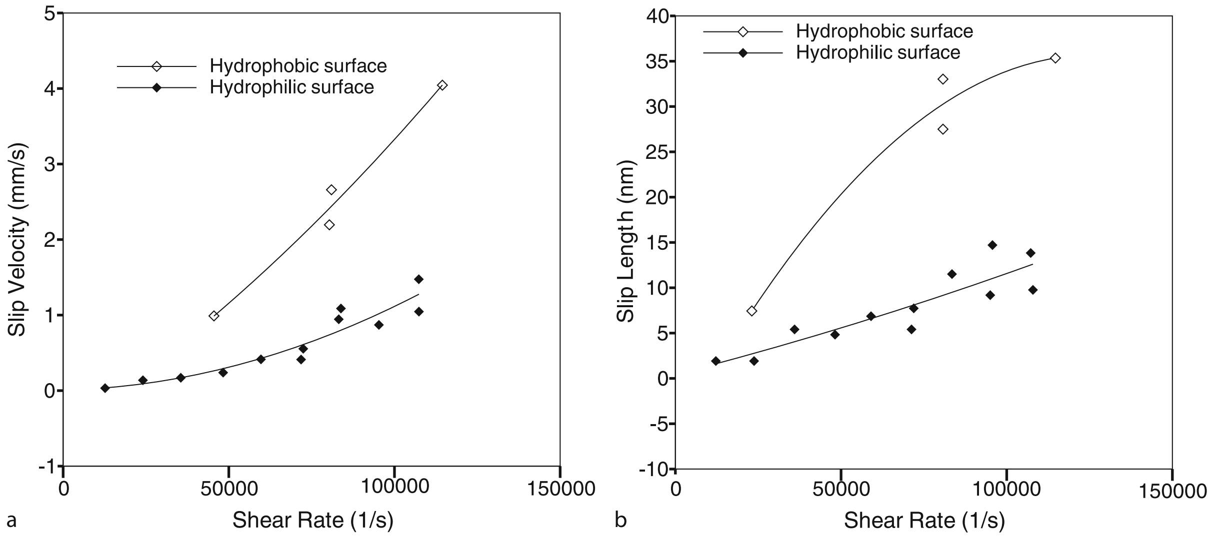
If there is slip at the walls of the channel, the Poiseuille flow velocity profile will be modified to

$$u(r) = \left(\frac{\Delta P}{4\mu}\right)\left[(R + L_{\mathrm{s}})^2 - r^2\right] \quad (4)$$

The flow rate can be obtained using the above slip flow boundary condition, and (assuming $L_{\mathrm{s}}/R \ll 1$) it can be derived that

$$Q_{\mathrm{slip}} = Q_{\mathrm{th}}\left(1 + \frac{4L_{\mathrm{s}}}{R}\right) \quad (5)$$

For any particular slip length of fluid flow, the slip flow rate increases with decreasing radius of the cylindrical channel. For the slip length $L_{\mathrm{s}} = 200\,\mathrm{nm}$, the flow rate with slip (Q_{slip}) is about 6% and 23% higher than the theoretical flow rate with no-slip (Q_{th}) for capillary radii of 13.3 μm and 3.48 μm respectively.



Boundary Slip of Liquids, Figure 2 Comparison of slip velocity and slip length between hydrophilic and hydrophobic surfaces as a function of shear rate

Choi et al. [4] presented the slip velocity and slip length of hydrophilic and hydrophobic microchannels (1 and 2 μm depth) based on flow rate and pressure drop measurements. Sample results from their study are compiled in Fig. 2. The flow rate for the hydrophobic surface is higher than that for the hydrophilic surface. The corresponding slip velocity and slip length for the hydrophobic surface are also higher than those for the hydrophilic surface. The slip velocity and slip length increase with strain rate.

Cheng and Giordano [5] reported the slip length data for different Newtonian fluids, i. e. silicone oil, hexane, decane and hexadecane (fluids having different molecular diameter), as a function of channel height (see Fig. 3). They observed the no-slip condition to be valid when water is the working fluid. However, the slip length is definite for other working fluids. The slip flow effect is insignificant for channel size greater than about 140 nm. Their study indicates the dependence of slip flow on the molecular diameter of the fluid and the fluid–channel wall interaction.

Hydrodynamic Force

The motion (steady or oscillatory) of a sphere towards a flat surface experiences a resistance to the motion. This resistance is due to the combined contribution from Stokes drag on the sphere, the drainage force and the drag force on the cantilever attached between the sphere and the force measuring apparatus, i. e. atomic force microscopy (AFM) or surface force apparatus (SFA). The exact hydrodynamic solutions of this resistance force for a sphere of radius a, approach velocity V, viscosity μ and closest separation distance h can be derived as [3]

$$F = f_{\text{slip}} \frac{6\pi \mu a^2 V}{h} \qquad (6)$$

For the no-slip boundary condition, $f_{\text{slip}} = 1$. Otherwise when there is slip, $f_{\text{slip}} < 1$, i. e.

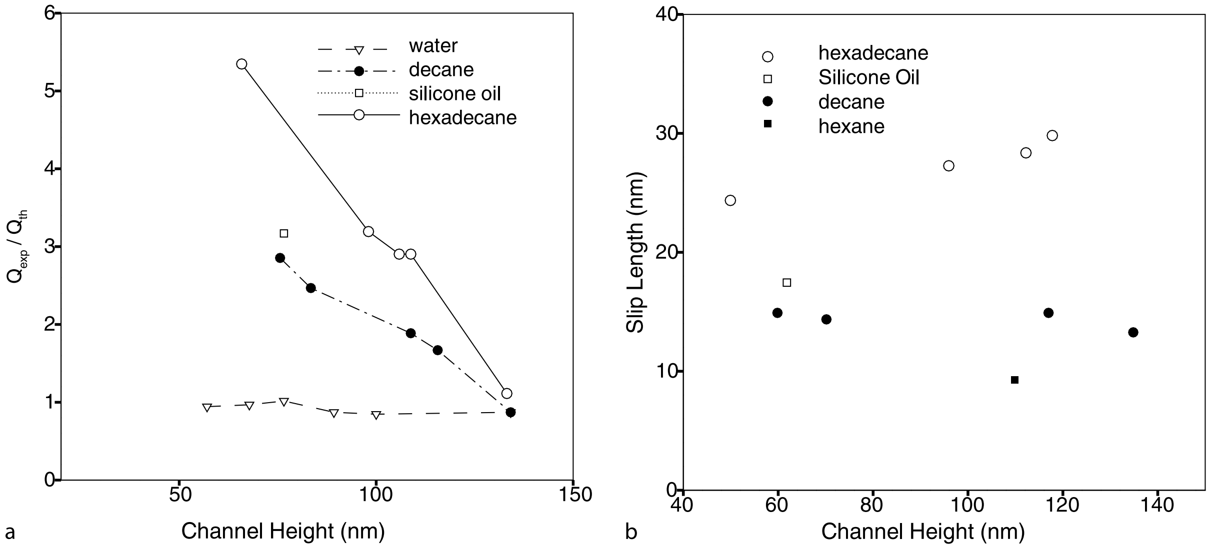
$$f_{\text{slip}} = \frac{h}{3L_{\text{s}}}\left[\left(1+\frac{h}{6L_{\text{s}}}\right)\ln\left(1+\frac{6L_{\text{s}}}{h}\right)-1\right] \qquad (7)$$

Thus the hydrodynamic force for the slip flow case is smaller in magnitude than that for the no-slip case.

Figure 4a shows a schematic of the device for drainage force measurement. Fig. 4b shows the hydrodynamic force versus inverse separation distance for fluids of different viscosity based on the measurements by Neto et al. [3]. The predicted drainage force based on the no-slip flow condition is also compared in Fig. 4b. It is clearly evident that the no-slip boundary condition is unable to describe the experimental data. The slip length obtained based on Eq. (6) and (7) is equal to 4 nm and 12 nm for lower and higher viscosity values respectively. Figure 4c shows the slip length as a function of the approach velocity and fluid viscosity indicating that slip length is a function of both the fluid type, i. e. viscosity, and strain rate, i. e. the approach velocity.

Particle Image Velocimetry (PIV)

Micrometre-resolution particle image velocimetry (PIV) can also be used for direct observation of slip length by



Boundary Slip of Liquids, Figure 3 (**a**) The ratio of experimental flow rate (Q_{exp}) to theoretical flow rate (Q_{th}) based on no-slip boundary condition and (**b**) the slip length as a function of channel height for different fluids (water, silicone oil, decane, hexane and hexadecane)

measuring the velocity profile in the near-wall region. Figure 5a shows a typical μ-PIV setup for microchannel velocity measurement. The velocity measurement in hydrophilic (uncoated glass) and hydrophobic (octadecyltrichlorosilane (OTS) coating) channels adopted from Trethway and Meinhart [6] is shown in Fig. 5b. Fluorescently dyed polystyrene particle of 300 nm diameter absorbs green (532 nm) Nd:YAG laser light which emits red (575 nm) light. The emitted light from the particles is collected by a CCD camera through an epi-fluorescent filter. The cross correlation between pair of particle images provides the velocity field information. The near-wall velocity field measurement of the microchannel (30 μm deep and 300 μm wide) shown in Fig. 5b indicates different velocity profile behaviour between the hydrophilic and hydrophobic channel. The hydrophobic channel shows a shifting of the velocity profile towards higher value and a finite non-zero velocity near the bottom wall, i. e. at about 450 nm from the wall surface, indicating slip flow behaviour.

Other Techniques

Sedimentation velocity and streaming potential measurements also provide indirect information about the slip length.

The sedimentation velocity of particles under gravity can be measured and compared with the predicted values based on no-slip and slip flow boundary conditions. The ratio of the sedimentation velocity as a function of slip length can be derived as

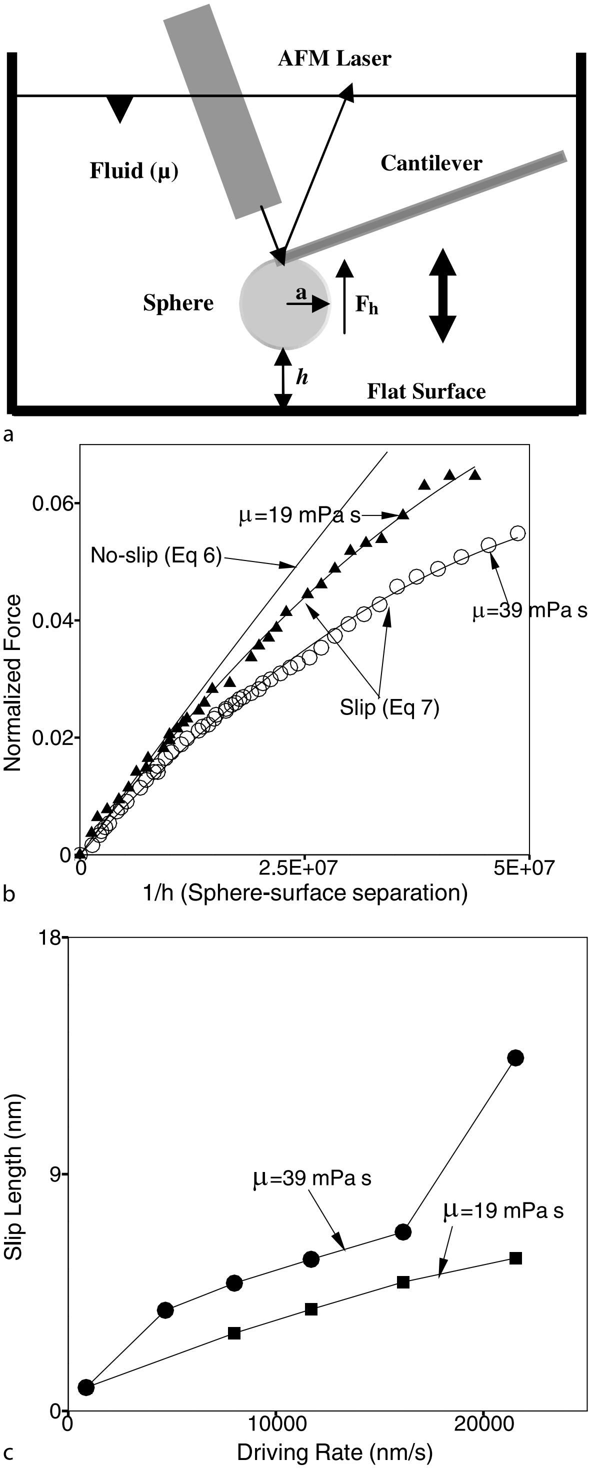
$$\frac{V_{\text{slip}}}{V_{\text{NS}}} = \frac{1 + 3L_{\text{s}}/a}{1 + 2L_{\text{s}}/a} \tag{8}$$

For small particles with radius a, the sedimentation velocity with slip (V_{slip}) for slip length L_{s} is larger than that with no-slip (V_{NS}). The comparison of actual velocity with the predicted velocity based on no-slip condition provides the slip length.

Streaming potential measurement of electrolyte flow inside a capillary depends on the slip length. The surface of the capillary acquires a net charge in contact with the electrolyte. The pressure-driven flow of the capillary creates an advection of charges resulting in surplus ions at one end of the capillary compared to the other end. If the two ends of the capillary are not short-circuited, a net steady-state potential difference, termed the streaming potential, develops. The streaming potential depends on the extent of slip. The ratio of streaming potential for slip (ΔV_{slip}) and no-slip (ΔV_{NS}) is given by

$$\frac{\Delta V_{\text{slip}}}{\Delta V_{\text{NS}}} = 1 + L_{\text{s}}\kappa \tag{9}$$

where κ is the Debye screening parameter, which gives the typical distance close to the surface where there is a net charge density in the liquid and $\kappa^{-1} = \left(\varepsilon_r \varepsilon_0 k_{\text{B}} T / 2e^2 n_0\right)^{1/2}$. Here ε_r is the dielectric constant of the liquid, ε_0 the permittivity of the vacuum, k_{B} Boltzmann's constant, T the temperature, e the electron charge



Boundary Slip of Liquids, Figure 4 (**a**) Schematic of the arrangement for slip length characterization, (**b**) the normalized hydrodynamic force versus inverse of separation for fluid of different viscosities and comparison with no-slip flow calculation and (**c**) slip length as a function of viscosity and driving rate

and n_0 the number density of ions in the bulk of the solution.

Molecular Dynamics Simulation

Molecular dynamics (MD) simulation is a useful tool for studying small-scale fluid flows. Numerical integration of Newton's law of motion for particles (atoms or molecules) is carried out:

$$m_i \frac{d^2 r_i}{dt^2} = \sum_j F_{ij} \tag{10}$$

where m_i is the particle mass, r_i the position of particle i and F_{ij} the interatomic or intermolecular force between particles i and j ($F_{ij} = -\nabla_i V_{ij}$). The Lennard-Jones two-body potential (V_{ij}) between particles is frequently used which is given by

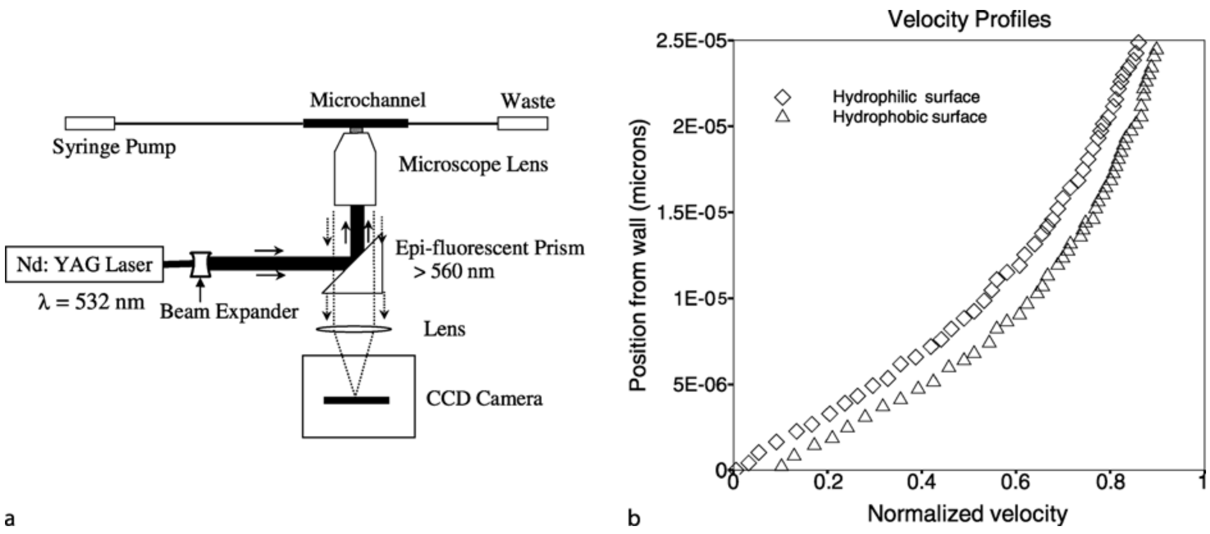
$$V_{ij} = \varepsilon \left[\left(\frac{\sigma}{r_{ij}} \right)^{12} - c_{ij} \left(\frac{\sigma}{r_{ij}} \right)^{6} \right] \tag{11}$$

where ε is an energy scale, σ the particle size and r_{ij} the distance between particles i and j. The constants c_{ij} allow variation of the relative intermolecular attraction between liquids and solids, which therefore represents wetting behaviour.

Barrat and Bocquet [7] carried out the molecular dynamics simulation of Couette and Poiseuille flows. In Couette flow, the upper wall is moved with a constant velocity and in Poiseuille flow an external force drives the flow. Sample results from molecular dynamics simulation are reproduced in Fig. 6. The application of no-slip boundary condition leads to the expected linear and parabolic velocity profile respectively for Couette and Poiseuille flow. However, the velocity profile obtained from molecular dynamics simulation shows a sudden change of velocity in the near-wall region indicating slip flow. The velocity profile for Couette flow away from the solid surface is linear with slope different from that of the no-slip case. The velocity for the slip flow case is higher than that observed for the no-slip case for Poiseuille flow. For both Couette and Poiseuille flow, the partial slip boundary condition at the wall predict similar bulk flow as that observed by molecular dynamics simulation. Some discrepancy in the velocity profile is observed in the near-wall region.

Physical Parameters Affecting Slip

The results reported in the previous section have established the occurrence of slip flow from both experimental and simulation studies. It is important to know various physical parameters affecting slip. The physical



Boundary Slip of Liquids, Figure 5 (**a**) Experimental arrangement for μ-PIV measurement and (**b**) velocity profile for hydrophobic and hydrophilic surfaces obtained from μ-PIV measurement

parameters affecting slip are summarized in the following sections.

Surface Roughness

Roughness influences the behaviour at liquid–solid interfaces. Roughness induces flow around it that leads to dissipation of the mechanical energy. Therefore, there is an increase in the overall resistance to flow and the tendency of slip decreases due to surface roughness. The roughness also influences the dewetting behaviour of the liquid. A high contact angle is indicative of a weak interaction between liquid and solid, and thus causing the fluid molecules to slide across the solid. Roughness can increase the tendency to produce a gas–liquid interface at the solid boundary. The surface behaves like a super-hydrophobic surface and the slip tendency increases.
However, systematic study of surface roughness is not easy to implement. It is difficult to produce suitable surfaces of controlled roughness. Most efforts to alter the surface roughness result in additional undesired changes to the interface properties.

Surface Wettability

It is generally believed that a liquid has a larger slip tendency for poorly wetted surfaces. Higher contact angle indicates weak interaction between the solid and liquid and therefore is easy to overcome. Many experiments and molecular dynamic simulations have confirmed that the level of hydrophobicity is one of the primary factors determining the level of slip.

Shear Rate

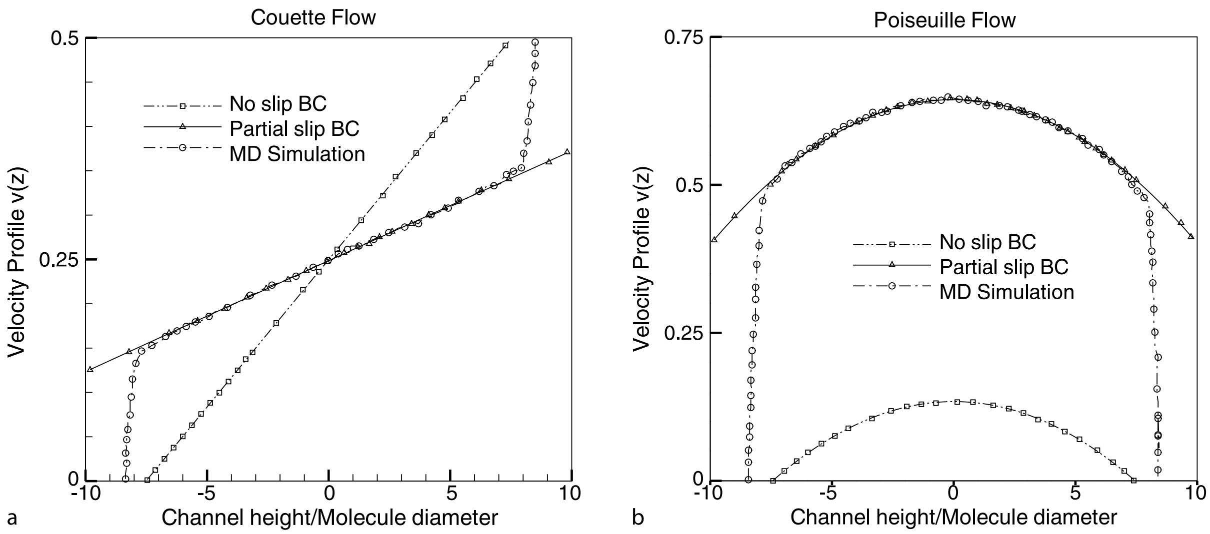
The slip length also depends on the shear rate imposed on the fluid particles. Thompson and Troian [2] have reported the molecular dynamics simulation of Couette flow at different shear rates. At lower shear rate, the velocity profile follows the no-slip boundary condition. The slip length increases with increase in shear rate. The critical shear rate for slip is very high for simple liquids, i. e. 10^{11} s^{-1} for water, indicating that slip flow can be achieved experimentally in very small devices at very high speeds. Experiments performed with SFA and AFM have also showed shear dependence slip in the hydrodynamic force measurements.

Dissolved Gas and Bubbles

Dissolved gases or bubbles near a solid also influence the slip flow behaviour. It has been observed experimentally that the amount of slip depends on the type and quantity of dissolved gas in the fluid. From sedimentation studies it has been reported that slip is not observed in vacuum conditions while there is a clear slip when a liquid sample is in contact with air. Slip in non-wetting systems depends strongly on the environment in which the experiment is performed. Dissolved gases or nano-bubbles in the near-wall region are thought to create localized defects increasing the possibility of slip.

Polarity

For electrolyte solutions and polar liquids, the amount of slip depends on the electrical properties of the liquid. Sed-



Boundary Slip of Liquids, Figure 6 Velocity profile for (**a**) Couette and (**b**) Poiseuille flow. Comparison between molecular dynamics simulation, no-slip boundary condition and partial slip boundary condition

imentation experiments report that slip is only observed for polar liquids. Drainage force experiments report slip to increase with increase in the dipolar moment of the liquid when liquids are polar. This phenomenon is attributed to the super-lattice structure in liquids due to the dipole–dipole interactions.

Possible Liquid Slip Mechanism

Slip flow phenomena can be explained by some possible mechanism. The fluid slip can be described as true or apparent slip. The true slip occurs at a molecular level, where liquid molecules are effectively sliding on the solid surface. The apparent slip occurs not at the solid–fluid interface but at the fluid–fluid interface where a thin layer of liquid/gas molecules is tightly bound to the solid surface. For apparent slip the velocity gradient close to the solid surface is so high that the bulk molecules beyond the layer of liquid/gas molecules appear to slide on the surface.

The true slip phenomena can be attributed to the liquid–liquid and liquid–solid interaction. If the viscous friction between liquid molecules at the interface is stronger than between molecules of the liquid and molecules of the solid, then the molecules can slide on the surface. This is true for hydrophobic surfaces but might also hold for hydrophilic surfaces. If the dimensions of the liquid molecules are of comparable size as the corrugation on the solid surface, then the molecules are trapped in the pits on the surface giving no-slip boundary conditions. But if their size is much smaller or much larger, they can slide on the surface.

For apparent slip, thin gas/liquid layers with a modified viscosity and/or mobility are created near the solid surface. At room temperature and pressure, there is always some residual gas dissolved in a liquid. Critical level of shear might induce cavitations in a liquid and the generated gas bubbles might adhere to the solid surface forming a thin gas layer at the solid surface onto which the liquid can slip. The other factor can be the critical shear rate at which a microscopic surface roughness or corrugation can favour the generation of turbulent flow layer at the interface, and thus modify the viscosity of this layer with respect to the bulk, even if the overall flow is laminar.

Key Research Findings

The correct specification of boundary condition of fluid flow near an interface or solid boundary is essential to obtain the analytical and numerical solution of fluid flow problems. The no-slip boundary condition is successful in describing a class of fluid flow problems. The applicability of the slip flow condition and the condition at which the no-slip boundary condition is invalid is of both academic interest and of practical interest. The recent developments of small-scale microfluidic systems have raised the importance of the specification of the correct boundary condition.

Barrat and Bocquet [7] reported slip in Couette and Poiseuille flow using molecular dynamics simulation (Fig. 6). Tretheway and Meinhart [6] reported a micrometre-resolution velocity profile in hydrophilic and hydrophobic microchannels of cross-section $30 \times 300\,\mu m^2$ using the μ-PIV technique (Fig. 5). Their

results showed significant fluid velocity near a hydrophobic (octadecyltrichlorosilane or OTS coated) microchannel wall and no-slip for a hydrophilic surface. Cheng and Giordano [5] reported pressure-driven flow of several classical fluids (hexane, decane, hexadecane and silicon oil) through lithographically produced channels. The results for water agree well with the theoretical prediction of no-slip boundary condition, for a channel height as small as 40 nm. However, for hexane, decane, hexadecane and silicone oil slip flow is observed when channel separation is reduced below about 100 nm (Fig. 3).

Choi et al. [4] examined the apparent slip effects of water in hydrophobic and hydrophilic microchannels experimentally using precision measurements of flow rate versus pressure drop. They compared their experimental results to that from analytical solution of flow through a channel with slip velocity at the wall. There was a clear difference between the flow of water on a hydrophilic and hydrophobic surface indicating the effect of slip flow (Fig. 2). Craig et al. [3] have reported clear evidence of boundary slip for a sphere–flat geometry from drainage force measurements using atomic force microscopy. The degree of slip is observed to be a function of both liquid viscosity and shear rate (Fig. 4).

Yang and Kwok [8] presented the analytical solution of fully developed electrokinetic flow subjected to sinusoidal pressure gradient or sinusoidal external electric field. The combined effect of slip flow and electrokinetics was demonstrated on the velocity profile in confined geometries. The velocity profile was observed to be a function of both slip coefficient and external electric field. They observed that both these effects play important roles for flow inside microchannels.

Ou and Rothstein [9] developed an ultra-hydrophobic surface with micrometre-sized ridges (20 – 30 μm wide) placed 20 – 120 μm apart aligned in the flow direction. They demonstrated maximum 25% drag reduction for flow inside these channels. From μ-PIV measurements, they showed the existence of slip flow at the air–water interface between the ridges, while the flow over the ridges obeys the no-slip condition. They attributed the existence of slip flow for drag reduction.

Future Directions for Research

The studies carried out so far have explained the slip flow phenomena to a great extent. However, the use of slip phenomena for analysis of different fluid flow problems is limited. The effect of various flow parameters, i. e. roughness, wettabilty, polarity and presence of nanobubbles or residual gases, on slip flow phenomena needs to be conclusively and systematically studied. The effect of temperature and concentration gradient on slip flow parameters needs to be properly characterized based on both molecular dynamics simulation and experiments. The effect of slip flow on turbulence production mechanism needs to be established. The development of advanced micro-/nano-manufacturing and measurement technology is expected to facilitate the systematic study of these parameters.

Manipulation of conditions required for generation of slip flow can have many practical applications. This will be beneficial in development of drag reduction and mixing enhancement technologies. This is particularly important for micro- and nanotechnologies, where the pressure penalty is very high and mixing is difficult due to the difficulty in generation of turbulent flow.

Bragg Diffraction Equation or Bragg's Law

Definition

If a crystal is irradiated with x-ray radiation most of the radiation passes through unhindered. But some part of the radiation will be deflected by the crystal, which is called Raylight scattering and can be visualized on photographic plates. But the equation can only be achieved (and thereby the reflection be observed), if the pitch length

(which is although the phase shift of the radiation before and after the deflection) is an integer multiple of the wavelength. The Bragg diffraction equation was developed by William Henry Bragg and his son William Lawrence Bragg in 1912.

Definition

The bubble actuated microfluidic switch is actuated by either thermal bubble or electrolysis bubble. The microfluid is driven by capillary force and stop by design of hydrophobic property in the microchannels. The switch function of the microfluidic system is to control the fluid sample into the individual desired outlet reservoir for the applications such as selective on-chip sample dosing, microfluidic/bio-sample on-chip transportation and Lab-on-a-Chip microsystem integration.

Overview

Some design concepts and prototypes of microfluidic switches have been demonstrated over the past decade. Doring et al. [1] demonstrated that a laminar flow could be steered into one of two outlet ports using a thermal bimorph cantilever, which was made by a bimetal structure and used as an active component for flow switching. Blankenstein et al. [2] reported that the differential hydrodynamic pressures, which were generated by external pumps, between the inlet ports were used to guide specific fluid sample stream into the desired outlet port. The sample injection into one of the five outlet ports has been demonstrated in their study. Gebhard et al. [3] demonstrated a fluidic oscillator employing a V-shaped fluidic circuit with feedback micro channels, in which a part of the output flow was fed back into the inlet region to control the main flow to be redirected to the other desired microchannel. Gebhard's work demonstrated that the fluid could be switched between two output microchannels via their design. Lee et al. [4] reported that $M \times N$ pre-focused microfluidic switches have been successfully demonstrated with several external pumps to switch continuous liquid from an inlet channel to any desired outlet channel in multi-ported outlet microchannels. In their studies, the theoretical model based on the potential flow theory was built to predict the performance of single and multiple flow switching. Also, Lemoff and Lee [5] reported an AC magnetohydrodynamic (MHD) microfluidic switch, in which the Lorentz force was used to propel an electrolytic solution. Their switch took advantage of integrating two AC MHD pumps into different arms of a fluidic Y-channel to make the fluid switch into or out of either arm. In these proposed research studies, various microfluidic switches have been successfully

demonstrated. Anyway, most proposed studies still suffer from the disadvantages such as the need of several external pumps and mechanical moving parts inside the fluidic chip. In addition, most of them could not perform precise fluidic switch into tiny microchannels due to leakage problems.

Some MEMS technologies have been drawn toward taking advantage of surface tension, which becomes a dominant force in microscale. The continuous electrowetting (CEW) requires a liquid metal in a filler liquid, limiting the medium that can be driven. A droplet movement of aqueous liquid based on electrical control of surface tension has been demonstrated with an electrolyte droplet in a filler fluid [6], still requiring two liquids in the system. In addition, the electrowetting (EW) [7] and electrowetting on dielectric (EWOD) [8] can be used to handle aqueous liquid in microscale without any second liquid medium. In these cases, the change in contact angle or the wettability shift is caused by the change in the solid-liquid surface tension.

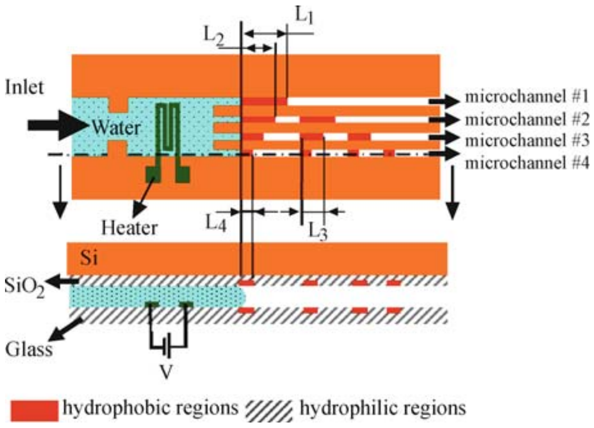
A novel microfluidic switch based on surface tension and distributed hydrophobic-patch design was just developed and reported in our group [9]. Both the capillary force and the barrier pressure are utilized in our proposed design to achieve the switching function. The trigger driving actuator in our reported concept-proof prototype relies only on the embedded heater, which generates thermal actuation bubbles, with time-sequence power control. The bubble actuator could be replaced by the electrolysis bubble actuator in a modified chip design. This kind of proposed fluidic switch devices could resolve the disadvantages in early proposed various microfluidic switches, such as the complicated electrical connections, the need of several external pumps, the mechanical moving parts inside the fluidic chip, and the leakage problems. Compared with other actuation mechanisms, the bubble actuator has the features of simple structure, no moving parts and being easy to be integrated with the control circuitry. However, for bio-applications by using thermal bubble actuation, the bio-samples might be broken or degraded either by the shear-stress acting on them due to the hydrodynamic movement of the fluids when the bubble grows and collapses, or by the local high temperature induced by the transient generation of the thermal bubble. It has been found that some pretreatment of the bioactive samples could lower these kinds of damage. For example, Okamoto et al. [10] successfully ejected DNA segments in a DNA micro-array device by using the thermal bubble jet-printing technology. To avoid the high temperature and high shear-stress damage from the thermal bubble, they optimized the DNA ejection solvent to improve volatility, solubility, wettability, viscosity and surface tension of DNA solution, and to promote spot separation by adding some additional chemicals. Maxwell et al. [11] also reported a microbubble bioparticle actuator that uses the micro thermal bubble actuation to manipulate the bioparticles. So far, they have demonstrated that bubble actuation could be used to actuate cell-sized particles and will use the bioparticle actuator to capture living cells. Besides, our group also successfully demonstrated cell sorting feature for liver cells by using electrolysis bubble actuator to actuate MEMS T-shape structure [12]. The MEMS design gets rid of PH value actuation to get high survival rate for delicate sorted liver cells. All of these results demonstrate promising research efforts for the MEMS bubble actuation technique to be integrated in biochips for bio-applications. In the following sections, we focus on the thermal-bubble actuated microfluidic switch based on surface tension and distributed hydrophobic-patch design. This device is taken as an example to understand the details about design concept, basic theory, operation principle as well as take a look at the function demonstration.

Basic Methodology

Design Concept of Bubble Actuated Microfluidic Switch

To introduce the concept and design details, a schematic representation of the 1×4 microfluidic switch with one inlet port and four outlet ports as shown in Fig. 1 is taken as a case study here. This case-study device, as shown in Fig. 1, consists of an embedded heater, a capillary system with hydrophilic microchannels, and a specific arrangement of hydrophobic patches. This device could be expanded to $1 \times N$ microfluidic switch via the similar design. Also the embedded heater could be replaced by electrolysis electrodes. In Fig. 1, L_i represents the length of each hydrophobic patch in the microchannel #*i*. From microchannel #1 to #4, L_i decreases with an increase of patch number in each microchannel. For the device design shown in Fig. 1, there are 1, 2, 3, and 4 separated hydrophobic patches in microchannel #1, #2, #3, and #4, respectively. These distributed patches have the same length in each microchannel.

In the $1 \times N$ microfluidic switch design, the switch mechanism among different microchannels is dominated by controlling the format and the timing of power input that generates thermal bubble actuation. During the growing process of the thermal bubble, the meniscus of the liquid in each microchannel stopping at the edges of the hydrophobic patches will be pushed forward as shown in Fig. 2. When the thermal bubble begins collapsing, the meniscus of the liquid in each microchannel will flow back till leaving the hydrophobic patch due to the barrier pressure if it stays on a hydrophobic patch. On the contrary, it will



Bubble Actuated Microfluidic Switch, Figure 1 The design concept of the microfluidic switches where $L_i > L_{i+1}$, i. e. $L_1 > L_2 > L_3 > L_4$. L_i represents the length of each hydrophobic patch in microchannel #*i*. All other regions in the microchannels are hydrophilic

flow forward till reaching the edge of the next hydrophobic patch region due to the capillary force if it stays on a hydrophilic region.

Figure 2 illustrates the operation principles of a 1×4 microfluidic switch based on the proposed design concept by using specific separated hydrophobic patches in microchannels. As a fluid sample is first introduced into the inlet from the left, the fluid is driven forward to the right by the capillary force and then stops at the edges of the first hydrophobic patches of each microchannel as shown in Fig. 1. For instance, if we want to control and guide the continuous liquid into the microchannel #1, the volume control of the actuating bubble is required to push the fluid to pass through the first hydrophobic patch region of the microchannel #1 but not to pass through all the second hydrophobic patches in other microchannels. Because the length of the hydrophobic patch in microchannel #1 is the longest, the fluid could pass through all the first patches of all microchannels if the volume of the actuating bubble could push the fluid to pass through the first hydrophobic patch region in the microchannel #1. Then, the continuous liquid could be driven along the microchannel #1 by the capillary force, and stopped at second patches of other microchannels by the barrier pressure, as shown in Fig. 2a. One challenge on this capillary system design, for this case, is to drive the fluid through the microchannel #1 and precisely stop the fluid before the second hydrophobic patches in the other microchannels via the micro design of the separation gaps between hydrophobic patches and the time-sequence control of bubble volume.

For another example, if we want to control the liquid to flow into the microchannel #3 only, we could control the bubble volume via heater power control to overcome the barrier pressures of all the hydrophobic patches in microchannel #3 step by step. As soon as the fluid passes through each one of hydrophobic patches of the microchannel #3, the thermal bubble immediately begins collapsing via the voltage control on the heater. At this moment, the meniscuses of fluid staying on the hydrophilic region will flow forward due to capillary force till reaching the next hydrophobic patch in the microchannel #3 and #4. However, the meniscuses staying on the hydrophobic patches will flow back due to barrier pressure till leaving the hydrophobic patch in the microchannel #1 and #2. After we generate the growth and collapse of the thermal bubble three times, the continuous liquid could be driven through the microchannel #3 due to the capillary force, as shown in Fig. 2b. Based on the similar operation principles, the fluid could be controlled and guided into any desired microchannel or multiple microchannels based on the needs. As shown in Fig. 2c, the fluid is simultaneously switched into two desired outlet ports, the microchannel #2 and #4. Firstly, we generate the large bubble twice to make the fluid pass through all hydrophobic patch regions of microchannel #2. Afterwards, we generate the small bubble twice to make the fluid pass through the last two of the hydrophobic patch regions in microchannel #4. Based on the hydrophobic-patch design and programmed time-sequence bubble actuation, the fluid could be switched into desired outlet ports in the capillary system without the need of external pumps and complicated MEMS moving parts.

Microfabrication of Case-Study Microfluidic Switch Prototype

The micro fabrication of our capillary system with microfluidic switch function is a four-mask process, as illustrated in Fig. 3. A standard p-type <100> silicon wafer is grown with 5000 Å thermal oxide that is patterned and etched as the oxide mask, and then etched by KOH solution to define 20 μm-depth microchannels. Then, this silicon substrate is grown with another 7000 Å thermal oxide to form the hydrophilic layer. Next, the 1% Teflon solution is spin-coated on the oxide layer to define our designed hydrophobic patch regions by a lift-off process. On the Pyrex glass substrate, photoresist and HF solution are used to define the patterns and form the recesses of 1 μm-depth. A 5000 Å aluminum layer is, then, evaporated and patterned as the heater and electrodes by another lift-off process. Next, another 1% Teflon solution is also spin-coated on the Pyrex glass to define the hydrophobic pattern regions by another lift-off process. Finally, the silicon wafer and Pyrex glass are aligned for the anodic bonding process.

Background and Theory

Barrier Pressure Analysis

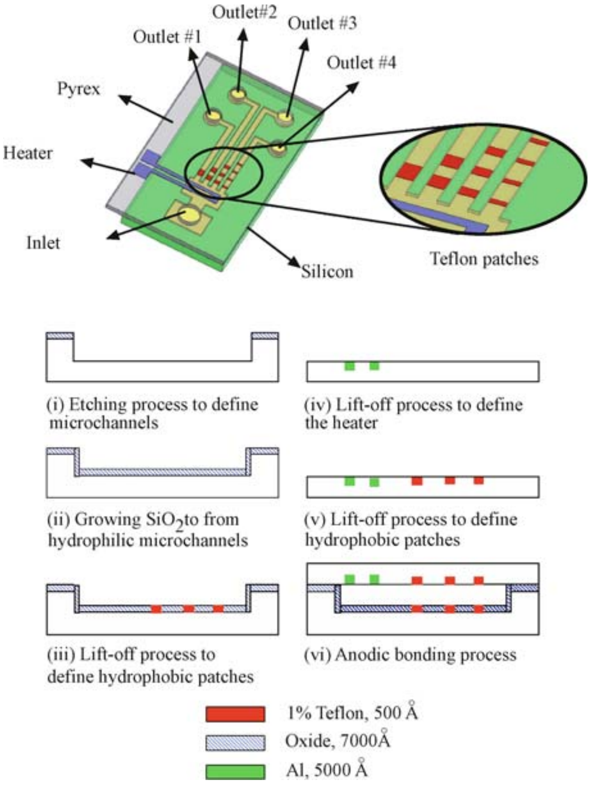
To study and design the capillary system with $1 \times N$ microfluidic switches, a theoretical model based on early literatures is proposed. The liquid actuation and control in the capillary system with microfluidic switch function is dominated by both barrier pressure and capillary force. Here, we model the liquid motion by using the total surface energy approach [13]. The surface energies are related to the equilibrium contact angle θ_c by Young's equation

$$\gamma_{sa} = \gamma_{sl} + \gamma_{la} \cos\theta_c \tag{1}$$

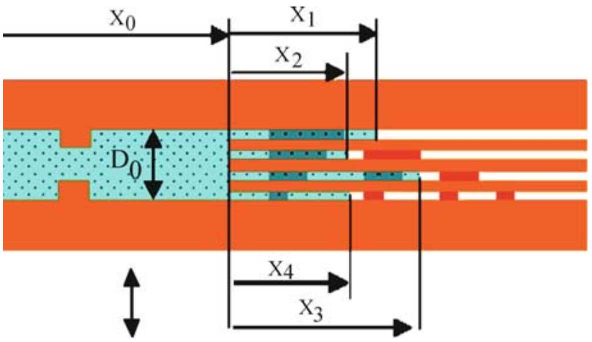
The total interfacial energy of the system could be modeled as

$$\begin{aligned} U_T &= A_{sl}\gamma_{sl} + A_{sa}\gamma_{sa} + A_{la}\gamma_{la} \\ &= (A_{sl} + A_{sa})\gamma_{sa} - A_{sl}\gamma_{la}\cos\theta_c + A_{la}\gamma_{la} \\ &= U_0 - A_{sl}\gamma_{la}\cos\theta_c + A_{la}\gamma_{la} \end{aligned} \tag{2}$$

where A_{sl}, A_{sa} and A_{la} are interface areas of solid-liquid, solid-air, and liquid-air, respectively, and γ_{sl}, γ_{sa}, and γ_{la} are the surface energies per unit area. The sum of $(A_{sl} + A_{sa})$ is invariant, so U_0 is a constant value.



Bubble Actuated Microfluidic Switch, Figure 3 Microfabrication processes for the capillary system



Bubble Actuated Microfluidic Switch, Figure 4 The meniscuses of the liquid stay at position x_1, x_2, x_3, x_4 in microchannel 1, 2, 3, 4, respectively, for a transient state. This is a general case for the analysis of pulling force and backward barrier pressure in the capillary system

When a liquid sample is introduced into the capillary system with a 1×4 microfluidic switch as shown in Fig. 1, it wicks by the capillary force and stops at the edges of hydrophobic patches due to the barrier pressure. To study the pulling force and backward barrier pressure in each microchannel, Fig. 4 illustrates a general case for the transient state with the liquid positions at x_1, x_2, x_3, and x_4 in microchannel #1, #2, #3, #4, respectively. The width of each outlet microchannel is much larger than the microchannel height, h, in the device, so the meniscus shape could be simplified as a one dimension problem. The effect of gravity is neglected because of shallow microchannels in the device. The meniscus is assumed to be a circular arc with a 2α angle where α is equal to $\pi/2-\theta_c$, as shown in Fig. 5. The total energy U_T is a function of the injected liquid volume V_L. The total energy U_T and the pressure P could be derived as follows [13].

$$U_T = U_0^* + \sum_{i=1}^{4}\left[-2D_i x_i \gamma_{la}\cos\theta_{c,i} + \gamma_{la}\frac{D_i h \alpha_i}{\sin\alpha_i}\right] \quad (3)$$

$$V_L = D_0 x_0 h + \sum_{i=1}^{4}\left[D_i x_i h - \frac{D_i h^2}{4\sin\alpha_i}\left(\frac{\alpha_i}{\sin\alpha_i} - \cos\alpha_i\right)\right] \quad (4)$$

where U_0^* is a constant value, D_i is the width of the microchannel #i, x_i is the meniscus in the microchannel #i, and $\theta_{c,i}$ is the contact angle between liquid and microchannel wall in microchannel #i. The pressure on the liquid is hence

$$P_1 = \frac{\partial U_T/\partial x_1}{\partial V_L/\partial x_1} = \frac{-2\gamma_{la}\cos\theta_{c,1}}{h},$$

$$P_2 = \frac{\partial U_T/\partial x_2}{\partial V_L/\partial x_2} = \frac{-2\gamma_{la}\cos\theta_{c,2}}{h},$$

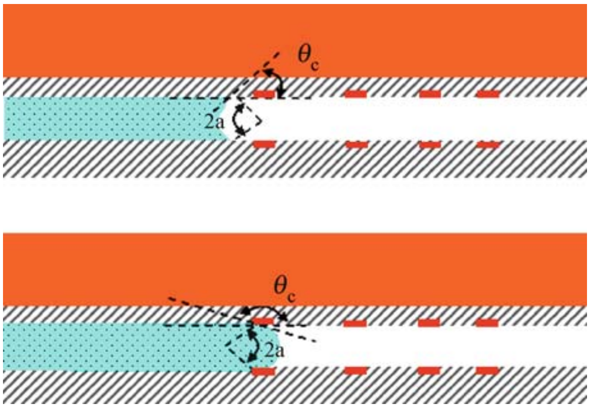
$$P_3 = \frac{\partial U_T/\partial x_3}{\partial V_L/\partial x_3} = \frac{-2\gamma_{la}\cos\theta_{c,3}}{h},$$

$$P_4 = \frac{\partial U_T/\partial x_4}{\partial V_L/\partial x_4} = \frac{-2\gamma_{la}\cos\theta_{c,4}}{h} \quad (5)$$

$$P = \frac{dU_T}{dV_L} = \sum_{i=1}^{4} P_i = \sum_{i=1}^{4}\left[\frac{\partial U_T/\partial x_i}{\partial V_L/\partial x_i}\right] = -\sum_{i=1}^{4}\frac{2\gamma_{la}\cos\theta_{c,i}}{h} \quad (6)$$

where P_1, P_2, P_3, and P_4 are the individual forward/backward pressure in the microchannel #1, #2, #3, and #4, respectively. P is the total pressure applied to the fluid due to capillary force and barrier pressure. When all the fluid in each microchannel stays at the hydrophobic regions, $P_1=P_2=P_3=P_4$ with the same contact angle θ_c.

In the device design, the sample liquid is DI water, the height is 20 µm and the width of each microchannel is 100 µm. According to Eq. (5), the internal liquid pressure is a function of the contact angle, which is related



Bubble Actuated Microfluidic Switch, Figure 5 The definition for the angles of meniscus shape stayed at (**a**) hydrophilic region (**b**) hydrophobic region

to the meniscus positions, x_1, x_2, x_3 and x_4. The contact angle $\theta_c = 20°$ of hydrophilic microchannels could produce a negative pressure of nearly 7 kPa to make the liquid flow forward. The contact angle $\theta_c = 120°$ of hydrophobic patches could generate a positive barrier pressure of nearly 4 kPa to stop the liquid. Figure 6 shows the pressure distribution in each microchannel of the device based on the above contact angle parameters. The positive sign on the pressure means a backward barrier pressure on the hydrophobic patch regions. The negative sign means a forward pulling pressure on the hydrophilic region in the capillary microchannels.

Based on the above, we could extend 1×4 microfluidic switch system to $1\times N$ microfluidic switch system with similar derivation to obtain the mathematical models for the injected volume, the total energy and the total pressure as follows.

$$U_T = U_0^* + \sum_{i=1}^{N}\left[-2D_i x_i \gamma_{la}\cos\theta_{c,i} + \gamma_{la}\frac{D_i h\alpha_i}{\sin\alpha_i}\right] \quad (7)$$

$$V_L = Dx_0 h + \sum_{i=1}^{N}\left[D_i x_i h - \frac{D_i h^2}{4\sin\alpha_i}\left(\frac{\alpha_i}{\sin\alpha_i} - \cos\alpha_i\right)\right] \quad (8)$$

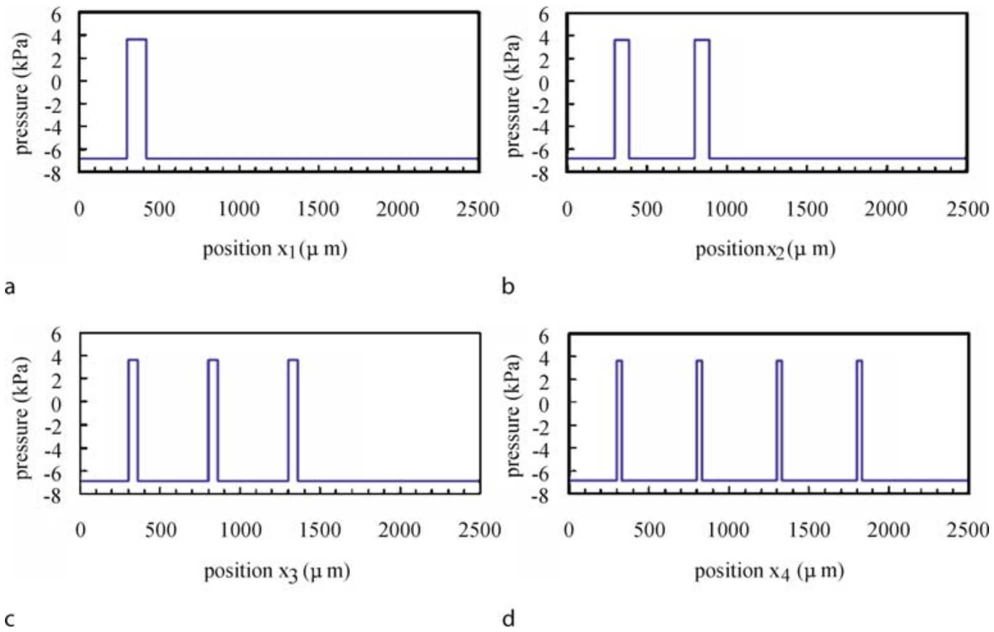
$$P = \frac{dU_T}{dV_L} = \sum_{i=1}^{N} P_i = \sum_{i=1}^{N}\left[\frac{\partial U_T/\partial x_i}{\partial V_L/\partial x_i}\right] = -\sum_{i=1}^{N}\frac{2\gamma_{la}\cos\theta_{c,i}}{h} \quad (9)$$

Thermal Bubble Nucleation

The growth and collapse of a micro-bubble via a micro-heater actuator, with the applications to ink-jet printers, have been studied extensively in the decades. It has been demonstrated that the pressure inside the bubble could reach several MPa during the initial bubble growth period, with the heating duration of within several microseconds. It should be highlighted that most previous researches regarding the bubble generation under a pulse heating show a nearly symmetric bubble growth and collapse periods, where the width of heating pulse was kept at several microseconds. In other words, the bubble growth velocity is nearly equal to the bubble collapse velocity, so there will be no net fluid flow after one cycle of bubble growth and collapse period. Recently, P. Deng et al. [14] have studied the bubble behavior under pulse heating with pulse width in the range from microseconds to milliseconds. They report that a relatively long pulse heating duration could change the near-symmetric bubble growth-collapse pattern by prolonging the vapor bubble condensation process.

Thermal Bubble Volume

The thermal bubble growth could be mainly classified into two modes in macro-scale bubble nucleation experiments, as described in an early literature report [15]. The first mode occurs at the initial stage of bubble growth that is hydrodynamically controlled and dominated by liquid inertia. For this first mode, the bubble diameter increases proportionally with heating time. The second mode occurs at the later stage of bubble growth that is dominated by the heat diffusion. The bubble grows at a slower rate and is proportional to the square root of heating time in this second mode. Recently, Tsai et al. [16] have investigated the transient bubble formation experiments on polysilicon micro-resistors. These studies demonstrate that the micro bubble nucleation processes could be classified into three groups depending on the input current. When the input current is low, no bubble is nucleated. For the middle range of the input current, a single spherical bubble is nucleated with a waiting period up to 2 s depending on the magnitude of the input current. After the resister temperature rises and reaches a steady state, the bubble growth rate is found proportional to the square root of heating time that is similar to the heat diffusion dominant model as proposed for the macro scale boiling experiments. From the experimental data, it is found that the bubble diameter, D, could be represented as $D = 2Ct^{1/2}$, where t is the heating time, and C is the bubble growth rate constant and determined by the heating rate.



Bubble Actuated Microfluidic Switch, Figure 6 Hydrophobic barrier pressure distribution versus meniscus positions x_1, x_2, x_3, x_4 along (**a**) microchannel #1 (**b**) microchannel #2 (**c**) microchannel #3 (**d**) microchannel #4, respectively. The positive sign on pressure means a backward barrier pressure. The negative sign means a forward pulling pressure on the hydrophilic region in the capillary microchannels

Furthermore, a further assumption of a perfectly spherical bubble is made for the shape of the vapor layer generated on a thin-film heater surface, the bubble volume, V, could be modeled as [17]

$$V(t) = \frac{\pi D^3}{6} = \frac{4\pi}{3} C^3 t^{3/2} \tag{10}$$

In the design, the width of each microchannel is much larger than its height, so the bubble volume could be simplified as a two-dimension problem.

$$V(t) = \frac{\pi D^2}{4} h = \pi h C^2 t \tag{11}$$

The bubble volume increases linearly with time in the case, so we could control the bubble volume via the time of applied voltage to control the liquid positions through hydrophobic patches of different length. In addition, the bubble growth rate is also affected by the amplitude of the applied regulation voltage, so we could shorten the heating duration by increasing the amplitude of the applied voltage. Thus, the bubble volume could be controlled by the heating duration and the applied-voltage amplitude.

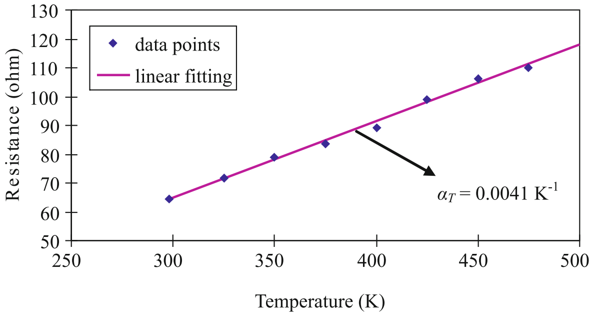
Thermal Energy

In fact, the heating rate is not fixed even if the heater is applied with a constant voltage. The power input to the heater is not constant because the heater resistance is continuously increasing with the temperature during the application of the heating pulse. For the square electrical voltage pulse with a time period, the thermal energy, Q, which is produced via a thin-film micro heater, could be derived by the following equation.

$$\begin{aligned} Q &= \int_0^{t_N} V_e I_e(t)\,dt = \int_0^{t_N} \frac{V_e^2}{R(T)}\,dt \\ &= \int_0^{t_N} \frac{V_e^2}{R_0(1+\alpha_T(T(t)-T_0))}\,dt \end{aligned} \tag{12}$$

where V_e, I_e, R and T are the applied voltage, the applied current, the heater resistance and temperature, respectively, α_T is the temperature coefficient of the Al wire resistor, t_N is the duration of the applied voltage pulse, and R_0 is the heater resistance at a reference temperature T_0. In the concept-proof prototype devices, the micro-heaters, as shown in Fig. 12a, are 30 μm wide Al wires with different resistances. In the following experimental demonstration, the micro-heater that we use for thermal bubble generation is characterized and has the resistance of 64.6 Ω at room temperature.

The relationship between thermal energy and the pulse duration would change due to the temperature effect. However, the thermal energy would increase with the applied heating duration. To characterize heater temperature, the



Bubble Actuated Microfluidic Switch, Figure 7 The characterized resistance for the micro heater versus the heater temperature. The Al micro heater has a nominal resistance of 64.6 Ω at the room temperature

relationship between the electric resistance and the temperature of the micro Al heater is studied. First, the heater is calibrated to obtain the temperature coefficient, α_{T}. The fluidic chip with the Al wire resistor is placed on a hot plate, whose temperature is controlled by a controller, and then the pad of the heater are connected to the input ports of a HP3457A multimeter. The resistance of the heater versus the temperature is characterized and recorded, as shown in Fig. 7. The temperature coefficient of the heater $\alpha_{\mathrm{T}}=0.0041\ \mathrm{K}^{-1}$is obtained by a linear fitting of the measured data which could help us to approach the real-time heater maximum temperature during the pulse heating process.

Mechanical Work

While a bubble expands or contracts in a liquid, mechanical work is transferred between the bubble and the surrounding liquid. The kinetic energy transferred from the expanding vapor microlayer on a thin-film heater surface could be used, in principle, to drive electromechanical microdevices such as micro actuators and micro pumps. The useful work converted from the thermal energy on the surface of a microheater is critical for these applications. The mechanical work, E_m, done by a vapor volume expansion on the surrounding liquid is [16]

$$E_m = \int P_{\mathrm{v}}\,\mathrm{d}V = \int_0^t P_{\mathrm{v}} \frac{\mathrm{d}V(t)}{\mathrm{d}t}\,\mathrm{d}t \qquad (13)$$

where P_{v} is the pressure within a bubble and $V(t)$ is the bubble volume. The microfluidic switch is activated to drive fluid forward when the bubble pressure overcomes the total barrier pressure, $P_{\mathrm{v}} > P$. Therefore, the mechanical work is used to overcome the barrier pressure and to increase the bubble volume. For reliability and controllability, we have to keep the total barrier pressure constant before the thermal bubble is activated each time, to make the mechanical work completely dominated by the bubble volume. The best way to keep the total barrier pressure constant is that the fluid must simultaneously pass all last hydrophobic patches at the desired turn-on microchannels. This is related to the operation principles that we will address next.

Bubble Actuated Microfluidic Switch, Table 1 Fifteen operation modes for the capillary system with a 1×4 microfluidic switch

Number of outlet ports on	Desired outlet ports (microchannel #*i*) on
One	1; 2; 3; 4
Two	1,2; 1,3; 1,4; 2,3; 2,4; 3,4
Three	1,2,3; 1,2,4; 1,3,4; 2,3,4
Fthe	1,2,3,4

Operation Principles

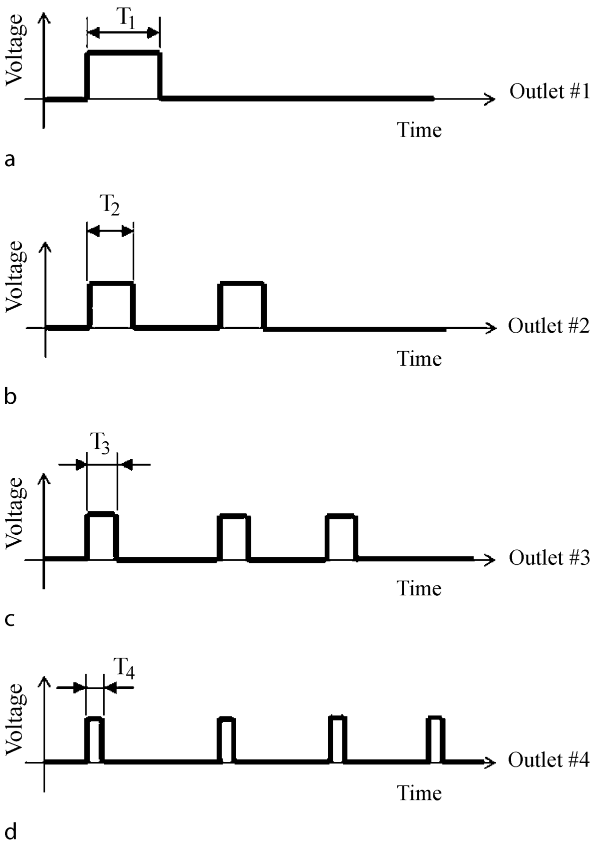
There are 15 operation modes for the capillary system with a 1×4 microfluidic switch, which could simultaneously switch the liquid into the desired outlet ports, as listed in Table 1. The operation modes could be divided into two parts, namely single and multiple output modes. We will discuss the required time-sequence power control for the bubble nucleation to function the fluidic switch appropriately for the capillary system as follows.

Single Output Modes

The sample liquid is assumed to be able to be pushed and pass the lengths of hydrophobic patches L_1, L_2, L_3 and L_4 in each microchannel, as shown in Fig. 1, with the voltage pulse widths T_1, T_2, T_3 and T_4 on the heater in capillary micro system. According to Eq. (11), the bubble volume increases proportionally to the heating time under a constant applied voltage. Thus, the relationship $T_1 > T_2 > T_3 > T_4$ is reasonably predicted. Therefore, we could control the fluid into one of microchannels by controlling the format and timing of heater power input, as shown in Fig. 8. For a $1 \times N$ microfluidic switch, if we desire to guide the liquid into the microchannel #i, the voltage pulse width t applied on the heater to generate actuating bubble must be $T_i \leqq t < T_{i-1}$ and the times of the bubble nucleation, i, is required to pass through all hydrophobic patches of microchannel #i. Also, the design on the separation gap between adjacent hydrophobic patches must be far enough to prohibit the fluid from passing through the microchannel #$i-1$ when we only intend to turn on microchannel #i.

Multiple Output Modes

Appling the similar principles, we could control the fluid into multiple microchannels based on the needs. For such multiple output modes, there are three different operation methods, as shown in Fig. 9, to control the fluid into the microchannel #2 and #4, for example, in the capillary system with a 1×4 microfluidic switch. The time-sequence actuation as shown in Fig. 9a, we would generate the growth and collapse of the thermal bubble six times to control the fluid to pass through the microchannel #4 and #2. The bubble pressure overcomes the barrier pressure to make the fluid pass through all hydrophobic patches of microchannel #2 and #4. Then, the capillary force pulls the fluid through to turn on microchannel #2 and #4. However, Fig. 9b demonstrates the same switch function with only four-time thermal-bubble actuation. These two methods have the common point which is firstly to control the fluid to pass through one of desired microchannels. According



Bubble Actuated Microfluidic Switch, Figure 8 Pulse widths and the times of bubble nucleation management in a single output mode (**a**) for the power control to turn on microchannel #1 only (**b**) for the power control to turn on microchannel #2 only (**c**) for the power control to turn on microchannel #3 only (**d**) for the power control to turn on microchannel #4 only

to Eq. (6), the total barrier pressure would decrease due to the effect of the capillary force which would produce a negative pressure. Hence, the magnitude of the total barrier pressure would be affected after the fluid pass through one of the microchannels. The total barrier pressure would decrease with the number of the turn-on microchannels which the fluid has passed through via capillary force.

To ensure the controllability and reliability of the microfluidic switches, the same total barrier pressure is set as the requirement in the design when the thermal bubble is activated each time. This means that the fluid has to be steady-state and stop at hydrophobic patches of each microchannels before each bubble starts being generated. For example, if we desire to control the fluid into the microchannel #2 and #4 simultaneously, we could follow the third method, as illustrated in Fig. 9c, which makes the microchannel #2 and #4 turned on simultaneously on the last time of bubble growth actuation. This procedure could also minimize the times of the bubble nucleation for the same fluidic switch purpose.

For a $1 \times N$ general microfluidic switch, we want the fluid liquid to be controlled into five specific outlet ports, for example, which are connected with microchannels #*X*, #*Y*, #*Z*, #*V* and #*W*. The lengths of hydrophobic patches in these five microchannels have the relationship of $L_X > L_Y > L_Z > L_V > L_W$. Here, L_X, L_Y, L_Z, L_V and L_W represent the length of hydrophobic patches in microchannel #*X*, #*Y*, #*Z*, #*V* and #*W*, respectively. Then, we could design the required time-sequence power control logics to control the thermal bubble actuator via the control of voltage pulse width and bubble-actuation times. The control logics for the voltage pulse width and the bubble actuation times is described and optimized as follows.

Step 1: $T_X \leqq t_1 < T_{X-1}$, and $(X-1)$ times bubble actuation with the voltage pulse time width t_1.

Step 2: $T_Y \leqq t_2 < T_{Y-1}$, and $[(Y-1)-(X-1))] = (Y-X)$ times bubble actuation with the voltage pulse time width t_2.

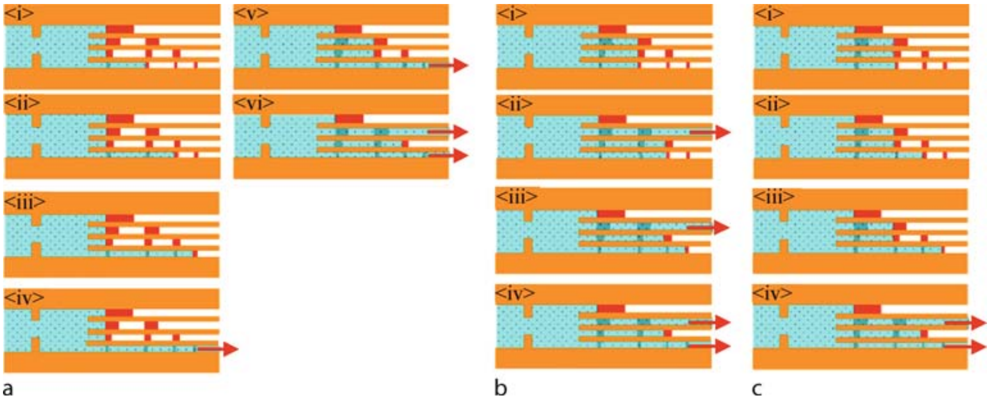
Step 3: $T_Z \leqq t_3 < T_{Z-1}$, and $[(Z-1)-(Y-1)] = (Z-Y)$ times bubble actuation with the voltage pulse time width t_3.

Step 4: $T_V \leqq t_4 < T_{V-1}$, and $[(V-1)-(Z-1)] = (V-Z)$ times bubble actuation with the voltage pulse time width t_4.

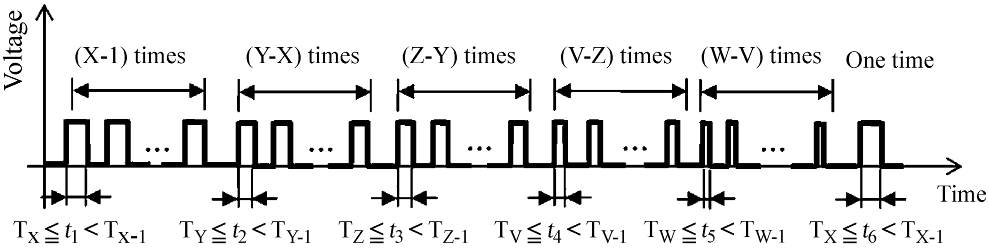
Step 5: $T_W \leqq t_5 < T_{W-1}$, and $[(W-1)-(V-1)] = (W-V)$ times bubble actuation with the voltage pulse time width t_5.

Step 6: $T_X \leqq t_6 < T_{X-1}$, and one more time bubble actuation with the voltage pulse time width t_6,

where t_i represents the required voltage pulse time width at each step; T_i is the required voltage pulse time width



Bubble Actuated Microfluidic Switch, Figure 9 The three different time-sequence power control logics to turn on microchannel #2 and #4 in the capillary system with the 1 × 4 microfluidic switch function



Bubble Actuated Microfluidic Switch, Figure 10 The optimized control logics to turn on microchannel #*X*, #*Y*, #*Z*, #*V* and #*W*. The t_i represents the required power pulse time width at each step. T_i is the required voltage pulse width on the heater to push the fluid to pass the first hydrophobic patch region in microchannel #*i*

on the heater to make the fluid pass through the first hydrophobic patch region in microchannel #*i*; *X*, *Y*, *Z*, *V* and *W* represent the desired turned-on microchannels. Therefore, we could simultaneously guide the fluid into specific desired microchannels by controlling the format and timing of power input based on the above generalized optimal operation steps, which are also summarized and shown in Fig. 10. The control logics could be applied to the capillary system with $1 \times N$ microfluidic switch function.

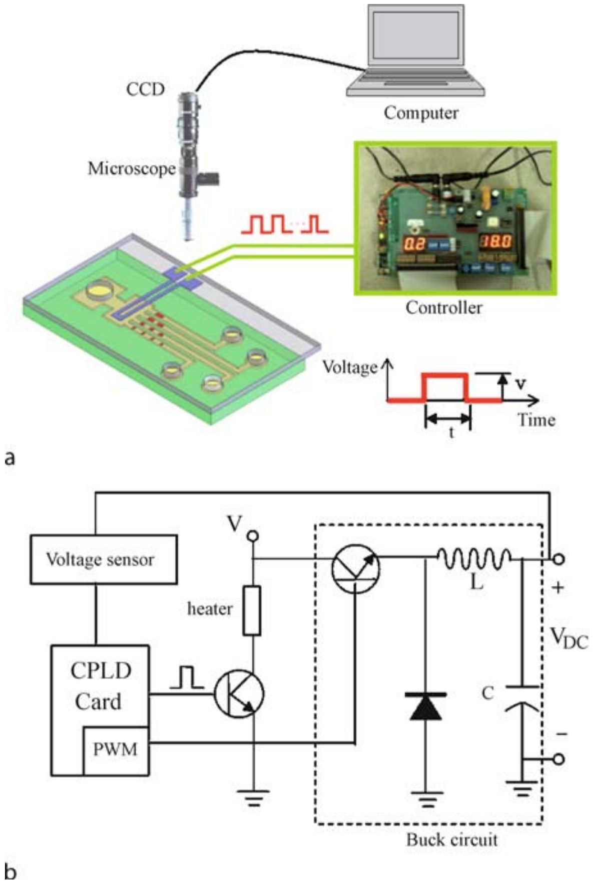
Experimental Results

Experimental Setup

The experimental setup which is utilized to observe the switch function is schematically represented in Fig. 11a. The volume of thermal bubble is controlled by the input pulse power of the heater with a preset duration which is programmed by the controller, composed of the Complex Programmable Logic Devices (CPLD) card, a buck circuit, and adaptors, as shown in Fig. 11a. In Fig. 11b, the programmable CPLD card is utilized to control the duration of the heating and to regulate the voltage amplitude by means of a buck circuit and a pulse width modulation (PWM) method. An optical microscope with a CCD camera is utilized to observe and record the switching process of the capillary system with $1 \times N$ microfluidic switches.

Experimental Demonstration

There are 15 operation modes, as shown in Table 1, for the controller design to operate the capillary system with a 1×4 microfluidic switch. In Fig. 12, two kinds of operation modes were recorded to demonstrate the fluidic switch functions for the capillary system with a 1×4 microfluidic switch. In Table 2, these designed dimensions of the hydrophobic patches are shown. The dyed DI water is introduced into the inlet, as shown in Fig. 12a, driven forward by the capillary force and finally stops at the edge of first hydrophobic patch in each microchannel, as shown in Fig. 12b. Figures 12c–f shows the results of the single-output mode demonstration – the continuous liquid is switched into the single desired outlet port via the control of the programmed bubble volume and the time sequence power control. Figure 12g demonstrates



Bubble Actuated Microfluidic Switch, Figure 11 (**a**) Schematic diagram of the experimental setup (**b**) the control circuit of the micro heater for a square voltage pulse with a preset duration

Bubble Actuated Microfluidic Switch, Table 2 Geometry parameters of the 1×4 microfluidic switch (unit: μm)

	Geometry parameters
Hydrophobic length	$L_1 = 120$; $L_2 = 90$; $L_3 = 60$; $L_4 = 30$
Microchannel width	$D_1 = D_2 = D_3 = D_4 = 100$
Microchannel depth	$h = 20$

the result of the multiple-output modes – the continuous liquid is simultaneously switched into two desired outlet ports, microchannel #1 and #4. This operation mode in the controller breaks the barrier pressures of all hydrophobic patches in microchannel #1 and #4 to continuously drive liquid forward by the capillary force.

According to Eq. (11), the relationship between bubble volume and heating duration is linear for the case. Here, the bubble volume is characterized via the captured images by a CCD camera, and recorded along with the heating time under two different applied voltages, 5 V and 10 V, on the 30 μm wide micro heater, as shown in Fig. 13. The bubble growth rate constant, C, could be experimentally determined by the slope of the fitting curve. The bubble growth rate constants are characterized to be 56 and 105 $\mu m/s^{1/2}$ for the applied voltage of 5 V and 10 V, respectively. These experimental results imply that the bubble volume could be controlled by the heating duration and the applied-voltage amplitude. Therefore, the bubble volume can be controlled via the time of applied voltage to control the liquid positions through hydrophobic patches of different length in the device design.

The experimental results in Fig. 14a show the pulse width versus the length of hydrophobic patches in a 1×4 microfluidic switch under different applied voltages, 5 V and 10 V. The required voltage pulse width could be shortened by the lager voltage or the shorter hydrophobic patches. Thus, the magnitude of the applied voltage on heater and the dimension design of the hydrophobic patches would dominate the operation speed of the microfluidic switches. Besides, the relationship between the length of hydrophobic patch and the required voltage pulse width is nearly linear. However, the required pulse width must be increasing with the length of hydrophobic patch. Therefore, the bubble volume can be controlled to push the fluid through the hydrophobic patches with different length by managing the voltage pulse width, and then to drive the continuous fluid into specific outlet ports based on the operational rules and control logics. Also, the maximum temperature of the heater during the heating period can be derived by means of measuring the resistance of the heater at the end of heating based on the curve shown in Fig. 7. The relationship between the heating-pulse width and the maximum temperature is shown in Fig. 14b.

The design in this case-study prototype device remains an issue for the reversible motion of the liquid. This case-study prototype device could be effectively used for the one shot of liquid in both single-output and multi-output modes on demand. For continuous random switch function, another problem appears if we turn on microchannel $\#X$ first and desire to next turn on only microchannel $\#Y$ where $X > Y$. In this continuous switch function, the microchannel $\#(X+1)$ will be also turned on in this case-study prototype device. Anyway, above issues could be resolved via the two-way bubble actuator design [18, 19], which could make the fluid flow backwards in the unwanted microchannel. In addition, this micro fluidic switch has the potential to be integrated into a wider fluidic network system with stop valves or micro flow discretizers which could be used for separation of liquid segments from a continuous source.

Key Research Findings

A capillary system with the appropriate design of bubble-actuated $1\times N$ microfluidic switches is successfully demonstrated to control continuous liquid into the desired outlets without the need of external pumps and MEMS mechanical moving parts. Theoretical models are proposed to study the liquid motion, which is dominated by both the barrier pressure and the capillary force in the device. This capillary micro-fluidic switch system is a valveless switch by means of the triggering bubble-actuator, the capillary force, the design of the distributed hydrophobic patches in the microchannels, and the time-sequence power control. The switch mechanism among

different microchannels in the case-study device is dominated by controlling the format and timing of power input that generates actuation bubbles. The design, synthesis and bubble control with its time-sequence control logics are presented via a case-study example of 1 × 4 thermal-bubble actuated microfluidic switches.

Future Directions for Research

This bubble actuated microfluidic switch could be effectively used for the one shot of liquid in both single-output and multi-output modes on demand. The reversible motion of the liquid is one further research direction. The long-term goal of this research work could be to develop integrated bio-analytical devices with the functions for specific flow guiding, specific flow injection, and precise liquid volume control.

Bubble growth; Explosive Boiling in Microchannels; Confined bubble growth

Definition

Bubble dynamics in a microchannel refers to the nucleation of a bubble on heated flow channel walls and its subsequent interaction with the single-phase or two-phase flow field. ►Subcooled flow boiling refers to the boiling process with the mean flow enthalpy below the saturated liquid enthalpy at the local pressure, while ►saturated flow boiling refers to the boiling process with the mean flow enthalpy at or above the saturated liquid enthalpy but below saturated vapor enthalpy at the local pressure.

Overview

The formation and subsequent growth of a vapor bubble on a heated wall covered with a liquid is controlled by the forces arising from the excess pressure inside the bubble, the surface tension forces at the liquid–vapor interface and at the ►contact line formed by the interface at the heater surface, and the inertia forces resulting from the motion of the flow as well as the interface. The resistance to the phase change process at the liquid–vapor interface is quite small in comparison to the conduction resistance in the liquid surrounding a bubble and is generally neglected in analyzing the bubble dynamics.

Basic Methodology

The bubble dynamics during flow boiling in microchannels has been studied using high-speed video imaging and numerical techniques. The ►nucleation of a bubble and its growth leading to a confined bubble, vapor plug and annular flow have been analyzed under flow boiling studies. The research has primarily been conducted with water and several refrigerants such as R-123 and FC72 as the working fluids.

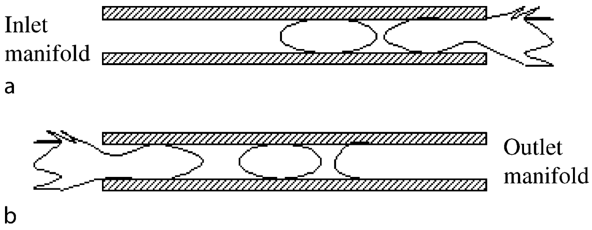
Key Research Findings

►Nucleation and *bubble growth*. Liquid enters a microchannel in a subcooled state and experiences a rise in temperature, while the local pressure falls due to frictional pressure drop along the channel in the flow direction. At some point downstream, the local saturation condition is reached. However, bubble nucleation will not occur immediately at this location as a certain degree of wall superheat is needed to activate a cavity according to the conditions originally suggested by Hsu [1]. The effect of the receding contact angle and the local flow field in front of a bubble was incorporated and the following equation is recommended [2] for nucleation of minimum and maximum cavity radii, $r_{c,min}$ and $r_{c,max}$:

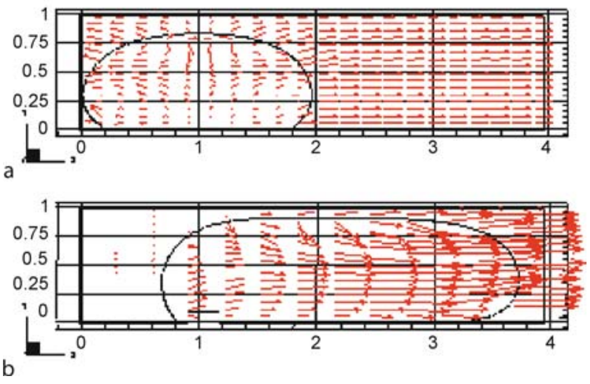
$$\{r_{c,min}, r_{c,max}\} = \frac{\delta_t \sin\theta_r}{2.2}\left(\frac{\Delta T_{Sat}}{\Delta T_{Sat}+\Delta T_{Sub}}\right) \cdot \left[1 \mp \sqrt{1 - \frac{8.8\sigma T_{Sat}(\Delta T_{Sat}+\Delta T_{Sub})}{\rho_V h_{LV}\delta_t \Delta T_{Sat}^2}}\right] \quad (1)$$

where $\delta_t = k/h$; k – thermal conductivity of the fluid, $W/(mK)$; h – single-phase heat transfer coefficient prior to nucleation; θ_r – receding contact angle of the bubble interface on the microchannel wall; ΔT_{sat} – local wall superheat ($= T_{wall} - T_{sat}$), °C; ΔT_{sub} – local liquid subcooling ($= T_{sat} - T_{fluid}$), °C; σ – surface tension, N/m; h_{LV} – latent heat of vaporization, J/kg; and ρ_V – vapor density, kg/m^3.

The experimental studies of Zhang et al. [3] and Li et al. [4], among others, confirm that the conventional nucleation theories of nucleation and bubble growth are valid for microchannel flows as well. The complex interactions due to nucleation, bubble growth and local heat transfer in



Bubble Dynamics in Microchannels, Figure 1 Flow boiling in microchannels with rapid evaporation leading to reversed flow in (**b**) [2]



Bubble Dynamics in Microchannels, Figure 2 Bubble interface movement (**a**) without and (**b**) with a flow restrictor on the left side in a 200 μm square microchannel [9]

smooth circular and rectangular glass channels were studied by Yen et al. [5]. Their results showed that the corners in a rectangular microchannel provided nucleation cavities that initiated the boiling process at lower qualities and resulted in a higher heat transfer coefficient.

As a result of the very high single-phase heat transfer coefficients in microchannels, combined with the small radii of available nucleation cavities on the channel walls, the local liquid subcooling could be very low at the inception of nucleation. Under low flow conditions, it may even be negative, indicating that the bulk liquid is in a superheated state at the location of bubble nucleation [2]. The resulting rapid evaporation at the bubble interface raises the local pressure, creating a condition for fluid backflow. Experimental and numerical studies available in the literature indicate that the instability is predominant at the low heat fluxes [6, 7]. Figure 1 shows the effects of the explosive nature of the bubble growth under high liquid superheat conditions at the onset of nucleate boiling. If the nucleation occurs near the entrance region, the liquid vapor mixture is pushed back into the inlet manifold causing flow instabilities due to vapor condensation in the inlet manifold. If the nucleation occurs near the exit of the channel, the explosive growth propels the forward interface of the expanding bubble into the exit manifold. Backflow is prevented because of the inertia and frictional resistance in the microchannel prior to the nucleation site.

The flow instabilities due to nucleation and explosive bubble growth can be prevented by incorporating a flow restrictor at the inlet to each channel [2, 8]. Mukherjee and Kandlikar [9] analyzed the bubble growth process numerically. Their results, shown in Fig. 2, confirmed that the backflow of the interface can be substantially reduced by controlling the flow resistance at the inlet of the microchannel.

The ▶flow patterns observed in the microchannels are largely similar to those observed in the conventional sized channels. However, the range of conditions and their transitions are somewhat different in microchannels than those observed in conventional sized channels. The influence of heat flux is more apparent during flow boiling in microchannels as compared to the adiabatic two-phase flows. As the bubbles are nucleated, they grow rapidly because surrounding liquid is superheated and the volume of the subcooled or lower temperature bulk core is limited due to small channel dimensions. The bubbly flow therefore does not exist for any appreciable length. The rapid growth of a bubble following its nucleation causes a succession of expanding vapor plugs that are separated by thinning liquid slugs. Eventually the flow assumes an annular flow pattern. Kandlikar [10] modeled the heat transfer process as an extension of pool boiling, in which the microchannel surfaces act as a bubble base that is periodically swept by rapidly moving liquid–vapor interface. This model is supported by the strong dependence of heat transfer coefficient on the heat flux experimentally observed at lower mass fluxes. Several investigators have applied the annular flow model, but prediction of the liquid film thickness poses considerable difficulties. There is a need for experimental data covering wider ranges of heat and mass fluxes and channel geometries for validating these models before they can be successfully applied to practical cases of interest.

Future Directions for Research

Bubble dynamics in microchannels is of great interest in a number of applications, including microchannel evaporators, high-flux heat removal systems for chip cooling applications, ink-jet printers, atomization nozzles and bubble pumps. The high heat transfer coupled with multidimensional heat conduction in the channel wall, and the rapid growth of the bubble at the microscale make it difficult to verify the analytical models. Future research is needed in understanding the heat transfer mechanism

during bubble growth. In this regard, the presence of a ► microlayer, if present, and its thickness and evaporation rate are areas where fundamental understanding is lacking.

Bubble Jet

Definition

The functional principle of a thermal *bubble jet* printhead is based on a current pulse applied to a microheater which leads to a very short heating pulse at the solid–liquid interface. This heating pulse leads to a small vapor bubble which expands explosively. The increasing vapor bubble leads to a volume displacement of the ink towards the nozzle and finally to a droplet ejection. The detaching of the vapor bubble from the hot surface results in a concurrent cooling down of the bubble which results in condensation and collapse of the bubble. The suction of the collapsing bubble and the capillary forces inside the printhead lead to refilling of the nozzle chamber that it is finished before the next shot after approximately 10 μs. The fast explosion of the bubble leads to a characteristic pressure behavior inside the liquid. Starting instantaneously with a very high pressure of about 7 MPa to 9 MPa right at the beginning of the vaporization, the pressure decreases exponentially during a few microseconds.

Bulk micromachining of silicon; Anisotropic silicon micromachining

Definition

Bulk micromachining (BMM) is a set of processes that enable the 3D sculpting of various materials (mainly silicon) to make small structures that serve as components for MEMS devices. Bulk micromachining builds mechanical elements by starting with a bulk material, and then etching away unwanted parts, and being left with useful mechanical devices. Typically, the substrate is ▶ photo–patterned, leaving a protective layer on the parts of the substrate that are to be retained. The substrate is then etched using a ▶ wet chemical etch process, ▶ dry chemical etch process, reactive plasma etch process or photo-etch process. The etch process "eats away" any exposed substrate material on the substrate. Bulk micromachining is a relatively simple and inexpensive fabrication technology to fabricate a micromachined device. It is especially well suited for applications that require only simple microstructures like microchannels, microcavities and free-standing microstructures such as micro-pit or micro-tip.

Overview

Bulk micromachining makes 3D micromechanical devices by etching deeply into a bulk material such as silicon, quartz, glass, plastic or even metal, where silicon and glass are the most common materials used in MEMS technology. These processes have been broadly applied in the fabrication of micromachined sensors, actuators, transducers and some functional structures. In practical applications, single-crystalline silicon is the most popular substrate to be used as the bulk material for bulk micromachining processes. The excellent electrical and mechanical properties of single-crystalline silicon make it a desirable material in the MEMS field and semiconductor industry. On the other hand, glass-based materials have also been extensively used in fabricating microfluidic channels for bioanalytical applications due to their low price and excellent material properties. These two materials have become the major materials for microfluidic and nanofluidic applications. They have also led to a focus on the development of different machining technologies to fabricate functional microfluidic devices in these two materials.

Table 1 summarizes the basic fabrication characteristics for these materials. Because of the rapid growth of the semiconductor industry, silicon has become one of the best-known materials in the world and can be obtained as a single-crystal structure at a reasonable price. The rapid growth of the demand for miniaturized devices also makes single-crystalline silicon the most popular material for bulk micromachining processes. However, silicon substrate is opaque in the UV-visible wavelength range such that it is difficult to observe micro- or nanofluids inside the fabricated microdevices. Also, the fabrication process is comparatively delicate and expensive even though the techniques for machining silicon substrates have been well developed, and there are plenty of tools to machine silicon into various kinds of structures.

Alternatively, silica-based devices are also important in micro- and nanofluidics since they provide advantages over other materials, including high chemical resistance and mechanical strength, large optical transmission range and good electrical insulation. Silica-based materials also have good biocompatibilities for most living cells. These materials in their native state have Si–OH functional groups on their surface, which provide an easy way to chemically modify the surface properties. However, silica-based materials such as quartz and borofloat glass are relatively expensive and rare in compare with general-purpose glass slides. These materials also have a low etch rate in hydrofluoric acid (HF)-based etchants. They also require expensive etching masks such as metal/polysilicon/nitride layer. Alternatively, soda-lime glass has several advantages over borofloat glass and quartz. The cost is much lower and the fabrication process is also much simpler and cheaper. The only drawback is that the impurities in the soda-lime glass is much more than the quartz and borofloat glasses, which may produce insoluble precipitates during etching process. In general, the amorphous structure of glass-based results in an isotropic etching pattern during wet chemical etching. As a result, the aspect ratio of the patterned structures is typically less than 0.5, which could limit their use for high-aspect-ratio microfluidic applications. Microfabrication of miniature analytical instruments on glass substrates for chemical and biomedical application has recently been widely studied. Various microfluidic devices have been fabricated on planar glass and quartz chips for μ-TAS such as capillary electrophoresis, electrochromatagraphy, DNA separations and semen testing. Planar glass chips fabricated by micromachining technologies meet the requirements of miniaturized total analysis

Bulk Micromachining, Table 1 Characteristics of typical materials for bulk micromachining in MEMS field

	Silicon	Quartz	Glass
Transparency	No	Yes	Yes

Structure aspect ratio	Wide range	Typically < 0.5	Typically < 0.5

systems. Considerable attention is now directed towards how to simplify, reduce the cost and reduce the time of the manufacturing processes.

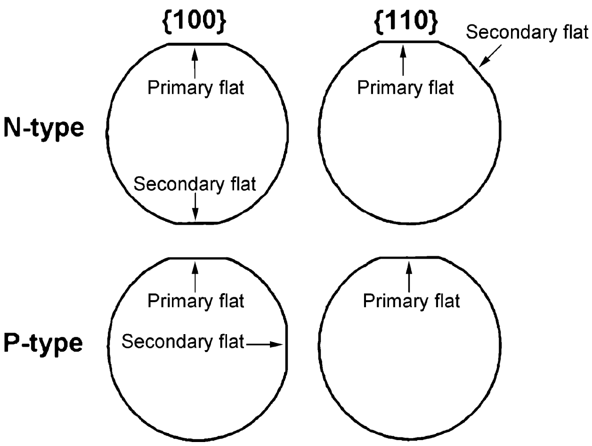
In this article, bulk micromachining techniques for fabricating microfluidic devices in silicon and glass materials are summarized. The details of the fabrication characteristics and fabrication protocols are described.

Basic Methodology

Bulk Micromachining of Silicon-Based Materials

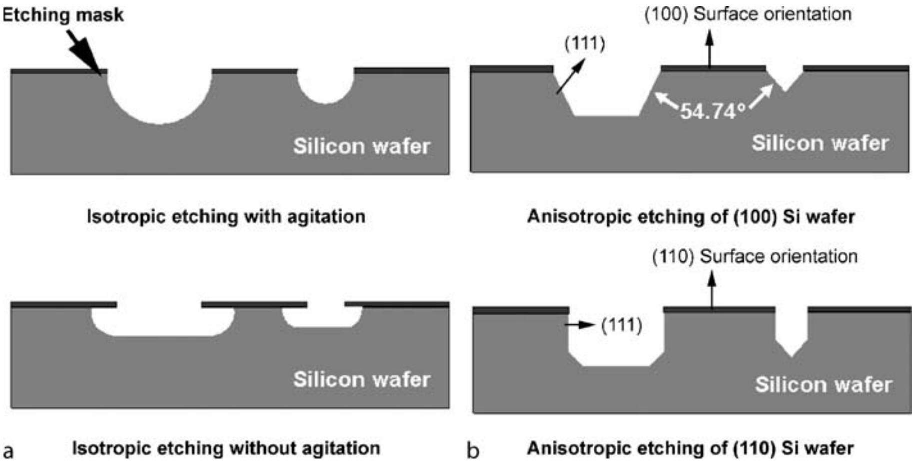
Bulk micromachining of silicon uses wet- or dry-etching techniques in conjunction with etch masks and etch-stop techniques to sculpt a microstructure from the silicon substrate. The purpose of silicon bulk micromachining is to selectively remove significant amounts of silicon from a substrate to fabricate 3D structures in bulk micromachined silicon. The available etching methods fall into three categories in terms of the state of the etchant: wet, vapor and plasma. Wet chemical etch is the most popular method among these techniques due to the process being cheap and easy. However, the geometries of etched features using the wet chemical etching technique are usually greatly corresponding to the crystal orientation of the silicon substrate. The etch rate of dry etching may depend on the selected etching recipe and the etching mechanism of the equipment. In general, silicon wafers are usually cut to give top surfaces that roughly correspond to the main crystal planes in silicon given by the Miller indices (100), (110) and (111). Figure 1 shows the geometrical shape of a wafer and the crystal direction and polarity. For microfluidic and nanofluidic purposes, (100) wafers are the most popular because of the possibilities for the crystallographic-dependent wet etching.

Wet bulk micromachining was first developed in the Bell Telephone Laboratories in the mid-1960s. Anisotropic etching of silicon was achieved in a wet chemical solution composed of KOH, alcohol and water. Bulk micromachining using chemical and electrochemical etching processes

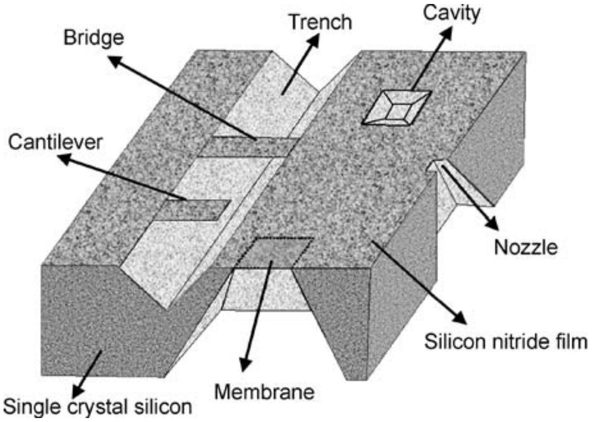


Bulk Micromachining, Figure 1 The geometrical shape of a wafer reveals the crystal direction and polarity

was pursued and became an extension of IC technology for the fabrication of 3D structures [1]. There are two major strategies, isotropic etching (crystal orientation independent) and anisotropic etching (crystal orientation dependent), adopted for this process. Figure 2 illustrates the possible features of the cross-section of a water substrate created using isotropic (Fig. 2a) and anisotropic (Fig. 2b) etching techniques. In general, the etched side wall is in round feature for a channel fabricated using ►isotropic etching since the etch rates in all directions are equal. However, a shallow dish-like feature would be obtained if the agitation during etching process is poor. On the other hand, the features created using ►anisotropic etching typically exhibit perfectly flat surfaces and are well defined. V-groove, U-groove and pyramidal pits can be fabricated with this approach. One can also form a famous feature of 54.74° sidewall while anisotropic etching (100) silicon. Figure 3 presents the typical structures which can be fabricated in (100) silicon using the anisotropic etching technique. The chemical reactions of wet etching rely on the oxidation of silicon to form compounds that can be physi-



Bulk Micromachining, Figure 2 The possible features of the cross-section of a water substrate created using isotropic (**a**) and anisotropic (**b**) etching techniques



Bulk Micromachining, Figure 3 Typical structures which can be fabricated in single-crystal silicon using the anisotropic etching technique

cally removed from the substrate. The etching characteristics of the etching result are defined by the compositions of the etching chemicals, the material exchange rate of reactants and products, and some other minor factors. These include the temperature of the etching solution, the existence of additives and the shapes of the masks used to define the etched regions [2]. Table 2 provides a generalized comparison of the various etchants in terms of many of these important properties [3]. An excellent review article describing the techniques for silicon bulk micromachining can be found in Ref. [3].

Isotropic Etching of Silicon

HNA is the most popular etchant for silicon isotropic etching. The etchant is usually composed of hydrofluoric acid (HF)/nitric acid (HNO_3)/acetic acid (CH_3COOH) with a volume ratio of 1:3:8. Regarding the chemical reaction mechanism, silicon is firstly oxidized by nitric acid to form silicon oxide which is then etched away by hydrofluoric acid. Acetic acid in the recipe acts as the diluent which is essential for achieving the reaction. Water can also be used to dilute the mixture of HF and HNO_3, but this leads to dissociation of nitric acid and significantly reduces the etching speed. The rate-determining reaction of the HNA etching process is the oxidation of silicon. Therefore, increasing the ratio of nitric acid in the HNA solution will increase the reaction rate of the process. However, the surface will be slightly rougher in comparison with the surface etched using a normal HNA solution. Some negatively charged additives such as bromide, iodine or CrO_3^- can be used to reduce the surface roughness. Note also that the HNA isotropic etch is sensitive to the doping concentration of the silicon substrate. The etch process is slowed down in rate about 150 times by regions of light doping ($10^{17}\,cm^{-3}$ n- or p-type) relative to more heavily doped regions [4, 5]. The overall reaction can be expressed as:

$$6HF + HNO_3 + Si \rightarrow H_2SiF_6 + HNO_2 + H_2O + H_2$$

Anisotropic Etching of Silicon

The most often used etchant for silicon anisotropic etching is KOH. The recipe is often mixed with isopropyl alcohol (IPA) to saturate the solution to increase the etch selectivity for (111) versus (100) planes. Generally, the etch selectivity on the (111) plane can be up to 400 times slower than on the (100) plane while using alkali hydroxide solutions as etchants for silicon anisotropic etching. In addition, the etch rate for KOH anisotropic etching

[1] Sublimation from solid source.
[2] Varies with wt% TMAH, can be controlled to yield very low roughness.
[3] Addition of Xe to vary stoichiometry in F or Br etch systems can yield optically smooth surfaces.
[4] Some formulations do not attack Al, but are not common.
[5] With added Si, polysilicic acid or pH control.
[6] Defined as 1) allowing wafer to be immersed directly with no special measures and 2) no alkali ions.
[7] Includes cost of equipment.

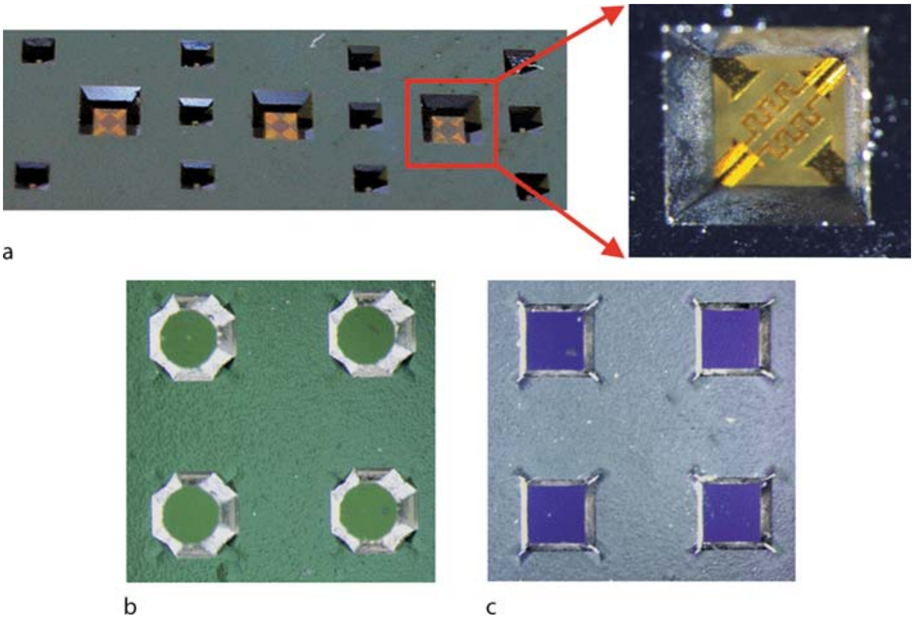
of silicon is highly dependent on the concentration and the temperature of KOH. A concentration in the range of 40–[%wt]50 and temperature in the range of $70-80\,°C$ are typically adopted for the KOH etch process. Note that concentrations below [%wt]20 are not used due to high surface roughness and the formation of potential insoluble precipitates.

The reaction mechanism of the etch process is not fully clear. Several researchers proposed physical models for silicon anisotropic etching from the viewpoints of energy band gap [4, 5] and Gibbs free energy [6]. Over these models, one equation describing the simplified reaction mechanism is addressed as follow:

$$Si + 2OH^- + 2H_2O \rightarrow SiO_2(OH)_2^{2-} + 2H_2$$

Impurity doping can also be applied for slowing down the etch rate for silicon anisotropic etching in alkali hydroxide solutions. The etch rate was drastically slowed down in regions doped with boron to a concentration of $2\times10^{19}\,cm^{-3}$ [7]. However, fabricating microstructures of complex and arbitrary geometry is very difficult since the geometry of the microstructure fabricated using anisotropic etching process is limited by the crystal orientation. In order to overcome this drawback, an advanced deep etching technique utilizing high-density plasma and a wafer bonding process were developed. Reactive ions can perform consecutive etching of Si wafers up to a depth of a few hundred micrometers, while maintaining smooth vertical sidewall profiles. The other technology, wafer bonding, permits a Si substrate to be attached to another substrate, typically Si or glass. Three-dimensional complex microstructures can be achieved with this combination [3].

Figure 4a presents photo images of a micro gas sensor array fabricated using wet bulk micromachining, a typi-

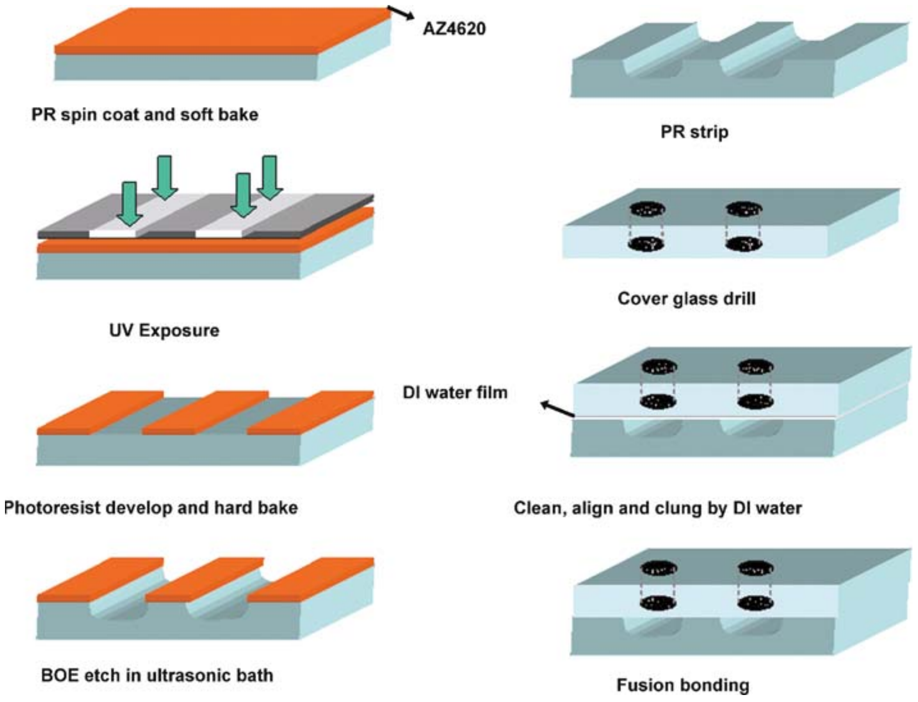


Bulk Micromachining, Figure 4 (**a**) Micro gas sensor array comprising micro-hotplates. (**b**) Etched mesa structures without convex corner compensation mask. (**c**) Etched mesa structures with convex corner compensation mask

cal application of silicon bulk micromachining. A micro gas sensor array comprising micro-hotplates with Pt resistance heaters was fabricated on a suspension silicon nitride film of 2 μm in thickness. The inset shows a close-up picture of a micro gas sensor. A wet bulk micromachining process was used to sculpt the silicon structure under the suspension micro-hotplates in order to eliminate thermal conduction and reduce thermal budget during operation. In addition to the cavity structure, mesa structures with convex corners are usually fabricated using wet bulk micromachining. However, convex corners where (111) planes meet are not stable during silicon anisotropic etching. These convex corners are rapidly undercut along {212} planes and other exposed unstable planes. Figure 4b shows the etched mesa structures with convex corner attacking features. This problem can be easily solved using corner compensation masks which preserve convex corners during the wet etching process. Figure 4c shows the etched mesa structures with the corner compensation design. A sharp convex corner was preserved after the etching process. On the other hand, undercut at convex corners also permits the creation of suspended structures such as cantilever beam and bridge structure. One special case for undercut of silicon substrate in anisotropic etch is mask misalignment. Mask misalignment with respect to the crystal lattice will result in uneven undercutting since the etching will proceed along crystal planes. The effect of misalignment is to enlarge the etched region. In general, if etched long enough, any mask-layer feature will result in a rectangular V-groove pit beneath a rectangular shape that is tangent to the mask features. Furthermore, the edges of the formed rectangular are oriented along ⟨110⟩ directions. A number of commercial and home-built computer simulation software packages have been developed to predict the etched pattern for silicon anisotropic etch [8].

Bulk Micromachining of Glass-Based Materials

Bulk micromachining of glass-based materials is a simple, fast and low-cost way to fabricate planar microfluidic devices. Here we present a fast process for bulk micromachining the glass-based materials especially for ►soda-lime glass. Rather than using a time-consuming vacuum deposition process to fabricate the mask required to etch the plates in an HF-based etchant, a 3 μm thick AZ4620 photoresist layer can be used as the masking material in the wet chemical etching process. An excellent surface quality can be obtained by an improved etching procedure. We also describe a shorter thermal bonding process without sophisticated polishing and cleaning procedures. A high bonding yield is obtained by using sintered alumina flats as the upper and underlying supports. This simple fabrication method will enable fabrication of microfluidic structures in an efficient way. The major contributions of the method is a novel process to remove the formed participant during the wet etching pro-



Bulk Micromachining, Figure 5 A simplified overview of the fabrication process which was used to form planar microfluidic channels on glass substrates

cess and a two-step baking process to prolong the survival time of the photoresist etch mask in the etchant. In the following we describe the details of the proposed method.

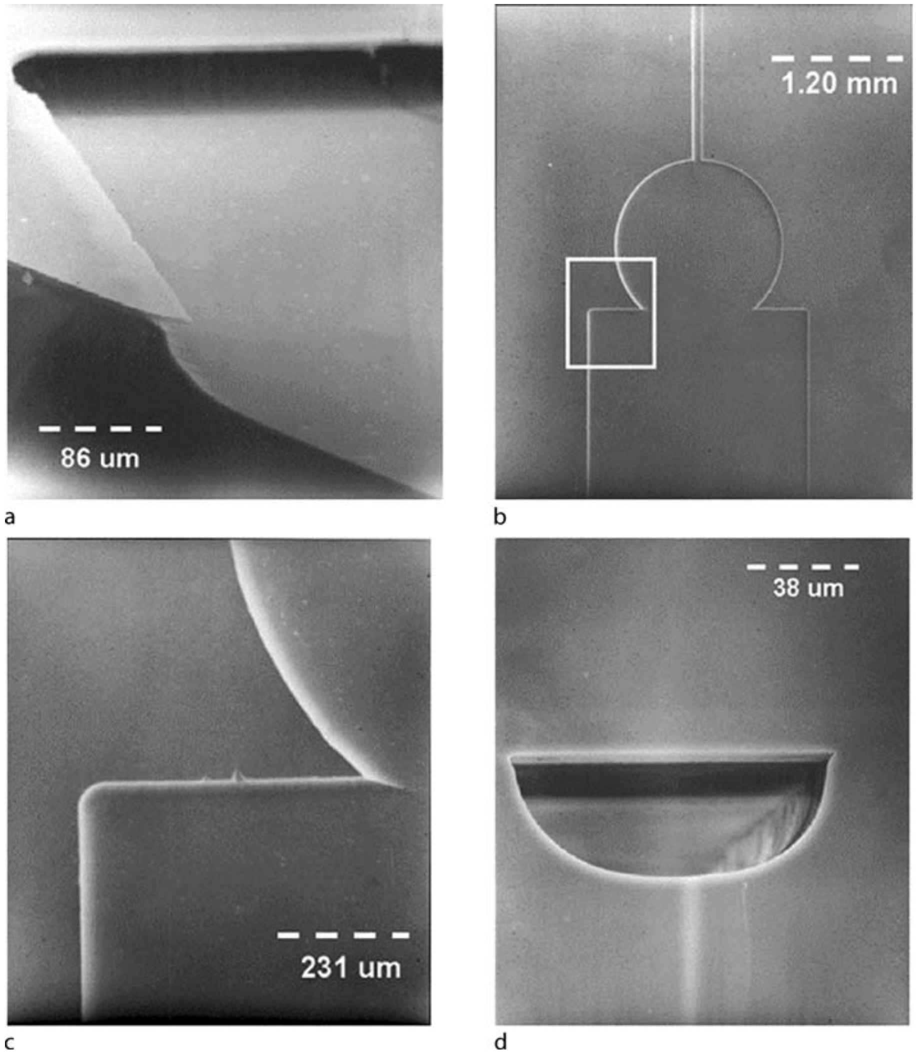
Soda-lime glass is a multicomponent mixture of SiO_2 (72.8%), Na_2O (13.7%), CaO (8.8%), MgO (4.0%) and small amounts of Fe_2O_3 (0.12%) and Al_2O_3 (0.1%). Insoluble products will be present and crystalline precipitates will be formed while etching soda-lime glass in HF-containing solution [10]. Since K_{sp} (solubility product constant at 25 °C) values of CaF_2 and MgF_2 are 4.0×10^{-11} and 6.4×10^{-9}, respectively, it is believed that most insoluble products are mainly CaF_2 and MgF_2. In order to solve the problem, 1 M HCl solution can be used to turn the precipitates into soluble products of $CaCl_2$ and $MgCl_2$. The equation below describes the chemical reaction for glass-based materials etched using HF-based etchants. The etch rate is about 0.9 µm/min for soda-lime glass etched in buffered HF solution (BOE, buffered oxide etchant) at room temperature and, with undoubtedly, the etching is isotropic inherently:

$$6HF + SiO_2 \rightarrow H_2SiF_6 + 2H_2O$$

In general, polished soda-lime glass or commercial microscope glass slides are preferred for this process. Note that the glass slides need to be annealed at 400 °C for 4 hours to relieve the residual stress inside the slides prior to the fabrication process. Otherwise, needle-like structures may form on the etched surface due to the stress corrosion effect, which may blur the glass and result in a rough surface. The simplified schematic for the fabrication process is shown in Fig. 5. The following describes the details of the fabrication process for wet bulk micromachining of microfluidic device in soda-lime glass [9].

Substrate Cleaning The glass substrates were firstly cleaned in a boiling Piranha solution (H_2SO_4 [%] : H_2O_2 [%] = 3 : 1; *Caution: Piranha solution is a very strong oxidant and is severely exothermic during reaction: it should be handled with extreme care*) for 10 min, then rinsed in DI water and blown-dry with nitrogen gas or CDA (clean dry air). The dehydration process was done by baking the glasses on a hot plate (100 °C) for 3 min to remove residual water molecules.

Lithography The glasses were then spin-coated with HMDS solution and baked on a hot plate (100 °C) for 3 min in order to improve the adhesion of the PR. The primer-treated substrates were coated with AZ 4620 positive PR, and a novel two-step baking process was used in this study. First, a soft-baking process was carried out

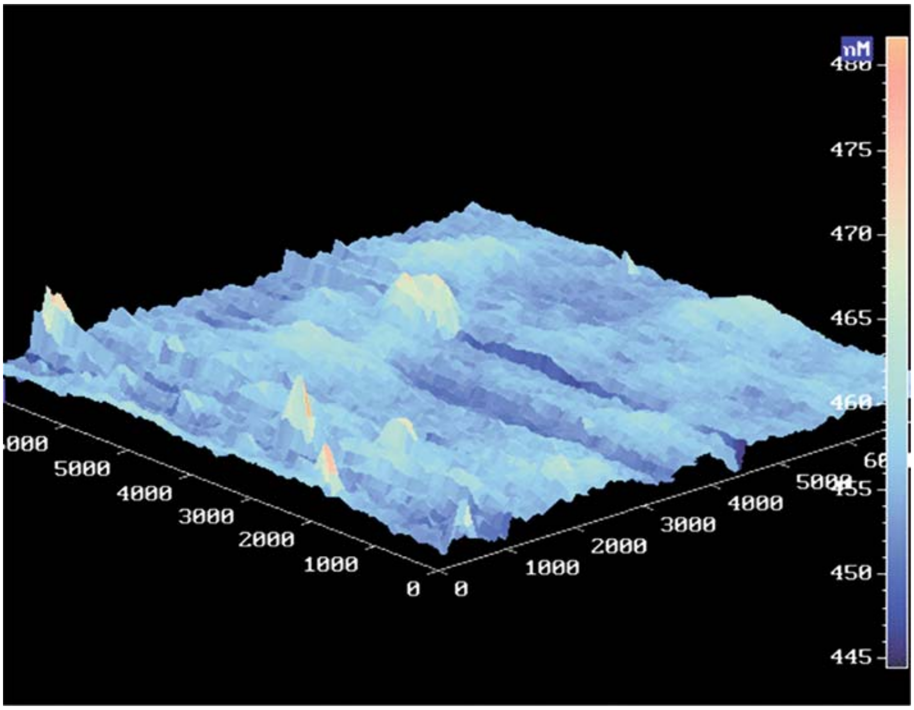


Bulk Micromachining, Figure 6 SEM images of the fabrication results of the proposed method. (**a**) Etched glass surface with PR etch mask. (**b**) After removing the PR mask. (**c**) Close-up view of a sharp corner. (**d**) Cross-sectional view of the sealed microfluidic channel after fusion bonding

at 100 °C for 1 min, 120 °C for 1.5 min, and then maintained at 100 °C for another 1 min. This two-step process can reduce the thermal stress between the glass substrate and the PR, resulting in longer survival time of the positive PR in BOE etchant. The thickness of the PR was approximately 3 μm after soft-baking. The UV lithography was carried out using a mask aligner and exposure dose was 180 mJ/cm^2. The developing of the PR was accomplished in 70 s by immersing the exposed substrate into the developer (one part AZ A400K developer : three parts DI water). After rinsing with DI water and blown-dry by N_2 gas, hard-baking of the PR was carried out at 120 °C for 1 min, 145 °C for 10 min, and then returned to 120 °C for 1 min.

Glass Etching After baking of the PR, the glass substrates were immersed in the BOE (6:1) etchant. The etching was done in an ultrasonic bath. In order to remove precipitated particles, we interrupted the etching process every 5 min and dipped the substrates in a 1 M HCl solution for 10 s during the etching process. After the HCl dipping, the substrates were then cleaned by dipping in DI water and then immersed into BOE etchant again. The etching and de-precipitation processes were iterated until the etching process was finished.

Glass Bonding The etched glass substrate and another cover glass with drilled via-holes were cleaned using boiling Piranha solution for 10 min and then rinsed by DI

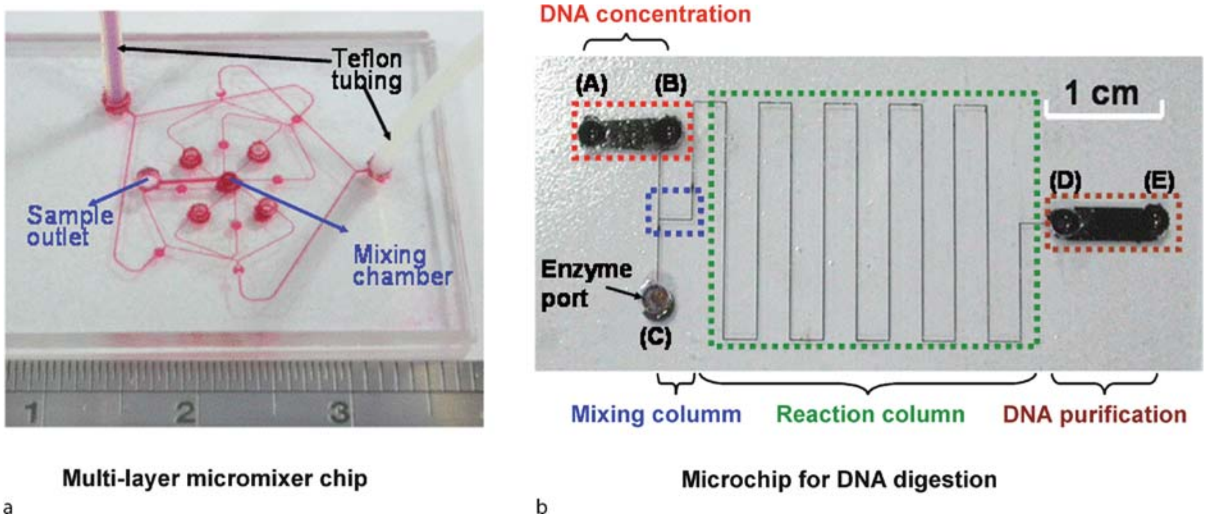


Bulk Micromachining, Figure 7 The surface profile of an etched glass substrate by using an atomic force microscope

water in ultrasonic bath for 3 min. The two glass flats were then carefully aligned and clung to each other by DI water. The atmospheric pressure will hold the two glasses tightly prior to ► thermal fusion bonding process. Bonding was performed by fusing the two glass substrates in a sintering oven at 580 °C for 20 min with a ramp rate of 5 °C/min. Polished alumina flats were stacked as upper and underlying plates which prevented the formation of fusion between glass substrate and alumina flats and kept the glass surface smooth. A sealed microfluidic device could be formed after bonding of the two glass plates.

Figure 6 shows SEM images of the fabrication results of the proposed method. Figure 6a is the etched glass substrate with PR etch mask. The feature of isotropic etching with an undercut structure of the glass substrate can be clearly seen. An etched microfluidic channel and a reservoir structure after removing the PR etch mask are shown in Fig. 6b. An etched microfluidic channel with a sharp geometry and smooth etched surface structures was observed. The close-up image of the inset in Fig. 6b is shown in Fig. 6c. It indicates that the edge of the sidewall is well defined due to good adhesion of PR on the glass substrate. Figure 6d shows a cross-sectional view of the bonded channel. The etched channel remained its original shape and the interface between the two glass substrates disappeared after the fusion bonding process. The bonding process can seal microfluidic channels of up to 3 mm in width without collapsing. It is also found that bonding temperature and holding time are the major factors for the fusion bonding process. Applied pressure and temperature ramping procedure only have minor effects on bonding quality. Temperature below 570 °C caused an incomplete bonding even though two plates were held for a long period of time. While temperature was higher than 580 °C and holding time was longer than 30 min, it resulted in fusion of the glass substrates and the alumina plates, causing cracking of the device due to the difference of the thermal expansion coefficients of the two materials. The bonding process can reduce the operation time, and, more importantly, preserve the original geometry of the etched channel with large area.

The depth and the surface roughness of the etched glass substrates were measured using a surface profilometer (Alpha-step 500). Three different locations on each glass substrate were measured. The average depth of the etched channels is 35.95 μm and the standard deviation is 0.39 μm for all 30 measured values. The etch rate is about 0.9 μm/min at room temperature and the etching is isotropic inherently. The high etch rate and uniformity of the wet etching process was due to the



Bulk Micromachining, Figure 8 Optical images of two microfluidic devices fabricated using the proposed fabrication process. (**a**) Microfluidic vortex mixer. (**b**) Microfluidic chip for rapid DNA digestion and purification

fact that appropriate agitation was achieved by performing the etching process in an ultrasonic bath. Furthermore, ultrasonic agitation will make the insoluble precipitate, such as Al_2O_3, suspend in the solution instead of being deposited on the glass substrates. Figure 7 shows the surface profile of an etched glass substrate by using a scanning probe microscope (Solver P7LS). The maximum peak-to-peak roughness is around 0.71 Å and the average surface roughness (R_a) is less than 0.1 Å inside a 3.0 μm × 5.0 μm scanned area. Figure 8 shows the optical images of two microfluidic devices fabricated using the proposed fabrication process. Figure 8a is a microfluidic vortex mixer fabricated in a three-layer glass substrate and Fig. 8b shows a microfluidic chip for rapid DNA digestion and purification. It is observed that the fabricated microfluidic devices have good surface flatness and good optical transmittance which are beneficial for optical detection afterwards. This simple fabrication process is suitable for fast prototyping and mass production of the microfluidic systems in low-cost glass substrates.

Future Directions for Research

The anisotropic wet etching of silicon is a unique fabrication process in the MEMS field. The need to develop new processes to fabricate functional 3D microstructures in various materials is urgent for progress in microfluidic systems, micro-sensors, micro-actuators and micro-instrumentation. At present, to integrate surface micromachined devices and standard IC devices with bulk micromachined structures to demonstrate a new functional MEMS application is still a challenge for researchers who work in this field. The cooperation of multidisciplinary researchers will be required to develop miniature systems with the most appropriate building philosophy and the best operation performance.

Capacitance cytometry; Capacitive sensing

Definition

A sensing method for detection, counting, or characterizing of the nanoliter droplets, cells or other microparticles by measuring the capacitance change between a pair of electrically charged and isolated conductors.

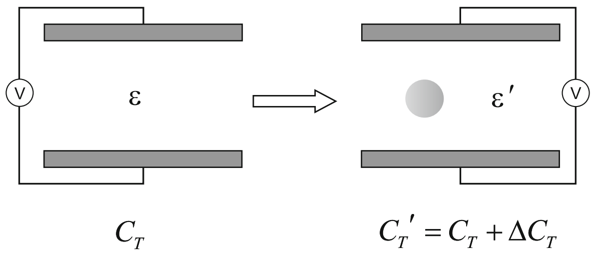
Overview

Capacitive sensors have been extensively applied in sensing pressure, acceleration, deformation, displacement, and position. In recent decades, capacitance methods have found new applications in biomedical analysis. By monitoring the cellular membrane capacitance, one can assay cell cycle progression [1], or differentiate normal and malignant cells [2]. With the latest development of microfluidics, capacitance sensors have been successfully integrated in Lab-on-a-Chip devices. Capacitance method renders an attractive option for detection because they are non-intrusive, highly sensitive and compatible with electrically conducting or insulating liquids.

Sohn and co-workers reported a novel device which can quantify the DNA content within the nucleus of single eukaryotic cells [3]. Since DNA molecules are highly charged in intracellular environment, they will be polarized in an applied low-frequency AC electric field. This polarization response can be measured as a change in total capacitance ΔC_T, across a pair of microelectrodes as individual cells suspended in buffer solution flow one by one through a microchannel (as shown in Fig. 1 and Fig. 2).

They found that there is a linear relationship between the capacitance and the DNA content of a cell. And they further showed that this relationship is not species-dependent. This innovative technique is termed as *capacitance cytometry*, which helps to reveal changes in cellular internal properties and determine the phase of individual cell in cell-cycle.

Chen et al. demonstrated a miniaturized coplanar capacitive sensor which can be integrated with microfluidic platform for detection of droplet position, size, and composition [4]. The inter-digitated, variable width design increases the capacitive signal for liquid structures with



Capacitance Method, Figure 1 Schematics of the capacitive sensing method. When a microparticle, like a cell, passes between a pair of electrodes, the capacitance of the system will be changed

non-uniform height profiles. The capacitive resolution and time response are 0.3 pF and 10 ms, respectively, allowing for accurate and fast sensing functions.

Based on a charge-based capacitance measurement method (CBCM), Ghafar–Zadeh and Sawan designed an accurate and simple topology circuit for measuring very small percentage of differential capacitance variations [5]. The simplified architecture and measurement linearity are highly advantageous in developing capacitive sensors for bio-particle detection.

CEC

Definition

capillary electrochromatography (CEC) is a hybrid separation technique of capillary electrophoresis (CE) and capillary liquid chromatography (μ-LC), and combines both separation mechanism of CE and μ-LC. Capillary chromatographic column with a typical stationary phase is employed as the separation bed. The mobile phase is driven by electroosmotic flow. The separation selectivity results from differences in the retentions on the stationary phase and the electrophoretic mobilities of analytes.

CEC–ESI–MS

Definition

Capillary electrochromatography–electrospray ionization–mass spectrometry (CEC–ESI–MS) is an analytical technique combining electrochromatographic separation and mass spectrometric detection with an electrospray ionization interface.

Overview

► Capillary electrochromatography (CEC) is a hybrid separation technique that combines features of both capillary electrophoresis (CE) and high-performance liquid chromatography employing capillary columns (micro-HPLC). Like HPLC, the chromatographic resolution in CEC is based on the interaction between the analytes and stationary phases. However, in CEC, the analytes move through the separation bed of the column, driven by the electroosmotic flow (EOF), which drives the mobile phase, as well as the self-electrophoretic mobility when charged analytes are separated. Because of the flat pluglike profile of the EOF, CEC offers greatly enhanced separation efficiency compared to HPLC. With the advancement in column technologies, CEC has become a powerful separation technique for the separation of both neutral and charged analytes.

► Mass spectrometry (MS) is one of most useful detection methods for CEC, because it offers many advantages over other conventional detection methods. Most importantly, MS provides information about the chemical structures and molecular weights of analytes. ► Electrospray ionization (ESI) that generates gas-phase ions from analytes dissolved in a liquid phase is a soft ionization interface technique for coupling CEC separation with MS. Thus, CEC–ESI–MS is a promising simultaneous separation and detection technique for biomolecules, because it integrates advantages of high separation efficiency and chromatographic selectivity in CEC and high sensitivity and chemical and molecular mass information in MS detection.

Basic Methodology

The two major parts of a CEC–MS instrumental system are a capillary electrochromatograph and mass spectrometer, which are coupled together by an ESI interface. A schematic diagram of a CEC–MS instrumental system is shown in Fig. 1. Electrochromatographic separation column and ESI interface are two key technologies in CEC–ESI–MS, which are described in the following.

Electrochromatographic Column Technology

Electrochromatographic separation of analytes is performed on stationary phase in electrochromatographic columns. As shown in Fig. 2, three types of columns, namely open tubular, packed and monolithic columns, are used in CEC. In the open tubular column, the stationary phase is bonded or coated on the inner wall of a capillary column. In the packed columns, the particles bonded with chromatographic stationary phases are packed inside the capillary. Frits at the ends of capillary are used for preventing the movement of particles; sol–gel silicate or organic polymer as well as tapered capillary are used to embed the particles so that they do not move during the separation. The monolithic columns, also known as continuous bed with continuous skeleton and micro-scaled throughpores, include polymer-based and silica-based monoliths. Polymeric monolith columns are prepared by in situ polymerization of organic monomers in the presence of a porogen reagent using various initiator techniques such as free radical polymerization or photopolymerization. Silica monoliths are prepared by a sol–gel process including hydrolysis and polycondensation of precursors in a defined solvent in situ to produce a hydrogel, which is then converted to a xerogel upon drying. In the monolith columns, the stationary phases are bonded on the monolithic matrix by in situ copolymerization or post-modifications of bare monolith. In recent years, monolithic columns have received much attention, because monolithic columns offer many advantages over conventional open-tubular and packed columns, including in-capillary preparation, fritless design, high sample capacity and the absence of bubbles during CEC operation. Chen and co-authors developed a series of chiral silica monolithic columns for the enantioseparation of amino acids, peptides and pharmaceutical compounds by CEC

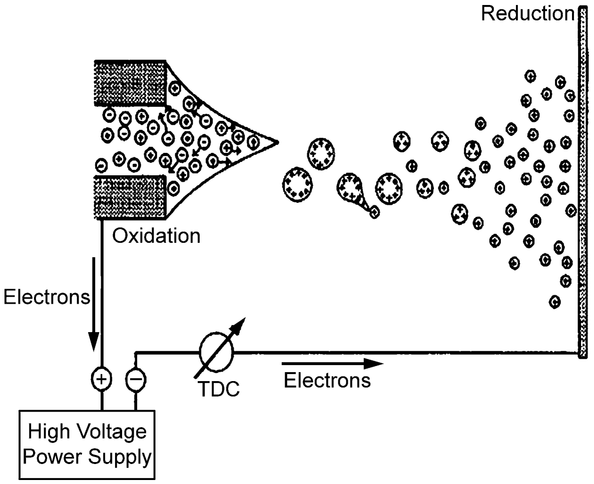
Capillary Electrochromatography–Electrospray Ionization–Mass Spectrometry: An Integrated Electrokinetic Analytical Technique, Figure 2 Schematic of three types of CEC columns



Capillary Electrochromatography–Electrospray Ionization–Mass Spectrometry: An Integrated Electrokinetic Analytical Technique, Figure 3 Schematic of major processes occurring in electrospray (from [4])

and micro-LC [1–3]. These chiral monolithic columns are expected to be used in CEC–ESI–MS for chiral separation. In the design of the electrochromatographic column for CEC–MS, three important factors, namely chromatographic selectivity to analytes, the magnitude and direction of electroosmotic flow and the compatibility with the mobile phases, must be taken into account. The flow rate of EOF is a very important factor, because it not only drives mobile phase and analytes, but also supports the generation of electrospray. A suitable flow rate of EOF for CEC–ESI is in the range of 50 to 300 nL/min. For achieving high efficiency of ionization compatible with MS detection, a minimum concentration of salts, surfactants and other additives in the mobile phase is necessary.

Electrospray Ionization Interface Technology

An ESI interface is an on-line combined interface of CEC and MS. ESI can be used for the analysis of almost all kinds of biomolecules which are polar and soluble in a solvent system, as well as capable of generating spray. ESI-MS has been used for the analysis of peptides, proteins, carbohydrates, DNA fragments and lipids. Figure 3 shows a schematic of major processes occurring in electrospray [4, 5]. The electrospray processes include:

- penetration of imposed electric field into liquid leads to formation of electric double layer in liquid;
- enrichment of surface of liquid by positive electrolyte ions leads to destabilization of meniscus and formation of cone and jet emitting droplets with excesses of positive ions; and

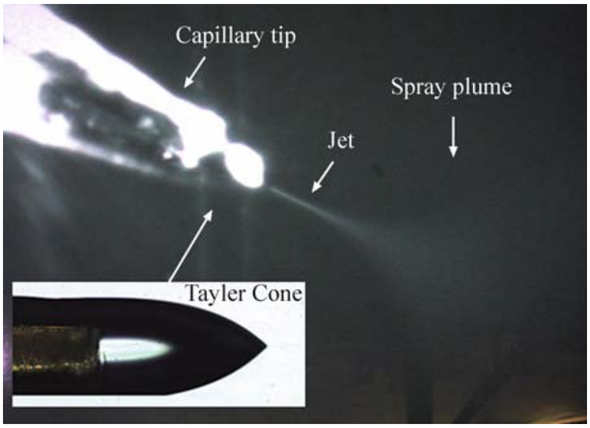
- charged droplets shrink by evaporation and split into smaller droplets and finally gas-phase ions [4, 5].

Figure 4 shows an image of an electrospray obtained at a silica capillary tip. A characteristic feature of electrospray ionization is the generation of multiple charged ions, which allow MS to be used in the analysis of large biomolecules of molecular masses far beyond 100 000. A series of signals including $[M+H]^{+}$, $[M+2H]^{2+}$, $[M+3H]^{3+}$ to $[M+nH]^{n+}$ can obtained from larger biomolecules. Samples used for ESI must be soluble, stable in solution and relatively clean. Salts and additives in the buffers must be kept at low concentration because they may reduce the ionization efficiency.

A suitable electrical connection between the CEC separation and the ESI emitter is a key for the CEC–ESI–MS coupling. Three main interfaces including coaxial sheath-flow interface, liquid junction interface and sheathless interface have been used in CE/CEC–ESI–MS. The main advantages of the sheath-flow interface are the wide flexibility in selection of separation electrolyte solutions, its reliability and the existence of several commercial designs which make it the most widely used interface in CE–ESI–MS routine analysis [6]. However, due to sample dilution and additional background noise from the sheath liquid, the sensitivity in the sheath-flow interface reduces in some cases. The liquid junction interface needs tedious capillary alignment and precise end-to-end butting of the separation capillary and spray tip [7]. Poor alignment causes low sensitivity and separation efficiency due to spreading of sample in the relatively large dead volume of the liquid junction.

The development of sheathless interfaces has attracted much attention because of the compatible flow rates of each technique, which leads to high desorption and ionization efficiency and, consequently, high sensitivity. Several sheathless designs have been reported including (1) the use of a single capillary where electrical contact is established by coating the capillary outlet with a conductive metal or polymer or by inserting a conductive wire into the outlet of the capillary or through a small pinhole in the wall of capillary, and (2) the use of two pieces of capillary where the CE capillary is connected to a short spray tip via a sleeve. The sleeves include a piece of microdialysis tubing, stainless steel tubing, a micro-tee and etched capillary widow [7].

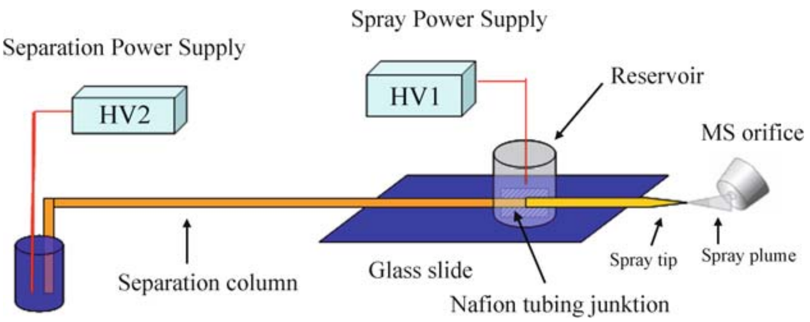
Recently, we developed a chip-scale electroosmotic pump/electrospray coupling device using monolithic silica as EOF-generating material and Nafion tubing as the connection for pumping and electrospray capillaries. This device can generate a very stable electrospray with the support of electroosmotic flow [8, 9]. With the modifications, this device can be used for the CEC–MS interface [10]. Figure 5 shows a schematic sheathless ESI interface of CEC-MS. An open-tubular capillary separation column and a sharply tapered spray capillary (4.5 cm in length) were butted together inside Nafion tubing (5 mm in length). Epoxy was applied around the outside of the Nafion tubing/capillary boundaries. After the epoxy dried, the connected capillary was mounted on a glass slide (2 cm × 5 cm). A PVC tube (5 mm i.d., 8 mm in height) was glued on the top of the Nafion junction to form a reservoir. The reservoir was filled with the same running electrolyte as employed in the separation, and electrospray voltage was applied through a platinum wire dipped into the reservoir and connected to the MS power supply (HV1). The use of an open reservoir rather than an enclosed/limited reservoir avoids problems due to gas bubbles in the liquid circuit. A common ground connection was also formed between the external power supply for CEC separation (HV2), the shielding of the ESI power supply (HV1) lead cable, and the mass spectrometer. Figure 6 shows a sheathless CE/CEC–ESI–MS interface mounted on PicoView nanoelectrospray assembly for Micromass QuattroLC MS. This device offers many advantages, such as ease of fabrication, ruggedness, durability and no dilution effects, over existing devices which require a sheath flow or liquid junction interface.



Capillary Electrochromatography–Electrospray Ionization–Mass Spectrometry: An Integrated Electrokinetic Analytical Technique, Figure 4 Image of nanoelectrospray

Mobile Phase in CEC–ESI–MS

In addition to CEC column and ESI interface technologies, the mobile phase is also an important factor for CEC–ESI–MS analysis. Electrochromatographic separation selectivity relies not only on the stationary phase, but also on the mobile phase. In the choice of mobile phase for CEC–ESI–



Capillary Electrochromatography–Electrospray Ionization–Mass Spectrometry: An Integrated Electrokinetic Analytical Technique, Figure 5 Sheathless ESI interface of CEC–MS (from [10])

MS analysis, both CEC separation selectivity and compatibility with ESI–MS detection should be taken into account. An ideal mobile phase for CEC–ESI–MS should meet various requirements:

- offering high electrochromatographic selectivity for the stationary phase,
- generating sufficient flow rate of EOF for driving the mobile phase and supporting a stable electrospray,
- producing highly efficient gas-phase ions of analytes for ESI, and
- offering high sensitivity and low contamination for MS detection.

Therefore, mobile phases used in CE/CEC–MS often contain exclusively volatile buffer additives, such as formic acid, acetic acid, trifluoroacetic acid, ammonium formate, ammonium acetate, ammonia or volatile organic amines. The mobile phase must be kept at the lowest level of conductivity. Salts, surfactants and other additives should be avoided or eliminated at the lowest level.

Key Research Findings

CEC–MS Applications

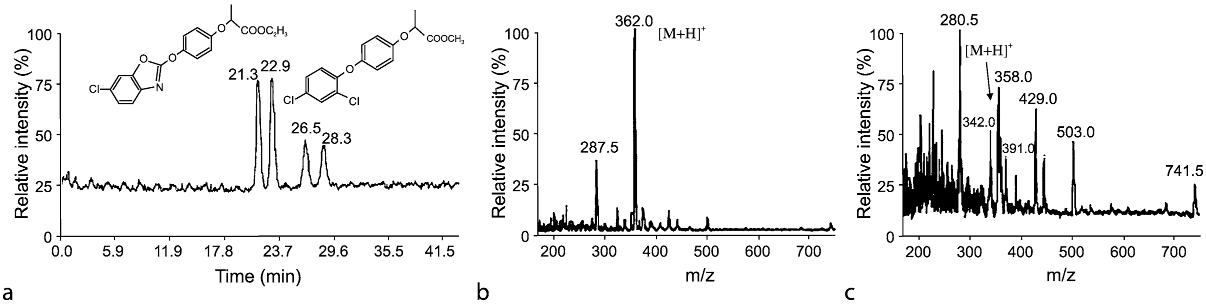
Although the number of papers reporting CEC–ESI–MS is not very many, CEC–ESI–MS has been applied to the analysis of a wide range of species from small ions to biomolecules. Several typical examples of applications are selected for review in the following.

CEC–MS Analysis of Chiral Compounds

CEC–ESI–MS has been successfully used for the analysis of chiral compounds. Coupling of CEC to MS offers many advantages for enantioseparation.

- Since the chiral selector is immobilized on the column matrix, there is no problem that the presence of nonvolatile chiral additives in CE–MS or MEKC–MS results in significant loss of electrospray efficiency and ion source contamination.
- MS detection provides high sensitivity and both molecular mass and structural information. Meanwhile, the CEC separation renders different retention times for enantiomers, as the enantiomers have the same molecular weight for MS detection.
- The nanoliter-scaled flow rates of EOF in CEC are suitable for an ESI source.

Mayer et al. reported open-tubular CEC–ESI–MS analysis of enantiomers of the chiral sedative–hypnotic drug hexobarbital by coupling a short Chirasil-Dex-coated capillary (15 and 25 cm × 50 μm i.d.) via a sheath liquid interface to a quadrupole mass spectrometer [11]. The mobile phase was 10 mM ammonium acetate buffer at pH 7, and the composition of the sheath liquid was 2-propanol/10 mM ammonium acetate at pH 7 (9:1, v/v). Schurig's group reported an on-line coupling of packed CEC with ESI–MS



Capillary Electrochromatography–Electrospray Ionization–Mass Spectrometry: An Integrated Electrokinetic Analytical Technique, Figure 7
Separation of the enantiomers of fenoxaprop ethyl (21.3 and 22.9 min) and diclofop methyl (26.5 and 28.3 min) on a 30 cm × 100 µm i.d. capillary packed with Chira-Dex-silica. Conditions: 20.5 kV; 10 bar; 0.5 mM ammonium acetate buffer in water/methanol (40:60) at pH 6.6. (**a**) Total ion chromatogram in the positive mode. TIC was acquired scanning from m/z 170 to 750. and coordination ion spray (CIS)–MS for the analysis of chiral model compounds including barbiturates and chlorinated alkyl phenoxypropanoates [12]. The separation of enantiomers by pressure-supported CEC is performed in capillaries packed with permethylated β-cyclodextrin-modified silica (Chira-Dex-silica). Figure 7 shows the electrochromatogram and mass spectra. It is interesting that silver(I), cobalt(II), copper(II) and lithium(I) ions have been used for the postcolumn conversion of the analytes to charged coordination compounds which were detected in the CIS–MS mode. In the CIS detection mode, the sensitivity was significantly improved with the addition of $CoCl_2$ in the sheath flow.

Zhang and Shamsi reported the combination of a chiral column tapered at the outlet end and coupled to ESI–MS for simultaneous analysis of (±)-warfarin and (±)-coumachlor [13]. The chiral CEC was performed in capillaries packed with 5.0 µm (3R, 4S)-Whelk-O1 chiral stationary phase. Acetonitrile/5 mM ammonium acetate (pH 4.0) (70:30, v/v) and methanol/5 mM ammonium acetate (pH 8.5) (70:30, v/v) were used as mobile phase and sheath liquid, respectively. It was found that the externally tapered column showed much more reproducible retention time compared to the untapered column. However, because of the fragile outlet end of the external taper, the tip tended to break during the voltage ramp or due to arcing in the spray chamber. To overcome this problem, the same group developed an internally tapered column technology [14], and recently used it in simultaneous enantioseparation and sensitive detection of eight β-blockers by CEC–ESI–MS packed with vancomycin chiral stationary phase [15]. A mixture containing mehanol/acetonitrile/acetic acid/triethylamine at 70:30:1.6:0.2 (v/v/v/v) was selected as optimum mobile phase.

CEC–MS Analysis of Amino Acids, Peptides and Proteins

Studies on proteomics need rapid identification and characterization of large numbers of components such as amino acids and peptides in protein digests. CEC–ESI–MS is a powerful technique for such proteomic studies. Several papers reported pressurized CEC (pCEC) coupled with ESI–MS for the analysis of peptides and/or protein digests, where C_{18} silicagel or mixed-mode C_{18}/strong anion-exchange stationary phase [16] packed column was used as reversed-phase CEC separation and a mixture of water and acetonitrile containing 5–20 mM ammonium acetate was used as a mobile phase. In pCEC, both pressure and electric field are applied across a capillary column simultaneously; the flow profile in the column is a combination of parabolic flow induced by the pressure and flat

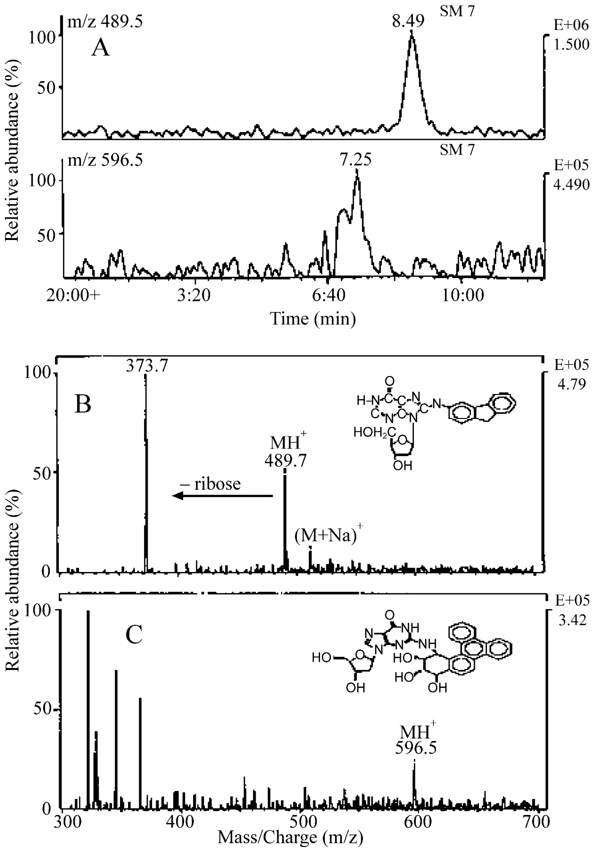
flow caused by the EOF. In pCEC, pressure is not only used to minimize bubble formation, but it also provides a means of tuning selectivity for the separation of charged analytes by varying the electric field. The disadvantage is that the instrumental setup is relatively complicated. Karger's group reported high-efficiency peptide analysis on monolithic polymeric column by pCEC–ESI–MS [17]. The monolithic column was prepared from a mixture of methacrylates, porogens and an initiator with thermally induced in situ polymerization. The monolithic media have properties of fast mass transfer and low pressure resistance, enabling fast separation and coupling to ESI–MS. The same group also reported a microfabricated device that integrates a monolithic polymeric separation channel, an injector and an interface for ESI–MS [18].

Gucek et al. [19] succeeded in the coupling of CEC to an ion trap MS via nanoelectrospray for attomole characterization of peptides. It was demonstrated that it was possible to obtain a stable spray without a sheath liquid being employed by using a conductively coated tip butted to the end of a CEC column packed with 3 μm Hypersil C_8 or C_{18} bonded silica particles. The mobile phase was 3.2 mM ammonium acetate in 50% acetonitrile. In this sheathless interface the maximum sensitivity was obtained at low operating voltages, the best performances were achieved if the system operated at a CEC current of 2 μA, with electric field strength not higher than 500 V/cm because of insufficient flow to sustain the spray or air bubble formation at the spray tip. However, when using the sheath flow interface in the following work of the same group, the setup could bear electric field up to 1000 V/cm and CEC currents in the range 15–20 μA without showing a decrease in performance [20]. Electroosmotically driven solvent gradients were employed for the separation of 12 phenylthiohydantoin (PTH)-amino acids by reversed-phase CEC using Zorbax ODS particle-packed column with a time-of-flight MS detection [21].

We recently reported an open-tubular CEC coupling with a sheathless ESI–MS for analysis of some amino acids and peptides [10]. We employed Lupamin, a high molecular



Capillary Electrochromatography–Electrospray Ionization–Mass Spectrometry: An Integrated Electrokinetic Analytical Technique, Figure 10 Extracted ion electrochromatograms of AAF-dG (m/z 489.5) and benzo[g]chrysene-dG (m/z 596.5) (**a**), and mass spectra of AAF-dG (**b**) and benzo[g]chrysene-dG (**c**) acquired from the 10^{-6} M concentration solution. (From [24])

weight linear polyvinylamine polymer, as stationary phase coated on the inner wall of an open-tubular capillary column. This column has several merits including easy preparation, low cost and good reliability. Positively charged amino groups in polyvinylamine in acidic conditions play three important roles:

- provide a strong reversed EOF for driving mobile phase and analytes from the inlet end of the separation capillary to the electrospray tip,
- function as a stationary phase by allowing specific chromatographic selectivity for resolving amino acids and peptides, and
- eliminate the adsorption of analyte resulting from the electrostatic adsorption in the case of bare silica capillary.

Figure 8 shows the selected ion electrochromatogram of a mixture of amino acids and peptides, in which a baseline separation was achieved.

CEC–MS Analysis of Carbohydrates

Novotny's group published several papers on CEC–MS analysis of carbohydrate mixtures [22, 23]. Ion trap tandem MS was coupled with CEC separation for separation and characterization of oligosaccharides [22, 23]. It was demonstrated that polar monolithic CEC columns containing either cyano or amino functional groups efficiently separated complex mixtures of carbohydrates with the use of mobile phases containing acetonitrile/dilute ammonium formate buffers. The separation of carbohydrate mixtures on both the cyano and amino columns is based on normal-phase mechanism. MS/MS detection mode can provide reliable data on the structural detail of glycans separated by CEC. Figure 9 shows electrochromatograms and MS/MS spectra of a mixture of oligosaccharide isomers [23].

CEC–MS Analysis of DNA Adducts

Human exposures to chemicals found in certain foods or environmental pollutants are linked to a higher risk for cancer. It is known that the initial step in chemical carcinogenesis is the covalent attachment of the chemical to DNA to produce DNA adducts. The structure identification of these DNA adducts is very important in cancer research. CEC–ESI–MS with shealth liquid interface has been demonstrated as a good tool for the analysis of DNA adducts as well as nucleosides with styrene oxide by Vouros and co-authors [24, 25]. Two common DNA adducts, acetylaminofluorene deoxyguanosine (AAF-dG) and an isomer of anti-benzo[g]chrysene 11,12-dihydrodiol 13,14-epoxide, were employed as model compounds. CEC separation was performed on a C_{18} silica gel-packed column and used a mixture of 60% acetonitrile and 5 mM ammonium acetate as the mobile phase. Figure 10 shows the extracted ion electrochromatograms and mass spectra of AAF-dG and benzo[g]chrysene-dG [25].

CEC–MS for Drug Analysis

CEC–MS is used as an analytical tool for pharmaceutical analysis. The CEC–ESI–MS analysis and quantification of a potential drug candidate from 13 structurally related compounds in extracted plasma were reported by Paterson et al. [26]. The CEC column was packed with an experimental 'mixed mode' stationary phase containing both C_{18} and sulfonic acid ligands. These phases promote stable electroosmotic flow across a wide range of pH values and allow a greater choice of buffer pH values. The mobile phase was acetonitrile/25 mM ammonium acetate (75:25) at pH 3.5 adjusted with acetic acid. Taylor et al. reported a CEC–ESI–MS analysis of mixtures of benzodiazepines, corticosteroids and thiazide diuretic drugs [27].

Separations were performed on a fused-silica capillary column packed with Hypersil ODS (3 μm) and Apex ODS (3 μm) particles and interfaced to a Platform MS using a triaxial inlet probe. Strickmann et al. [28] reported the separation of the non-steroidal anti-inflammatory drug etodolac and its phase I metabolites, 6-hydroxy etodolac, 7-hydroxy etodolac and 8-(1'-hydroxyethyl) etodolac, by pCEC coupled with ESI-MS detection. LiChrospher 100 RP-18, 5 μm particles were packed inside a 100 μm i.d. capillary and served as stationary phase. Ammonium formate (10 mM; pH 3.0)/acetonitrile (50:50) was used as the mobile phase. An automated CEC–MS(/MS) using mixed modes of reversed-phase (C_{18}/C_6) and ion-exchange (strong cation exchange, SCX) chromatography columns was used for the separation and detection of drug standards: salbutamol and salmeterol [29], as well as corticosteroids [30].

Future Research Directions

CEC–ESI–MS is a new integrated separation and detection technique for the analysis of biomolecules. It is still in the development stage. The following topics are considered as future research directions including

- new CEC column technology,
- new interface technology coupling CEC with ESI–MS,
- new electrospray principle and instrumental technology,
- microfluidic CEC–ESI devices coupled with MS and
- new applications of CEC–ESI–MS in bioanalysis.

Capillary Electrophoresis

Synonyms

Capillary zone electrophoresis; Capillary electrophoretic separation

Definition

Capillary electrophoresis (CE) is a routine analytical technique for fast and efficient separation of charged species. Under the influence of an electric field, the ionic species in a sample that is introduced as a plug (or zone) into an electrolyte at one end of a capillary will be separated into discrete bands when they migrate to the other end of the capillary at different electrophoretic velocities. However, Joule heating is an inevitable phenomenon in CE that limits the performance of electrophoretic separation.

Surface tension driven filling

Definition

Capillary filling refers to the filling of an open or closed conduit or a reservoir with the aid of capillary (surface tension) actuation mechanisms.

Overview

Capillary-driven filling of microchannels finds important applications in the Micro-Electrical-Mechanical-Systems (MEMS) and micro-total analysis systems for bio-medical and biotechnological applications. A comprehensive theoretical understanding of the capillary filling process can guide the designer to optimize the internal structure of the chip, such as the chambers, binding pillars, splits, valves, etc, in order to avoid any potential filling problem (including air-bubble entrapment and clogging) and to achieve high throughputs.

Basic Methodology

In a generic form, one can write the equation of motion describing the advancement of a liquid meniscus in a gas-filled capillary as

$$\frac{\mathrm{d}}{\mathrm{d}t}(MV_c) = \sum F \qquad (1)$$

where M is the fluid mass being transported, V_c is the velocity of its center of mass and $\sum F = F_{\text{surface tension}} + F_{\text{viscous}} + F_{\text{gravity}}$. Microchannel flows are typically characterized with low Bond numbers (which are indicators of

	Circular microchannel of radius R	Rectangular microchannels of width w and height h
t^*	$\frac{8t\eta}{\rho R^2}$	$\frac{t\pi^4\eta}{8\rho w^2\varepsilon^2\left\{1-\frac{2\varepsilon}{\pi}\tanh\left(\frac{\pi}{2\varepsilon}\right)\right\}}$, where $\varepsilon=\frac{h}{w}$
s^*	$\sqrt{\frac{\eta^2}{\gamma_{lv}\rho R}}\frac{4s}{R}$	$\frac{s\pi^3\eta}{16\varepsilon^2\left\{1-\frac{2\varepsilon}{\pi}\tanh\left(\frac{\pi}{2\varepsilon}\right)\right\}}\sqrt{\frac{\varepsilon}{(1+\varepsilon)\gamma_{lv}\rho w^3}}$
D	$\cos\theta+\frac{Bo}{4}$, where $Bo=\frac{2\rho gRz_0}{\gamma_{lv}}$	$\cos\theta+\frac{\varepsilon}{2(1+\varepsilon)}Bo$, where $Bo=\frac{\rho gwz_0}{\gamma_{lv}}$

the ratio of gravity to surface tension force), and therefore the gravity force is neglected in this analysis. For a capillary advancement by a distance s, simple estimates of various terms appearing in eq. (1) can be made for circular and rectangular microchannels, as summarized in Table 1. In Table 1, ρ is the fluid density, γ_{lv} is the liquid-vapour interfacial tension, η is the fluid viscosity and θ is the contact angle at the interface. In case the fluid is supplied to the capillary channel with the aid of a hydrostatic head, z_0, then there is an additional driving force because of the hydrostatic pressure, which is equal to $\rho g\pi R^2 z_0$ for the circular tube and $\rho gwhz_0$ for the rectangular channel. With the initial conditions of $ds/dt=0$ at $t=0$ and $s=s_0$ at $t=0$, eq. (1) can be solved with the above specification of forces, to yield a general non-dimensional form of the solution as

$$s^{*2}-s_0^{*2}=D\left(t^*-1+\exp(-t^*)\right) \tag{2}$$

where the various non-dimensional parameters are defined as described in Table 2.

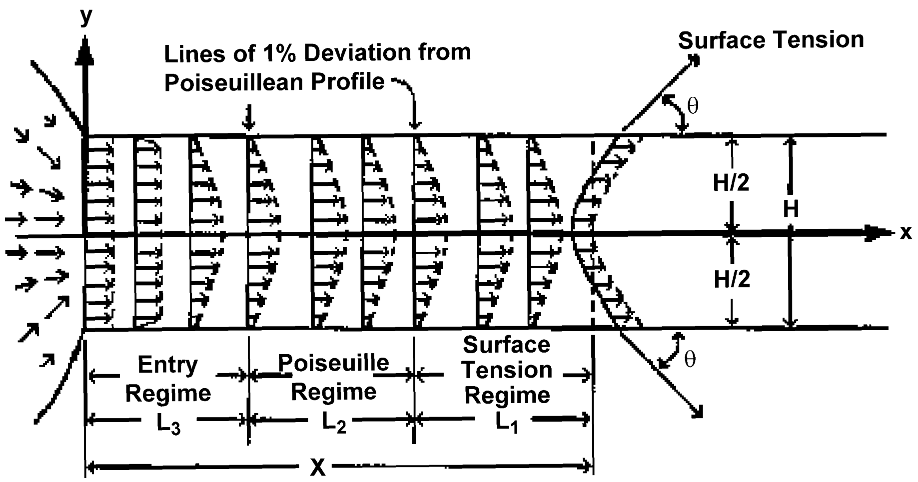
Although quite simplistic in nature, the solution given by eq. (2) may be far from being practical, because of certain unrealistic conditions in-built with the same. In reality, these simplifications can be relaxed to some extent, with the following considerations:

(i) Eq. (1) suffers from a fundamental drawback that as $t\to 0$, $M\to 0$ (since $s\to 0$), giving rise to an ill-posed problem with infinite initial acceleration. This ambiguity can be physically resolved by referring to the equation of continuity, based on which it can be inferred that in the onset of the capillary motion, the liquid present in the dipped portion of the capillary and/or the bulk reservoir to which it is connected also starts moving at the same time. This additional mass of fluid inducted into the motion initially is known as the added mass, m_0. This added mass can be approximated by executing a potential flow analysis for an incoming spherical liquid element that moves with a velocity ds/dt. Executing this analysis, one can obtain the following approximate expressions [1]:

$$\begin{aligned} m_0 &\approx \frac{3\rho\pi R^3}{8} && \text{for a cylindrical tube} \\ &\approx \frac{\rho\pi H^2}{8} && \text{for a rectangular channel of height } H \text{ and unit width} \end{aligned} \tag{3}$$

The above is equivalent to the introduction of an additional term in the left hand side of eq. (1), which eliminates the prediction of an unrealistic initial burst as $t\to 0^+$.

(ii) The consideration of fully developed Poiseuillean flow for drag force calculations may not be practically valid. Classically, the flow through any closed conduit is expected to pass through an entrance region of length L_1, followed by a fully developed regime of length L_2 (which is characterized by a so-called Poiseuillean velocity profile). However, since surface effects tend to dominate in microfluidic channels, a third regime also comes into play, unlike the cases with their macroscale counterparts. This third regime physically originates due to a deviation of the velocity profile from a classical Poiseuillean velocity profile, on account of strong interplay of adhesion and cohesion forces, which gives rise to a dynamically evolving contact angle between the interface and the channel wall. This regime (of length L_3, say) is the so-called menis-



Capillary Filling, Figure 1 Velocity profiles corresponding to the flow into a capillary tube from a droplet

Coefficient	Value for $0 \leq \frac{x}{r_h} < 0.25$	Value for $0.25 \leq \frac{x}{r_h} < 0.35$	Value for $0.35 \leq \frac{x}{r_h} < 1$
a_0	2.36	4.88	1.29
a_1	0.95	−22.4	−2.89
a_2	−24.93	28.0	1.61

cus traction regime (refer to Fig. 1) [2, 3]. In reality, the total length of the fluid column (s_1, say) may vary, as the fluid advances inside the conduit. In case $s_1 < L_1 + L_3$, one has $L_2 = 0$, and hence, the entrance region and the meniscus traction region interact directly. The additional resistances because of the presence of these regimes, in practice, cannot be represented by simple mathematical expressions. However, experimental and/or full-scale computational results can be utilized to a good effect for specification of this enhanced resistance. For example, for the entrance regime, the numerical work of Lew and Fung [4] can be effectively utilized to express the net drag force gradient ($\mathrm{d}F_{\text{viscous}}/\mathrm{d}x$), in terms of its fully developed counterpart ($\mathrm{d}F^*_{\text{viscous}}/\mathrm{d}x$) as

$$\frac{\mathrm{d}F_{\text{viscous}}}{\mathrm{d}x} = \left[1 + f\left(\frac{x}{r_\mathrm{h}}\right)\right] \frac{\mathrm{d}F^*_{\text{viscous}}}{\mathrm{d}x} \quad (4)$$

where r_h is the hydraulic radius of the conduit and the function $f(x/r_\mathrm{h})$ takes care of the enhanced flow resistance in the entry region. Using the numerical results reported in Lew and Fung [4], the function $f(x/r_\mathrm{h})$ can be fitted in the following form:

$$f\left(\frac{x}{r_\mathrm{h}}\right) = a_0 + a_1\left(\frac{x}{r_\mathrm{h}}\right) + a_2\left(\frac{x}{r_\mathrm{h}}\right)^2 \quad (5)$$

where the coefficients a_0, a_1, and a_2 are tabulated in Table 3. It is interesting to observe from the above numerical data that $f(x/r_\mathrm{h})$ is positive everywhere, and becomes zero for $f(x/r_\mathrm{h})$ greater than 0.7 (i.e., when the flow becomes almost fully developed). Equation (4) can subsequently be integrated to obtain the drag force in the entrance regime (per unit width), as

$$F_{D,e} = \left[\int_0^X \frac{\mathrm{d}F^*_{\text{viscous}}}{\mathrm{d}x}\mathrm{d}x + \int_0^X f\left(\frac{x}{r_\mathrm{h}}\right)\frac{\mathrm{d}F^*_{\text{viscous}}}{\mathrm{d}x}\mathrm{d}x\right]$$
$$= r_\mathrm{h}\left[\frac{X}{r_\mathrm{h}} + \int_0^{X/r_\mathrm{h}} f\left(\frac{x}{r_\mathrm{h}}\right) d\left(\frac{x}{r_\mathrm{h}}\right)\right]\frac{\mathrm{d}F^*_{\text{viscous}}}{\mathrm{d}x} \quad (6)$$

where X is the axial length of the entry region under concern. It can be noted here that the term appearing in the above expression can also be expressed as a polynomial function (on integration of expression 5), which may be symbolically represented as $f_1(x/r_\mathrm{h})$ (say). It is extremely critical to recognize here that the net frictional resistance force needs to be quantified using distinctive mathematical expressions, depending on the different flow regimes existing within the channel. For instance, in situations where only the entrance and surface traction regimes exist, they

interact directly with each other. In that case, no Poiseuille flow regime exists, and the net resistance is a combination of the resistances offered by the entrance region and meniscus traction regime. For this, one needs to evaluate the flow resistance offered by the meniscus traction regime separately, based on the corresponding velocity profile. Without any further calculations, it may be concluded at this point that the surface traction regime must have near wall velocity components perpendicular to the wall, so that fluid sticks to the wall. This implies that local axial component of velocity also should increase, in order to satisfy the equation of continuity. If meniscus shape is maintained, the axial velocity component would then become gradually independent of y at the end of the meniscus traction regime. This implies that the boundary conditions for meniscus traction regime are just the inverse of those corresponding to the entry regime (i. e., inlet boundary condition for the entrance regime is same as exit boundary condition for the meniscus traction regime, and vise versa). Therefore, gradient of drag force for the meniscus traction regime can be expressed as (drawing analogy from equation 6)

$$\frac{\mathrm{d}F_{\mathrm{viscous}}}{\mathrm{d}x} = \left[1 + f\left(\frac{x_1 - x}{r_\mathrm{h}}\right)\right]\frac{\mathrm{d}F^*_{\mathrm{viscous}}}{\mathrm{d}x} \tag{7}$$

where x_1 is the total axial length of flow within the channel. A typical situation may be of interest in this regard, when $(x_{\max}/r_\mathrm{h})$ is less than or equal to 2×0.7, (that is, 1.4), i. e., when the Poiseuille flow regime does not exist, and the net drag force is given by a superposition as:

$$\begin{aligned} F_{\mathrm{viscous}} &= w r_\mathrm{h}\left[\frac{\bar{x}_1}{r_\mathrm{h}} + \int_0^{\bar{x}_1/2r_\mathrm{h}} f\left(\frac{x}{r_\mathrm{h}}\right) d\left(\frac{x}{r_\mathrm{h}}\right)\right. \\ &\quad \left. + \int_{\bar{x}_1/2r_\mathrm{h}}^{\bar{x}_1/r_\mathrm{h}} f\left(\frac{\bar{x}_1 - x}{r_\mathrm{h}}\right) d\left(\frac{x}{r_\mathrm{h}}\right)\right]\frac{dF^*_{\mathrm{viscous}}}{dx} \\ &= w r_\mathrm{h}\left[\frac{\bar{x}_1}{r_\mathrm{h}} + 2 f_1\left(\frac{\bar{x}_1}{2r_\mathrm{h}}\right)\right]\frac{dF^*_{\mathrm{viscous}}}{dx} \end{aligned} \tag{8}$$

where $\bar{x}_1$ is the total instantaneous axial length (averaged over the cross section) occupied by the fluid (which is equivalent to the parameter s as introduced earlier). In the most general situation, however, all the three regimes exist (when $(x_{\max}/r_\mathrm{h})$ is greater than 1.4), and the net drag force can be expressed as

$$F_{\mathrm{viscous}} = w r_\mathrm{h}\left[\frac{\bar{x}_1}{r_\mathrm{h}} + 2 f_1|_{\max}\right]\frac{\mathrm{d}F^*_{\mathrm{viscous}}}{\mathrm{d}x} \tag{9}$$

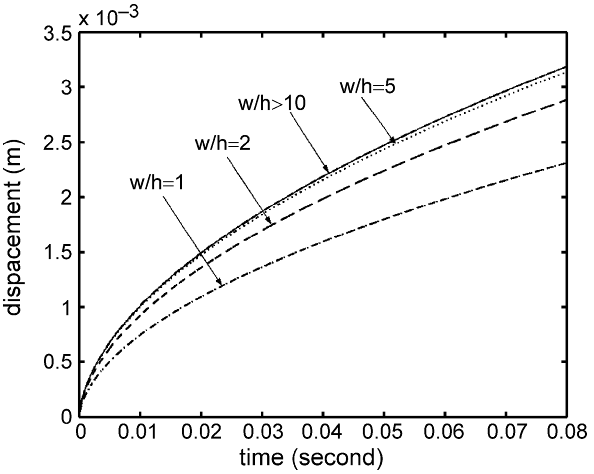
Overall, a realistic estimation of the drag force appearing in equation (1) can be obtained as

$$\begin{aligned} F_{\mathrm{viscous}} &= w r_\mathrm{h}\left[\frac{\bar{x}_1}{r_\mathrm{h}} + 2 f_1\left(\frac{\bar{x}_1}{r_\mathrm{h}}\right)\right]\frac{\mathrm{d}F^*_{\mathrm{viscous}}}{\mathrm{d}x} \\ &\qquad \textit{for} \quad 0 \le \frac{\bar{x}_1}{r_\mathrm{h}} \le 1.4 \\ &= w r_\mathrm{h}\left[\frac{\bar{x}_1}{r_\mathrm{h}} + 2 f_1|_{\max}\right]\frac{\mathrm{d}F^*_{\mathrm{viscous}}}{\mathrm{d}x} \\ &\qquad \textit{for} \quad \frac{\bar{x}_1}{r_\mathrm{h}} > 1.4 \end{aligned} \tag{10}$$

where $\mathrm{d}F^*_{\mathrm{viscous}}/\mathrm{d}x$ is described as

$$\begin{aligned} \frac{\mathrm{d}F^*_{\mathrm{viscous}}}{\mathrm{d}x} &= 8\pi\mu U && \text{for cylindrical microchannels} \\ &= 12\mu U/H && \text{for rectangular microchannels of unit width} \end{aligned}$$

(iii) The contact angle, θ, as appearing in the description of the surface tension, does not remain as fixed during the capillary advancement. Rather, it may undergo a dynamic evolution; on account of capillary slip mechanisms. On a microscopic scale, a possible mechanism in which such slip phenomena might occur on rough solid surfaces could be explained from the perspective that the contact line 'jumps' across indentations while moving along the solid boundary. This effectively leads a generalized expression of the variation of the effective contact angle with the con-



Capillary Filling, Figure 2 Typical displacement characteristics of the capillary meniscus, with variations in the channel aspect ratio (for simulation data, see Chakraborty [3])

tact line velocity in the following form [5]:

$$G(\theta) = G(\theta_0) + Ca \ln\left(\frac{K}{l_d}\right) + Ca \ln Ca \tag{11}$$

where Ca is the capillary number ($Ca = \frac{\eta U}{\gamma_{lv}}$), U being the cross-sectional-averaged axial speed of flow. In eq. (11), θ_0 is the microscopic static contact angle, K is a slipping model dependent constant, l_d denotes the scale of wall roughness and G(θ) is defined as [5]

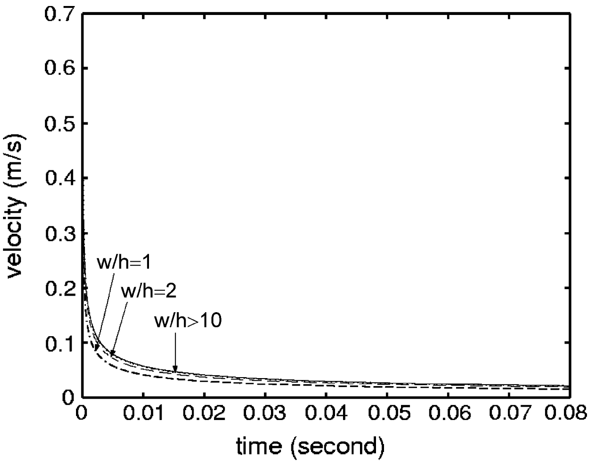
$$G(\theta) = \int_0^\theta [f(\phi)]^{-1} d\phi \tag{12a}$$

$$\begin{aligned} f(\phi) = 2\sin\phi \Big\{ & q^2\left(\phi^2 - \sin^2\phi\right) \\ & + 2q\left[\phi(\pi-\phi) + \sin^2\phi\right] \\ & + (\pi-\phi)^2 - \sin^2\phi \Big\} \\ & \Big/ \Big\{ \left(\phi^2 - \sin^2\phi\right) \\ & \times [(\pi-\phi) + \sin\phi\cos\phi] \\ & + (\phi - \sin\phi\cos\phi)\left[(\pi-\phi)^2 - \sin^2\phi\right] \Big\} \end{aligned} \tag{12b}$$

where q is the viscosity ratio of the two fluids forming the capillary. Moreover, in reality, the microscopic contact angle, θ_0, can itself be dependent on the capillary flow velocity [6]. This gives rise to an additional velocity dependent frictional force, as appearing in eq. (7). The source of this frictional force is the excitation of damped capillary waves at the liquid-vapour interface due the contact line motions over the wall roughness elements. From experimentally obtained data [6], this can be modeled approximately in the following form:

$$F = 2\gamma_{lv}(w + h) BCa^x \tag{13}$$

where B and x are experimentally fitted constants. Some typical values of the various parameters pertinent to the specific slip model presented above are as follows [6]: $K = 0.3$, $l_d = 5000$Å, $B = 2.5$, $x = 0.3$. A physical basis of the introduction of the Ca-dependent and slip-modulated frictional force, F, can be provided as follows. As mentioned earlier, the contact line jumps across the indentations on the solid boundaries, as the contact line moves forward. During the jump, the liquid-vapour interface is pulled forward by the interfacial tension and is retarded by the liquid viscosity. The jump speed is therefore of the order of γ_{lv}/η, i. e., $Ca{\sim}1$. Because of the restoring effects, the liquid-vapour interface actually executes a time-periodic motion on a local scale. Further, the contact line actually slips during the jump process, and the corresponding dissipative effects associated with this jump are responsible for the additional frictional force, which gives rise to a velocity dependent θ_0. One potential slip scenario is that the contact line actually leaves the solid surface on one side of the indentation and reattaches itself on the other side of the indentation, since, without that detachment, the large viscous stress near the contact line would retard the movement the same significantly, so that local jump speeds with $Ca{\sim}1$ would not be realizable.



Capillary Filling, Figure 3 Typical displacement characteristics of the capillary meniscus, with variations in the channel aspect ratio (for simulation data, see Chakraborty [3])

Figures 2 and 3 depict typical displacement and velocity characteristics of the capillary meniscus, as a parametric function of the aspect ratio (w/h) of the microchannel. For more detailed explanations of the pertinent quantitative variations, one may refer to the work of Chakraborty [3].

Key Research Findings

The capillary filling model described as above is somewhat generic in nature and the effects of other driving forces (electric or magnetic fields, for instance) can conveniently be accommodated in the pertinent description of equation of motion. As a first example, one may refer to the capillary flow between parallel plates in the presence of an electromagnetic field [7], with the components of the electric and the magnetic field as $(0, 0, -E)$ and $(B\cos\alpha, B\sin\alpha, 0)$, respectively, where α is the inclination angle of the magnetic field relative to the channel axis. The separation between the two plates, h, is assumed to be much narrower in comparison to the channel width. Axial length of the channel is L. The angle between the direction of gravitational acceleration and the axial direc-

tion of motion is taken to be ϕ. For simplicity, the flow is assumed to be hydrodynamically fully developed, for which the velocity profile can be obtained by introducing the Lorentz (electromagnetic) force term in the linear momentum conservation equation, as

$$-\frac{\mathrm{d}p}{\mathrm{d}x}+\eta\frac{\mathrm{d}^2u}{\mathrm{d}y^2}-B^2\sigma_e\sin^2\alpha u+B\sigma_e E\sin\alpha+\rho g\sin\phi=0 \tag{14}$$

where σ_e is the electrical conductivity of the fluid and y represents the transverse direction in the plane of flow. The no-slip condition is assumed to prevail at the solid boundaries, i. e., $u(\pm h/2=0)$. The pressure boundary conditions are as follows: $p|_{x=0}=0$, and $p|_{x=s}=-\Delta p$ (which represents the pressure at the convex side of the interface), where Δp is the pressure drop across the meniscus, given by $\Delta p=(2\gamma_{lv}\cos\theta)/h$. With the aid of these boundary conditions and noting that $\mathrm{d}s/\mathrm{d}t=\frac{1}{h}\int_{-h/2}^{h/2}u\,\mathrm{d}y$, one can obtain an expression for the capillary filling time as (with $s=0$ at $t=0$)

$$\begin{aligned}t^*=&\left\{\frac{A}{(D_1+D_2)\left(\left(1-2D_4/\sqrt{A}\right)\sinh\left(\sqrt{A}/2\right)\right)}\right\}\\&-\left\{\frac{WeD_3}{(D_1+D_2)^2\left(\left(1-2D_4/\sqrt{A}\right)\sinh\left(\sqrt{A}/2\right)\right)}\right\}\\&\times\ln\left[1+\frac{D_1+D_2}{WeD_3}\frac{s}{L}\right]\end{aligned} \tag{15}$$

The various non-dimensional parameters appearing in eq. (15) are defined as follows: $t^*=tc_0/L$ (where $c_0=(\rho gh^2\sin\phi)/(3\eta)$), $D_1=aHa^2\sin\alpha$ (where $a=E/(c_0B)$, $Ha=Bh\sqrt{\sigma_e/\eta}$), $D_2=3$, $D_3=(-(\mathrm{d}p)/(\mathrm{d}x))\,(h^2/L^2)\mathrm{Re}$ (where $\mathrm{Re}=(Lc_0\rho^2)/\eta^2$), $A=Ha^2\sin^2\alpha$, $D_4=\left(2\exp(\sqrt{A}/2)\right)/\left(\exp(\sqrt{A})+1\right)$, $We=(2\gamma_{\mathrm{lv}}\cos\alpha)/\left(\rho c_0^2h\right)$. The percentage reduction in filling time because of

$$\psi=1-\frac{\text{filling time with EMF}}{\text{filling time without EMF}} \tag{16}$$

The above theoretical model has been numerically simulated in the work of Tso and Sundndaravadivelu [7]. Some major conclusions drawn from their studies can be summarized as follows:

1. The presence of electric field aids the flow, and thereby reduces the flow time for relatively large values of Ha. However, this effect is not unbounded, as it attains an asymptotic saturation with $a\approx 5$. Beyond this limit, any practical filling time reduction cannot be effectively realized by increasing the electric field strength, for a given magnetic field strength.
2. Effect of the angle α on the value of ψ is more significant for small values of a $(0\le a\le 5)$ only.

It needs to be noted here that the above results should better be interpreted from a qualitative viewpoint rather than an accurate quantitative viewpoint, since this analysis neglects the influences of dynamic contact angle, surface roughness, long range molecular forces, EDL effects and the electrical control of surface tension forces.

Dynamic interfacial effects due to capillary advancement in the presence of electroosmotic flows in hydrophobic circular microchannels have recently been investigated by Yang et al. [8]. In a general sense, their theoretical development is based on the prototype equation of motion of the form of eq. (1), with an additional term appearing in the right hand side to model the electroosmotic body force. Not only that, the quantification of the viscous drag force is also adapted to accommodate the influences of electroosmotic slip. To address these issues carefully, one may first derive an expression for electroosmotic flow velocity in presence of an axial electric field strength of E_1 in the solution, as

$$v_x=-\frac{\varepsilon_1\zeta E_1}{\eta}\left[1-\frac{J_0(j\kappa r)}{J_0(j\kappa R)}+j\beta\kappa\frac{J_0(j\kappa R)}{j\kappa R}\right] \tag{17}$$

where ε_1 is the permittivity of the electrolye being transported, ζ is the zeta-potential (see the article on 'Electric double layer fundamentals' for further details), J_0 is the zeroth-order Bessel function of the first kind, $j=\sqrt{-1}$, κ is the inverse of the characteristic electric double layer thickness and β is the slip coefficient (such that $v_z(R)=\beta\left((\partial v_z(R))/\partial r\right)$). The electrical charge density, as obtained by solving the Poisson–Boltzmann equation, can also be expressed in terms of the above-mentioned parameters, as

$$\rho_e=-\varepsilon_1\kappa^2\zeta\frac{J_0(j\kappa r)}{J_0(j\kappa R)} \tag{18}$$

It needs to be noted here that since the surface tension is fundamentally originated from the intermolecular forces and can be related to the thermodynamic work of adhesion and cohesion, the slip length can be estimated by appealing to the pertinent molecular theories as [8]

$$\beta=-\delta\left[\exp\{\alpha A\gamma_{lv}(1-\cos\theta)/k_BT\}-1\right] \tag{19}$$

where δ, A and α, respectively, are the average distances between the centers of the adjacent liquid molecules, the

effective surface area and the fraction of A composed of solid surface. For simplistic estimates, one may assume the liquid molecules to be spherical, with $A = \pi\delta^2$. Typical values of these parameters are $\delta = O\left(10^{-1}\right)$ nm and $\alpha = 1/6$ [8]. Based on these considerations, the electrosmotic body force and the viscous drag force can be estimated as

$$\begin{aligned} F_{\text{electroosmotic}} &= 2\pi s E_1 \int_0^R \rho_e r\,\mathrm{d}r \\ &= -2\pi s E_1 \varepsilon_1 \kappa^2 \zeta \frac{R}{j\kappa} \frac{J_1(j\kappa R)}{J_0(j\kappa R)} \end{aligned} \tag{20}$$

where J_1 is the zeroth-order Bessel function of the first kind.

$$\begin{aligned} F_{\text{viscous}} &= 2\pi R s \left(\eta \frac{\partial v_z(R)}{\partial r}\right) \\ &= 2\pi R \eta s \frac{\mathrm{d}s}{\mathrm{d}t} \frac{j\kappa \frac{J_1(j\kappa R)}{J_0(j\kappa R)}}{1 + j\beta\kappa \frac{J_1(j\kappa R)}{J_0(j\kappa R)} - \frac{2}{j\kappa R} \frac{J_1(j\kappa R)}{J_0(j\kappa R)}} \end{aligned} \tag{21}$$

Noting further that for thin electric double layers, κR is normally larger than 1000, which implies that $-j\left(\left(J_1(j\kappa R)\right)/\left(J_0(j\kappa R)\right)\right) \approx 1$, a simplified expression for eq. (1) can be obtained for this case as

$$\begin{aligned} &\rho\pi R^2 \left[s \frac{d^2 s}{dt^2} + \left(\frac{\mathrm{d}s}{\mathrm{d}t}\right)^2 \right] \\ &= 2\pi R \gamma_{lv} \cos\theta - 2\pi s E_1 \varepsilon_1 \kappa^2 \zeta \frac{R}{\kappa} + 2\pi R \eta \frac{\kappa}{1 - \beta\kappa} s \frac{\mathrm{d}s}{\mathrm{d}t} \end{aligned} \tag{22}$$

It is extremely important to note at this point the electric field E_1 is not the net axial electric field imposed on the capillary, but only the axial electric field acting on the electrolyte (remaining part of the capillary being occupied by a gas of permittivity ε_2, which is displaced by the electrolyte during its capillary advancement). If the electric field acting on the gas phase is E_2, then one can write: $\varepsilon_1 E_1 = \varepsilon_2 E_2$. If V_0 is the net axial voltage that acts on the capillary of total length L, then one can write

$$E_1 = \frac{V_0 \varepsilon_2}{\varepsilon_1 L + (\varepsilon_2 - \varepsilon_1) s} \tag{23}$$

With the initial conditions of $\mathrm{d}s/\mathrm{d}t = 0$ at $t = 0$ and $s = s_0$ at $t = 0$, eq. (23) can be numerically solved, to yield the displacement and velocity characteristics of the advancing capillary meniscus. Since the effect of added mass in not incorporated in eq. (22), a non-zero value of s_0 is required to avoid the prediction of an unrealistic initial burst at $t = 0$, as explained earlier. One major conclusion that can be drawn from the numerical simulation studies of Yang et al. [8], based on the above model, that while liquid slip on hydrophobic surfaces may increase the flow velocity, the presence of a capillary pressure across the liquid-vapour interface can suppress the electroosmotic flow and significantly decrease the flow performance.

The marching velocity of a capillary meniscus can also be obtained from the surface energy considerations, by relating the instantaneous position or velocity of the capillary front with the gradients of the net interfacial energy. The final forms of the governing equations, as expected, turn out to be of identical nature as the equations of capillary motion described earlier. For the mathematical details, one may refer to the recent work of Yang et al. [9].

Future Directions for Research

Although capillary filling of microchannels have been extensively investigated over the past few years, studies on capillary filling of nanochannels have only been very few. Tas et al. [10], in a recent study, investigated the capillary filling speed of water in nanochannels. In their studies, the above authors experimentally measured the capillary filling speed of water in nanochannels with a rectangular cross section and a height of the order of 100 nm, over a length of 1 cm. In a qualitative sense, the measured position of the meniscus as a function of time was found to qualitatively follow the Washburn model (refer to the article on 'Surface Tension Driven Flow', for details of this model). Quantitatively, however, a lowering of capillary filling speed could be noted, which might be attributed to the electro-viscous effects and stronger surface influences over nanoscopic length scales. Future efforts need to be directed to develop more rigorous mathematical models to predict the quantitative trends of capillary filling in nanofluidic channels, to resolve these issues.

Capillary valves

Definition

Capillary force valves are fluid control structures that use superficial tension at the interface between different fluids to block and/or restore the entrance of fluids in microchannels filled with a second immiscible fluid. For most of the microfluidic applications the second fluid is air, and the liquid–air interface at a narrow hydrophobic stricture is used to prevent the liquid from entering a capillary.

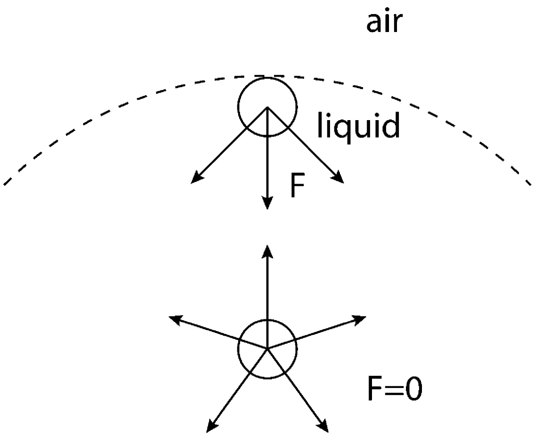
Overview

Capillary forces result from the interaction of liquid, gas and solid surfaces, at the interface between them. In the liquid phase, molecules are held together by cohesive forces. In the bulk of the liquid, the cohesive forces between one molecule and the surrounding molecules are balanced. However, for the same molecule at the edge of the liquid, the cohesive forces with other liquid molecules are larger than the interaction with air molecules (Fig. 1). As a result, the liquid molecules at the interface are pulled together towards the liquid. The overall effect of these forces is to minimize the free surface of the liquid that is exposed to air. The proportionality between the decrease in energy of the surface that results from decreasing the surface is described by the *surface tension*:

$$\gamma = \frac{\mathrm{d}G}{\mathrm{d}A}$$

where dG is the change in energy [N m], dA is the change in area [m^2] and γ is the surface tension or surface energy [N/m].

Of interest for capillary forces is the contact between three phases: liquid, solid and vapor (air). Three forces are present, trying simultaneously to minimize the contact area between the three phases. At equilibrium, the forces at the triple interface are balanced (Fig. 2) and the relationship between them is described by the Young–Dupree



Capillary Force Valves, Figure 1 Superficial tension forces at the interface between a liquid and air. For molecules in the liquid there is a balance of the cohesive forces ($F = 0$), while for molecules closer to the interface, the cohesive forces with other molecules in the liquid are larger than the interaction with air molecules (resultant force F towards the bulk of the liquid)

equation:

$$\gamma_{AS}L = \gamma_{LS}L + \gamma_{LA}L \times \cos\Theta$$

where L is the length of the triple contact line and Θ is the contact angle between the liquid and the solid. It is interesting to observe the vertical component pulling on the solid surface in the case of wetting and pushing in the case of non-wetting surfaces.

Capillary forces are critical at the microscale. The surface tension is responsible for the increased pressure in a bubble trapped in a capillary, and for the increased pressure required to push liquid into an empty non-wetting capillary (Fig. 3). The relation between surface tension and pressure is given by the Laplace equation:

$$\Delta P = \gamma C$$

where C is the curvature of the liquid surface. Depending of the shape of the capillary, different formulas for the curvature are available:

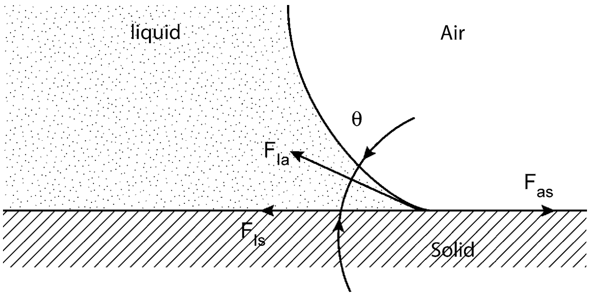
$$C = \frac{2}{R}$$

$$C = \frac{1}{R_1} + \frac{1}{R_2}$$

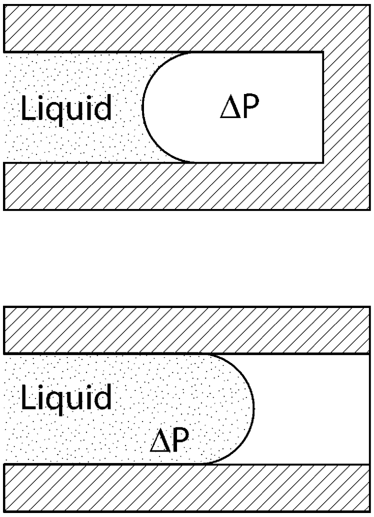
where R is the curvature radius for the liquid in a circular capillary and R_1 and R_2 are the curvatures in a non-circular capillary.

Basic Methodology

The behavior of air and liquids in capillaries is of critical importance at the microscale. After their fabrication, most of the channels in microfluidic devices are filled with air. In general, before the microfluidic devices are used for their designed purpose, the air inside the microfluidic channels has to be replaced by the working fluid. However, there are many applications where not all the air is replaced at once, and the advance of fluid inside the microfluidic channels is controlled through capillary force valves.



Capillary Force Valves, Figure 2 Capillary forces at the interaction between air, liquid and solid surfaces. Each of these forces works to minimize the energy of the interface between liquid and solid, air and solid, liquid and air: F_{ls}, F_{as}, F_{la}, respectively. At equilibrium, the horizontal projection of F_{la} and F_{ls} and F_{as} cancel each other. The corresponding angle between F_{la} and F_{ls} is the contact angle between liquid and solid (Θ)

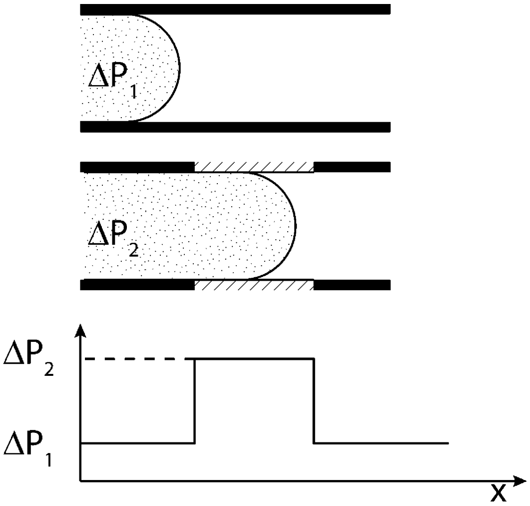


Capillary Force Valves, Figure 3 Capillary forces in hydrophilic capillaries result in increased pressure in trapped air bubbles. Capillary forces in hydrophobic capillaries prevent liquid from entering the capillary, and can be overcome by larger pressure

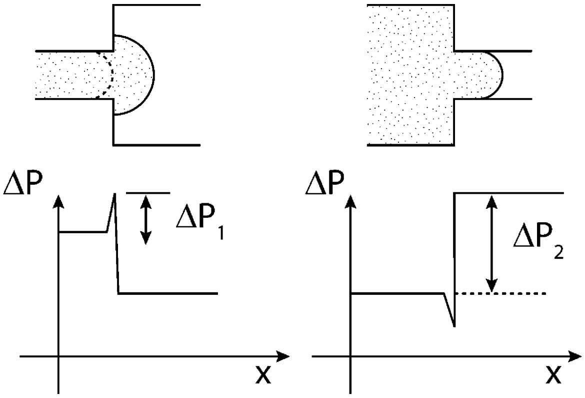
Two major strategies for making valves using the capillary forces are through the use of (a) local changes of contact angle and (b) local changes of surface geometry.

(a) The use of hydrophobic patches in a capillary relies on the increased pressure that is required to push the liquid over the area of larger contact angle (Fig. 4). The increased contact angle between the liquid and the capillary in the region of the hydrophobic patch results in a larger pressure necessary for moving the liquid over that region. After passing the patch, the pressure required for moving the liquid returns to pre-patch values. The combination of hydrophobic patches on the bottom of the channel is of interest for microfluidic devices where precise valving is required, or for liquids with different characteristics.

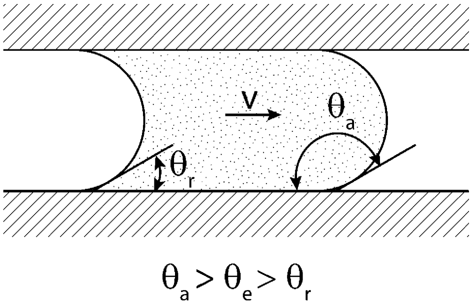
One other particular effect of practical interest whenever capillary forces are used is the difference between advancing and receding angles for the same fluid in the same capillary. This phenomenon is also known as hysteresis and manifests itself as larger contact angle at the advancing edge of a liquid–solid interface compared to the equilibrium contact angle which is itself larger than the contact angle at the receding edge of the liquid–solid interface (Fig. 5). The origin of this is partially in the roughness of the surface and can have interesting effects when moving columns of liquids through capillaries [1].



Capillary Force Valves, Figure 4 Schematics of a capillary valve using a hydrophobic patch. The pressure required to move the liquid (ΔP_1) is higher when the liquid–air interface reaches the region of increased hydrophobicity (ΔP_2)



Capillary Force Valves, Figure 6 Schematics of capillary valves using changes in the diameter of the capillary. Rapid enlargement of a capillary changes the physical angle between the liquid interface and the solid surface and can form a temporary barrier for the advancing liquid (ΔP_1). Reducing the diameter of a hydrophobic capillary reduces the radius of curvature of the interface and requires larger pressure (ΔP_2) to move the liquid and could also function as a valving mechanism



Capillary Force Valves, Figure 5 Hysteresis in contact angle. The contact angle at the advancing interface (Θ_a) is usually larger than the equilibrium contact angle (Θ_e), and larger than the contact angle at the trailing interface (Θ_t)

(b) The larger contact angle at advancing interfaces can be used in capillary valves as well, in combination with local change of the shape of the surface or the change in the diameter of the capillary (Fig. 6). This approach to controlling a liquid–air interface can be used alone or in combination with the hydrophobic patches. Although the fluid control is usually less precise for valves using changes in diameter compared to valves using hydrophobic patches, their implementation in microfluidic devices is overall easier.

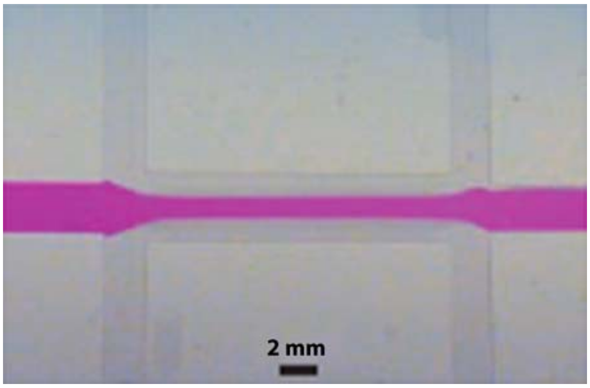
Key Research Findings

For the majority of microfluidic devices the initial filling (priming) of the device with liquid or the formation of air bubbles inside can render the device unusable. However, there are numerous examples that use the liquid–air interfaces to control the flow of liquid for different applications. Wall-less control of the flow of liquid streams has been demonstrated on micropatterned hydrophobic surfaces (Fig. 7) [2]. Micropatterned patches have been used to precisely stop the liquid flow at a certain position inside a channel without the need for moving parts (Fig. 8) [3], and for the accurate metering of nanoliter volumes of liquids in microchannels [4, 5]. Handling of minute volumes of fluids and mixing inside a capillary have been reported. Through the use of passive valves to control the flow of fluid and air bubbles expanded from side chambers, volumes of liquids down to 25 pL can be handled precisely (Fig. 9) [6]. The hydrophobic nature of the liquid–wall interaction was critical for stable and complete separation of picoliter volumes of fluid [7].

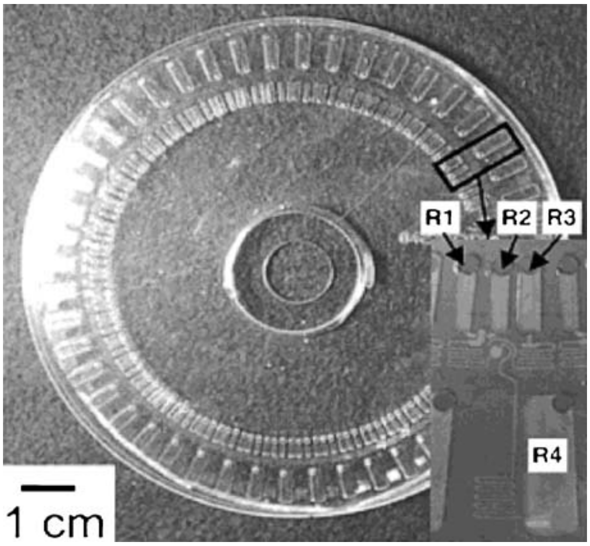
Capillary valves are burst valves, i. e. once the liquid passes through them they no longer function as valves. Resetting a capillary valve requires the formation of the liquid–liquid or liquid–gas interface at the location of hydrophobic interaction. This can be achieved by the injection of gas or liquid, usually in a small volume, from a reservoir or generated on the chip [6, 8].

Future Directions for Research

Capillary valves have no moving parts, are simple and easy to implement and thus are very attractive for low-cost microfluidic devices. At the same time, several areas of improvement are under scrutiny, to increase the performance of the valve, to improve the integration and to

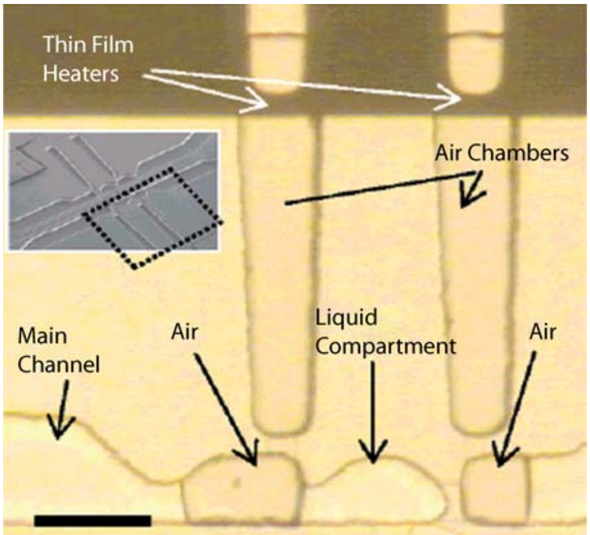


Capillary Force Valves, Figure 7 Hydrophilic and hydrophobic patches are used to control the flow of liquid streams (here rhodamine in water) in a wall-less configuration, just by relying on the surface tension of the liquid [2]



Capillary Force Valves, Figure 8 Capillary burst valves are used to control the sequential mixing of reagents in a Lab-on-a-CD type device. The solutions of enzyme, inhibitor and substrate were loaded in reservoirs that were connected to channels labeled R1, R2 and R3, respectively. R4 is a reservoir for waste collection. The rotation of the disk at different speeds controls the opening of the valves, and the sequence of mixing the enzyme with the inhibitor, followed by mixing with the substrate, and detection [3]

expand the range of applications. Continuous efforts are made to enlarge the variety of liquids that can be handled by new approaches to surface patterning in microcapillaries. The integration of an increasing number of valves for the implementation of complex reaction protocols is also an area of active research, especially, but not limited to, Lab-on-a-CD type devices [9]. Finally, while microfluidic devices are developed for applications outside the laboratory, it becomes increasingly important to



Capillary Force Valves, Figure 9 A volume of 25 pL is isolated by the creation of two new liquid–air interfaces, through the use of two thermal actuators. Two air bubbles isolate the separated volume from the rest of the liquid in the main channel [6]

provide robust valve designs that would ensure functioning over a wider range of temperatures, storage conditions and operator training, etc.

Catalyst Testing

Definition

A branch of combinatorial chemistry used for developin develop in an empirical or semi-empirical manner new and more efficient catalysts.

Most often, in the heterogeneous catalysis the catalysts are solids–usually metals, very often precious metals–while the reactants are liquid or gaseous. The catalysts are usually composed of a number of (metal) components in various combinations. The tests are performed in parallel under the otherwise equal temperature and pressure conditions in a large number of microreactors. In each microreactor the combination of the tested catalyst components is different and this results in a different yield or selectivity of the test reaction. This is usually evaluated by composition analysis of the reaction products. The results are stored in a combinatorial library and processed mathematically to determine the optimum combination.

Cation Exchange Membrane

Definition

An ion-exchange membrane that interacts with cations and have a variety of anion functional groups affixed to the membrane ($-COO^-$, $-SO_3^-$, $-PO_3^{2-}$, $-C_6H_4O^-$, etc). These functionalities allow cations to pass through the membrane and prevents anions from passing through the membrane. The ability of the membrane to bind ions is greatly dependant on the pH of the solution and the ions of interest.

Liquid–vapor phase change; Multiphase flows

Definition

Cavitation is the process of nucleation in a liquid and subsequent formation of gas/vapor phase when the pressure falls below a critical value. Researchers studying cavitation address topics ranging from the initial appearance of cavities in liquids (cavitation inception) to the development of large-scale cavities (supercavitation).

Overview

Cavitation, the phenomenon that causes liquids to rupture and to form vaporous/gas cavities when subjected to sufficiently low pressures, can occur in any machine handling liquid when requisite hydrodynamic conditions develop (Fig. 1). Cavitation, in many cases, is an undesirable phenomenon in hydraulic machinery that can limit performance, lower efficiency, introduce sever structural vibration, generate acoustic noise, choke flow and cause catastrophic damage [1]. The pernicious effects of hydrodynamic cavitation on conventional fluid machinery have been recognized and actively researched in the last century. Present knowledge (experimental and analytical) of cavitation has contributed immensely towards improving the design of conventional scale fluid machinery.

Recent developments in microelectromechanical systems (MEMS) have enabled the integration and fabrication of numerous micro components such as pumps, valves and nozzles into complex high-speed microfluidic machines. These systems posses geometrical dimensions in the range $1-1000\,\mu m$, which are 10^3-10^4 times less than conventional machines, and operate at liquid flow speeds up to $300\,m/s$. It has been confirmed that microfluidic systems, like their large-scale counterparts, are susceptible to the deleterious effects of cavitation when appropriate hydro-

dynamic conditions develop. Cavitation damage in micro-orifices has been reported by Mishra and Peles [2]. Small pits on the silicon surface have been detected after only 7 – 8 hours of operation under cavitating flow.

Hydrodynamic cavitation, in the context of high-speed (750,000 – 1,200,000 rpm) MEMS turbopumps (Fig. 2) being developed for millimeter-scale, liquid bipropellant, high-pressure rocket engines, has been experimentally investigated for working fluids like water and ethanol by Pennathur et al. [3] with 900 µm hydrofoil cascades, which are characteristic of the centrifugal MIT micro turbopump. It was found that cavitation can seriously affect the efficiency and performance of the pump. The above investigation instigated two main design changes wherein the pump inlet pressure was raised, and a secondary boost pump was added in series with the main pump to produce the required pumping power. The experimental part of this research demonstrated that cavitation is clearly part of the engineering environment of MEMS fluid devices as exemplified by Fig. 3, and cavitation concerns are as important as they are in large-scale fluid devices.

Basic Methodology

A very useful parameter for quantifying cavitating flows of various intensities is the cavitation number, σ, given by

$$\sigma = \frac{P_\infty - P_\mathrm{v}}{\frac{1}{2}\rho V_\infty^2} \tag{1}$$

where P_∞ is the free stream pressure (or some characteristic pressure), P_v is the vapor pressure, ρ is the density and V_∞ is the velocity of the free stream. Of particular importance in the study of cavitation inception is the minimum pressure coefficient ($C_{\mathrm{p_{min}}}$) given by

$$C_{\mathrm{p_{min}}} = \frac{P_\mathrm{min} - P_\infty}{\frac{1}{2}\rho V_\infty^2} \tag{2}$$

where P_min is the minimum pressure in the liquid. Classical theory for scaling cavitation states that the cavitation number at inception cavitation equals $-C_{\mathrm{p_{min}}}$ and the cavitation number is sufficient to link one cavitation flow state to another provided the form of the flow field and its boundaries remain geometrically and kinematically similar. However, it has long been known that real flows often do not obey the classical theory because of so called scale effects, which arise from changes in velocity, size, fluid properties, nuclei size and distribution, etc. [1]. It has also been reported that nuclei and viscous effects are responsible for most scaling effects. As a direct result, several studies have been conducted that clearly demonstrate the role of viscous and nuclei effects on the excitation (inception) of cavitation. Nevertheless, due to the complexity of the scaling effect, serious questions remain as to how to scale cavitation.

Scaling Cavitation at the Microscale

Various known factors affecting cavitation in conventional scale systems are altered in microscale systems, such as flow dimensionless parameters, component geometries, liquid contaminants (nuclei sources) and surface roughness and chemistry (surface energy). The differences arise from various causes including microfabrication constraints, typical choice of device materials and the Reynolds number. Subsequent sections will discuss each effect in detail.

Geometrical Effects

Even when ignoring all scaling effects, conventional scale knowledge cannot be used to model cavitation in microsystems simply because scaling requires the model and prototype to be geometrically similar. However, microfabricated devices usually possess geometries that are considerably different from their conventional-sized counterparts.

The deep reactive ion etching (DRIE) technique, first presented in the mid- to late 1990s, facilitated the fabrication of numerous innovative microsystems, especially power-MEMS systems. Since most MEMS devices involve some form of lithography-based microfabrication, the use of flat substrates is required. Often, these flat substrates involve the use of DRIE methods and result in structures characterized by extrusion of two-dimensional features into the third dimension as illustrated in Fig. 2. Therefore, microfluidic components are often limited in their geometrical appearance, which precludes full three-dimensional shapes commonly found in many large-scale fluidic devices such as pumps hydrofoils, turbine blades and vanes, mixers, etc.

Nuclei Effects

The term nuclei refers to the impurities that cause weak spots in the liquid and, thus, promote cavitation events. Generally, nuclei can be categorized into two groups: stream nuclei and surface nuclei. Stream nuclei consist of undissolved gases or uncondensed vapor trapped in solid particles or in microbubbles moving with the flow, while surface nuclei originate in the solid–fluid boundary in the cracks, crevices and other surface imperfections. The importance of nuclei in dictating cavitation events has drawn considerable attention and resulted in various technical investigations.

Various mechanisms by which nuclei are formed have been suggested over the years. Holl [6] argued that the nuclei sources best applicable to most pragmatic engineering situations are non-condensable gases in crevices, either on particles flowing with the stream (stream nuclei) or on the solid boundaries of a body (surface nuclei). Billet [7] listed several experimental investigations that show stream nuclei to be the dominant source of cavitation nuclei in conventional scale systems. However, Holl [6] suggested that the source of cavitation depends on the surface energy characteristics of the system (i. e., hydrophobic vs. hydrophilic) and on the system size scale. Systems made of hydrophobic surfaces are very dependent upon surface nuclei, whereas systems made of hydrophilic surfaces depend upon stream nuclei.

In microsystems, the dimension, shape and chemistry of surface nuclei and relative size of the stream nuclei are altered. Microscale hydraulic devices are primarily fabricated from silicon by various microfabrication etching processes (primarily by DRIE processes), and possess vastly different surface chemistry (different material) and surface topography (different fabrication methods from those used in the construction of large-scale hydraulic devices). For example, the DRIE process forms deep trenches on the silicon wafer with a characteristic scalloped sidewall possessing a peak-to-peak roughness of $\sim 0.3\ \mu$m. Furthermore, the surface nuclei become increasingly important with respect to the stream nuclei as the length scale diminishes. This can be better understood by considering the time available for the stream nuclei growth. As system size is reduced (for a given velocity value), the dwell-time of a nucleus in the low-pressure region diminishes. Consequently, the nucleus has insufficient time to grow and become active. On the other hand, the time available for growth of the surface nuclei is not necessarily hampered as the system dimensions drop. The bubble conveniently dwells in the low-pressure region before it is torn from the surface due to the action of drag forces.

It should be noted that most conventional-scale investigations have been carried out with tap or natural water, in which the stream nuclei are mainly in the $10-100\ \mu$m size range. As stated by the specialist committee on water quality and cavitation, one key criterion for cavitation inception testing is the availability of a sufficient number of microbubbles in that size range. However, for microscale devices the applications typically dictate stringent requirement for stream contaminants not larger than $\sim 1\ \mu$m. It follows that most experimental data on stream nuclei size and distribution are not in the range applicable to the working fluid employed in microscale devices.

In light of the importance of the stream nuclei in conventional-scale cavitation, the problem of identifying cavitation nuclei size and concentration in the working fluid has received considerable attention. Photography, holography, acoustical and optical scattering, coulter counters and acoustical attenuation have all been used to detect and measure the size concentrations/distributions of cavitation nuclei. However, these methods do not directly measure the tensile strength of most nuclei and, therefore, provide limited information on the critical tension that makes a nucleus unstable. The cavitation susceptibility meter (CSM) was intended to directly measure the active nuclei concentration as a function of applied tension in a flow through a small venturi tube, where cavitation was induced by carefully controlled conditions. However,

stringent operational limitations in the form of laminar flow separation and surface nuclei effects, which are difficult to eliminate, bring into question the practical utility of CSMs over a wide range of applied tension [8]. Nevertheless, as long as CSMs are used for measuring relative differences of nuclei between different water sources they could be quite useful for direct water quality measurements.

Dimensionless Flow Parameters

Three main dimensionless parameters most likely dominating cavitation in microsystems are the cavitation (σ), Reynolds (Re), and Weber (We) numbers. Although early work on cavitation scaling [6] has suggested the We number as a possible parameter affecting cavitation, it has been found that nuclei together with viscous effects are responsible for most scaling effects in conventional-scale systems, and, therefore, the primary dimensionless parameters in large-scale systems are the Reynolds and cCavitation numbers (although in some circumstances other dimensionless parameters such as the Froude, Strouhal and Weber numbers are important).

High-velocity microsystems operate at considerably lower Reynolds numbers than their large-scale counterparts. For example, the maximum hydrofoil-based Reynolds number of the exceptionally high-speed MIT micro turbopump [3] is no more than $\sim 10{,}000$, while at conventional scale typical Reynolds numbers are of the order of $\sim 10^5$ to $\sim 10^8$. The vast majority of available data on limited and developed cavitation are for Reynolds number much higher than the range observed/attainable in microsystems. This has important consequences on the extension of conventional data to microsystems because it has long been recognized that viscous effects are significant for both inception and developed cavitation. For hydrofoils the problem becomes even more significant since different chord lengths yielded different cavitation inception–Reynolds number curves [1]. This suggests that there is an additional size or speed effect separate from the Reynolds number. Although Brennen [1] speculated that the ratio of nuclei size to hydrofoil length is the missing parameter, no definite conclusion could be reached in the absence of information on the nuclei.

Although the surface tension force is important in the excitation and initial growth stages of a cavitating bubble, surface forces hardly have any affect on the global flow field once the individual bubble has matured to a substantial macro size. In microdomains, on the other hand, a bubble is unable to grow beyond the microdevice domain and continues to be influenced by surface tension forces since they are dominant at those length scales. It follows that the Weber number (or/and the capillary number) assumes an increasingly important position as system size diminishes.

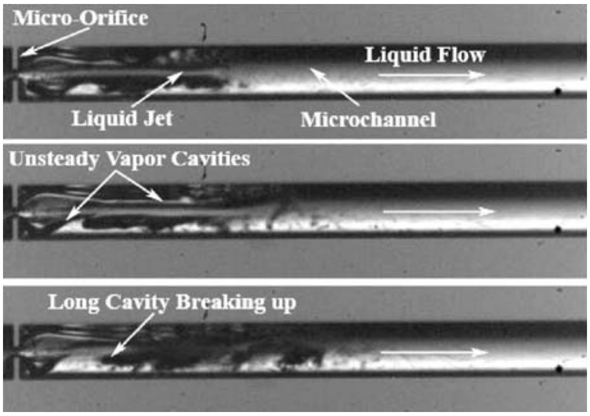
Key Research Findings

Unlike flow boiling, cavitation has not received considerable attention at the microscale. Nevertheless, several reports have been recently published that clearly show that conventional-scale knowledge and data cannot be simply employed to predict cavitation in microdomains. Mishra and Peles [2, 4, 5] studied hydrodynamic cavitation through micro-orifice entranced in microchannels. Their results revealed several key deviations in respect to macroscale systems. It was shown that the orifice size influences cavitation inception. An increase in the orifice size for a fixed microchannel width resulted in an increase in the cavitation inception number. Such a size scale effect has been observed by various authors even at the macroscale. The cavitation inception data presented by [9] for a fixed β (orifice-to-channel hydraulic diameter ratio) are smaller in magnitude than the results of [10] suggesting that the pipe diameter influences cavitation inception. It was shown that the cavitation number at inception (σ_i) varies with area (orifice-to-channel) aspect ratio (A_0/A_p) and a higher A_0/A_p results in a larger σ_i. The data indicate the presence of a dominant size scale effect on cavitation inception even at the microscale. Moreover, the σ_i values obtained from the Mishra and Peles experiments are considerably lower than any previous studies with larger orifices [9, 10]. This can be attributed to the small nuclei residence time and the surface tension forces, which are significant at the microscale and can aid in delaying the rupture of the liquid.

When they continued to reduce the cavitation number by reducing the exit pressure the *Vena Contracta* (the location where the static pressure drops to its minimum and the velocity rises to its maximum) static pressure approached the vapor pressure of water and caused flow rate choking irrespective of the inlet pressures. Although flow rate choking has been reported even in macroscale studies [9, 10], microflows readily transition from incipient to choking conditions since even a single vapor bubble in the microchannel is sufficient to choke the flow. In experiments conducted on larger orifices inside larger pipes, the cavitation number had to be reduced significantly beyond inception before flow rate choking is detected [9, 10]. Tullis [10] reported a 59% increase in the flow rate beyond inception to cause choking, whereas in the study of Mishra and Peles only a $1-2\%$ increase in the flow rate beyond inception was sufficient to cause choking in all microdevices. Similarly, Pennathur et al. [3] indicated a sharp transition into large attached supercavities and flow chocking

from cavitation inception in the investigation of flow over a 900 μm chord hydrofoil cascade. This phenomenon has not been reported for large-scale hydraulic equipment and it appears to be characteristic of microcavitating flows.

Mishra and Peles [5] performed a cavitating flow visualization study of a 40 μm wide micro-orifice entranced inside a 200 μm wide microchannel. They revealed various cavitating flow morphologies depending on the cavitation number and longitudinal position downstream of the orifice. At cavitation number slightly lower than σ_i inchoate cavitation bubbles appears immediately downstream of the orifice which collapse within a few microchannel diameters downstream. Further reduction in the cavitation number resulted in the emergence of a thin liquid jet from the micro-orifice. The jet appeared to be surrounded by two elongated bubbles at the top and the bottom, which stretched for a few microchannel diameters downstream (Fig. 4).



Cavitation in Microdomains, Figure 4 Developed cavitation with shedding ($\sigma = 0.227$)

Desinent cavitation is defined as the threshold cavitation number when the flow returns back to single-phase flows from cavitating conditions. The desinent cavitation number was considerably higher than the incipient cavitation number. Although the cavitation hysteresis (difference between incipient and desinent cavitation) phenomenon has been observed in macroscale [9, 10] its effects seem to be ameliorated with decrease in size of the system [5].

Future Directions for Research

In the future the microfluidics community will need to seriously address cavitation in order to enable the practical realization of many high-velocity microscale fluid machines. While the last decade has witnessed significant advances in power-MEMS technology, one of the most deleterious phenomena effecting hydraulic system, cavitation, is not very well understood at the microscale. Better knowledge of surface and stream nuclei effects at diminishing lengths and other scaling effects like viscous and surface tension will require careful study.

Definition

Cell adhesion results from specific attractive interactions between molecules on the cell surface and a substrate, which may be coated with more than one kind of molecule. Cell detachment represents the termination of these interactions by physical, chemical, electrical, optical, or other means.

Overview

Cells adhere to surfaces when attractive forces exist between the cell surface and the substrate of interest. In vivo, cells in animal tissues adhere to the extracellular matrix, by binding of adhesion receptors in the cell's membrane to the proteins of the extracellular matrix. Extracellular matrix is an interdigitating network of proteins and polysaccharides secreted by the cells themselves. For successful cultivation of anchorage dependent cells in a microfluidic device, it is necessary to provide means for the cells to attach to the device surface. Some surfaces, such as glass or poly(methyl methacrylate) (PMMA), may be naturally adhesive to certain cell types. It is generally accepted that the natural adhesiveness of these materials comes from their ability to support adsorption of serum proteins added to the culture medium, or extracellular matrix proteins secreted by the cells. In general, weakly hydrophobic surfaces will support adsorption of proteins, which are also hydrophobic, resulting in the cell attachment mediated by the adhesion receptors. In contrast, highly hydrophilic materials such as poly(ehtylene glycol) (PEG) will prevent protein adsorption and as a result prevent cell attachment.

More effective and specific cell adhesion can be achieved by taking advantage of unique receptors present on the cell surface and the specific attractive interactions that these receptors have with certain biomolecules called ligands. Often, cells of different types have different receptors on their surfaces and hence the ligand-receptor bond is like a lock and key connection. One cell type may have receptors that bind to a particular ligand but another cell type may be lacking that kind of receptor. A ligand-coated substrate will therefore bind cells of the former type, but not of the latter type.

Specifically, integrins are a group of adhesion receptors that mediate a large number of cell-matrix interactions. They are heterodimers, consisting of an α and β subunit. In vertebrates, at least 18 types of α subuntis and 8 types of β subunits are known. The differential adhesion properties of different cell types, come from the fact that different combinations of αβ sub-units are present in different cell types. Many cells contain integrins (e. g. α5β1) that can bind to an extracellular matrix protein, fibronectin. These integrins will bind to the type III repeats of fibronectin, specifically recognizing the Arg-Gly-Asp (RGD) peptide sequence.

Specific interactions between the cell surface receptors and their ligands (proteins or peptides) form the basis of cell adhesion in microfluidic devices. This entry will review methods of immobilizing ligands in microfluidic devices to achieve selective cell adhesion.

The detachment of cells from a substrate requires the disruption of the bonds that exist between cell surface receptors and ligands on the substrate. As such, cell detachment is difficult to achieve within microfluidic devices since receptor-ligand bonds tend to be strong. For example, although the dissociation constants (K_d) for a sin-

gle integrin receptor is relatively low (between 10^{-6} and 10^{-8} mol/l), binding of thousands of integrins present in the single cell to their ligands results in a firm anchoring of the cell to the surface. Thus, another factor that influences cell release is the density of receptors on the surfaces of a given cell. A higher receptor density will result in more receptor-ligand bonds forming, making it more difficult to detach the cell from the substrate. However, depending on the cell type and on the way the ligand is tethered to the substrate, cells can be detached using physical or chemical methods. Some examples of cell detachment techniques will also be described in this entry.

Basic Methodology

Cell Adhesion

The attachment of cells to surfaces is inherently a function of surface composition. The most commonly used materials in microfluidic device fabrication are silicon dioxide (glass), poly(dimethyl siloxane) (PDMS), and silicon. PDMS and silicon are hydrophobic and this characteristic can be exploited to coat these surfaces with ligands by adsorption. An alternative approach is to bind ligands covalently to surfaces. This approach is preferred when a strong adhesive force between targeted cells and the microfluidic device surface is required. This approach also results in highly reproducible surface coatings that are not affected by fluid flow, thus enabling application of high flow rates over prolonged times. Silicon, silicon dioxide, and PDMS surfaces are capable of chemically binding to a family of molecules known as alkoxysilanes. These molecules are comprised of one silicon atom bonded to three alkoxy groups and a fourth functional group capable of binding to other molecules. One approach to tether ligands to alkoxysilane molecules involves a coupling agent, namely the N-y-maleimidobutyryloxy succinimide ester, more commonly known as GMBS. This molecule contains two N-hyroxysuccinimide (NHS) ester groups that can bind to sulfhydryl groups (SH) and primary amine groups (NH_2). Hence, a silane containing a sulfhdryl group can be first attached to the microfluidic device surface, GMBS can then be attached to the silane, and finally any molecule with a primary amine group can be attached to the GMBS. Since primary amine groups are found on virtually all biomolecules (amino acids, antibodies, polypeptides, etc.), this three step technique is very versatile.

The binding of silanes to silicon, silicon dioxide, or PDMS surfaces requires activation of these surfaces with an oxygen plasma. For microfluidic devices made of glass and PDMS, oxygen plasmas are typically used to activate these surfaces prior to bonding them together, hence the silane treatment can immediately follow the bonding step. The oxygen plasma treatment disrupts the silicon-silicon and silicon-oxygen bonds in these surfaces, making them susceptible to bonding with alkoxysilanes, as illustrated in Fig. 1. The silane molecules are typically dissolved in an organic solvent such as ethanol in low concentrations (typically around 4 – 5% by volume) and the solution is injected directly into the microfluidic device and allowed to react for 30 min. Care must be taken while handling silanes because they are hazardous and moisture sensitive. Unreacted silane must be removed by rinsing the device with ethanol prior to introducing GMBS. GMBS is also dissolved in ethanol (a typical concentration is 28% by volume) and requires a 15 min reaction time period. After removing the unreacted GMBS, the device is rinsed with phosphate buffered saline (PBS) and finally, a solution of the ligand in PBS can be injected into the device. After 30 min of reaction time, the device is rinsed once again with PBS and is thereafter ready to capture cells by adhesion.

The concentration of ligand in the final step determines the ligand surface density that is ultimately achieved on the microfluidic device surface. This concentration can either be adjusted to ensure complete coverage of the surface or modulated when other molecules also need to be bound to the surface. An example of such a situation is when non-specific adhesive interactions between cells and the microfluidic device surface must be minimized. This type of *screening* can be accomplished by attaching poly(ethylene glycol) (also known as PEG) to the device surface in addition to the ligand molecules. The biological non-adhesiveness of PEG is very well known and its incorporation into the surface modification process described above can be readily accomplished using commercially available PEG that is functionalized with amine groups. The incorporation of PEG ensures that the only adhesive interactions that occur between cells and the microfluidic device are those between receptors on the cells and ligands on the device surface.

For microfluidic devices made with polymers such as poly(methyl methacrylate) (PMMA) and polycarbonate (PC), a different approach must be used to bind ligands to the device surface. The most common approach is the use of carbodiimide chemistry. For PMMA devices, a layer of carboxylic acid groups must first be generated by exposing the devices to an oxygen plasma or to ultraviolet light [1]. This step is not required for PC since the polymer already contains carboxylic acid groups. The next step is the attachment of the carbodiimide molecule to the surface over a 4 h time period, followed by a rinse with PBS and introduction of the ligand solution in PBS for an overnight coupling reaction (Fig. 2). Reagents and protocols for this process can be obtained commercially as kits.

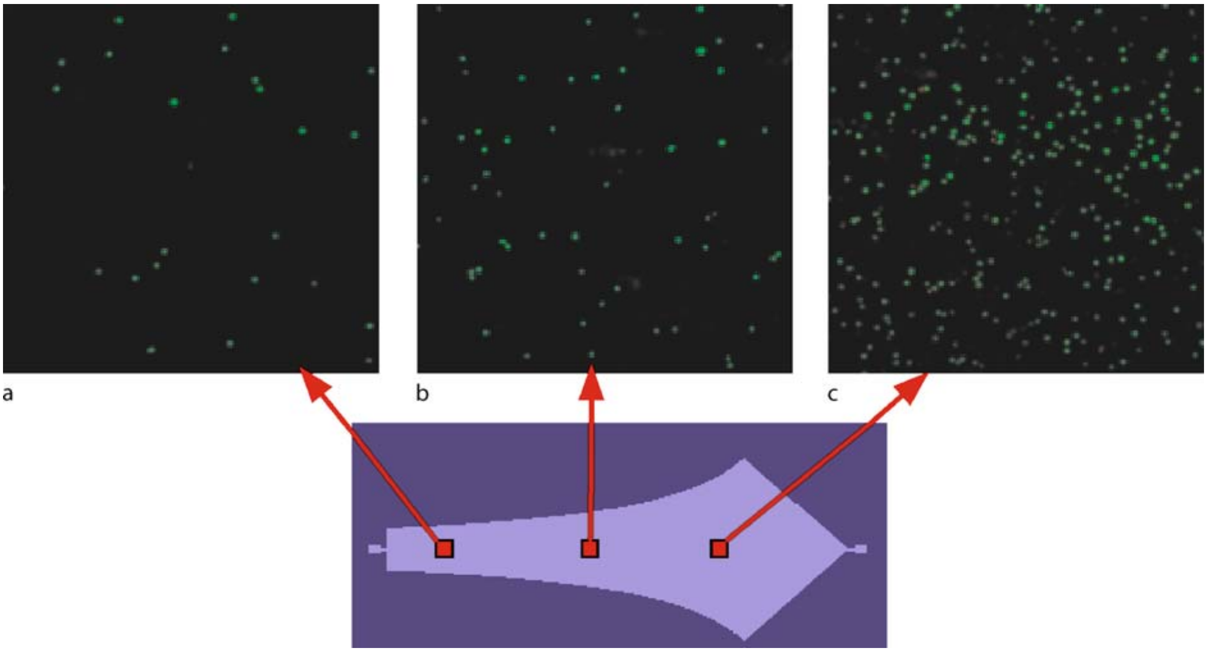
Cell Adhesion and Detachment, Figure 2 Chemical reaction scheme for the attachment of a biomolecule to the surface of polymeric microfluidic devices made of PMMA or PC. The carbodiimide coupling process starts with a reaction with carboxylic acid groups on the surface

Cell Detachment

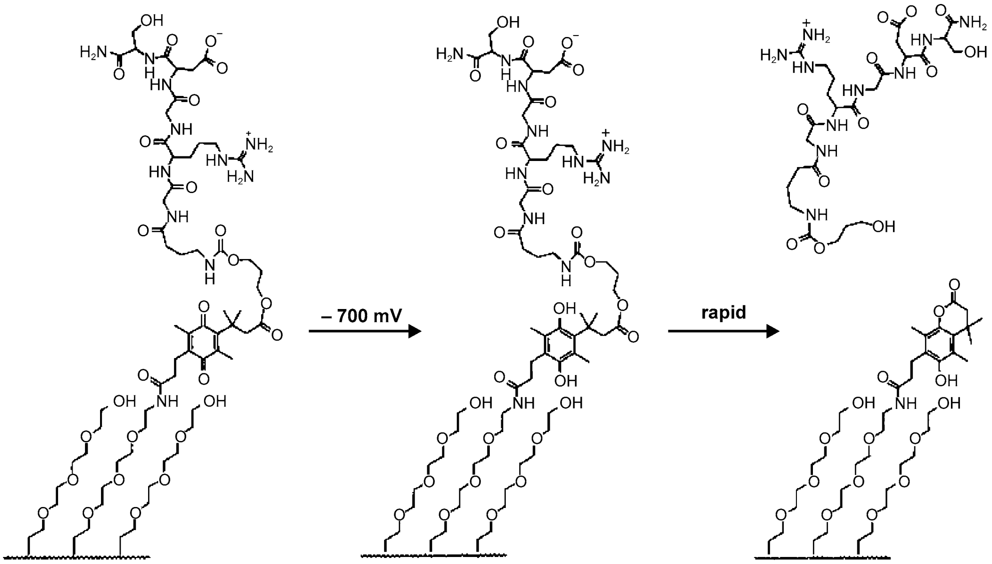
The detachment of cells adhered to any surface requires the application of a force that is greater in magnitude to the force of adhesion. In standard monolayer, culture cells are detached by application of a proteolytic enzyme, trypsin. This is often impractical in microfluidic devices since it requires application of a rinsing solution, followed by incubation in a trypsin solution and finally the serum containing quenching solution.

For cells adhered within microfluidic devices, the easiest mode of detachment is by means of fluid flow. As demonstrated by Murthy et al. [5] (Fig. 3), the cell adhesion within microfluidic devices is dependent on the magnitude of flow-induced fluid shear forces. Under most conditions, increasing the magnitude of fluid shear forces (by, for example, increasing the flow rate) will result in lower cell adhesion. Therefore it is possible to design a system wherein cells are captured selectively while flowing through the device at a slow rate, and these captured cells can then be detached from the surface by flushing the device at a faster flow rate [2]. The main advantage of this approach is its simplicity; however the main limitation is that if the ligand-receptor bonds between the device surface and the cells are very strong, then it may be impossible to detach the cells without using very high shear forces that would almost certainly damage the cells.

An alternative approach is to design surface coatings that can facilitate cell detachment when an external stimulus is applied, such as an electrical potential or a small temperature change. An example of the former is a surface coating that consists of ligands bound to the surface via an electroactive chemical functional group [3]. The electroactive group, which is a quinone ester, is such that it undergoes a chemical change to a lactone upon the application of an electrical potential of −700 mV. When this change occurs, the ligand that was originally bound to the quinone ester is released, as shown in Fig. 4. Any cells that are attached to the surface via the ligand, would also then be released. From a microfabrication stand-



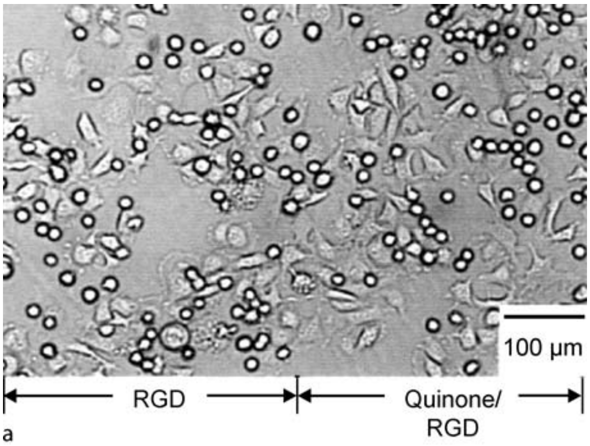
Cell Adhesion and Detachment, Figure 3 Selective adhesion of T lymphocytes in a microfluidic device as a function of shear stress. The device geometry, shown in blue, is such that the fluid shear stress decreases along the length of the device. This device was coated with the anti-CD5 antibody, which adheres to certain T lymphocytes. A mixture of T lymphocytes (stained green), and B lymphocytes (stained red) was passed through the device and the adhered cells were essentially all T lymphocytes (97% purity)

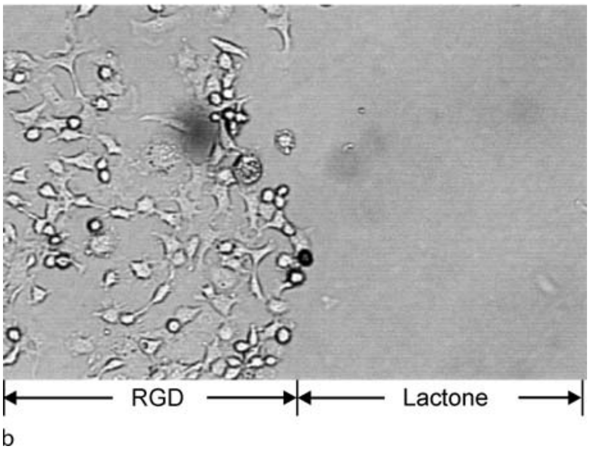


Cell Adhesion and Detachment, Figure 4 A self-assembled monolayer with an electroactive functional group bound to the RGD peptide. This quinine group is converted into a lactone group upon the application of an electrical potential and this change releases the RGD group from the surface. Taken from [3]

point, this approach is slightly more complex because it requires the incorporation of electrodes into the device structure.

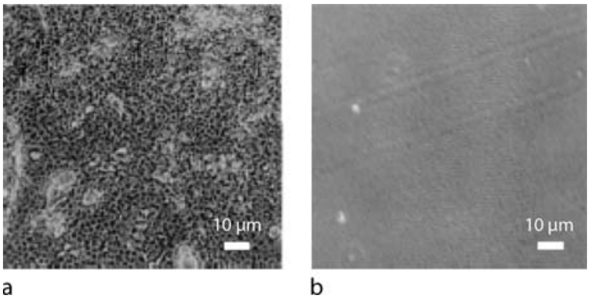
Poly(N-isopropylacrylamide) (also known as PNIPAM) is a material that undergoes a physical change when its temperature is changed from 37°C to 20°C [4]. This change





Cell Adhesion and Detachment, Figure 5 Release of cells from a surface coated with self assembled monolayers coupled to the RGD peptide. The left side of the surface has a monolayer that is not electroactive and the right side of the surface has a monolayer that contains the electroactive quinone group. Fibroblast cells initially adhere on both sides of the surface (**a**). Upon the application of an electrical potential, the quinone groups are converted to lactone groups and release the RGD groups along with the cells attached to these groups (**b**). Taken from [3]

is a phase transformation caused by rearrangements at the molecular level and results in a macroscopically observable change in hydrophobicity. PNIPAM is hydrophobic at 37°C and becomes hydrophilic at 20°C. This change can be reversed by raising the temperature back to 37°C. The hydrophobic PNIPAM surface at 37°C allows cell adhesion because the proteins on the cell surface are also moderately hydrophobic. The adhered cells can then be released by lowering the temperature to 20°C. The advantages of this technique include the ability to create PNIPAM surface by either solution chemistry techniques or vapor deposition, and the ability to form patterns of PNIPAM on any surface.



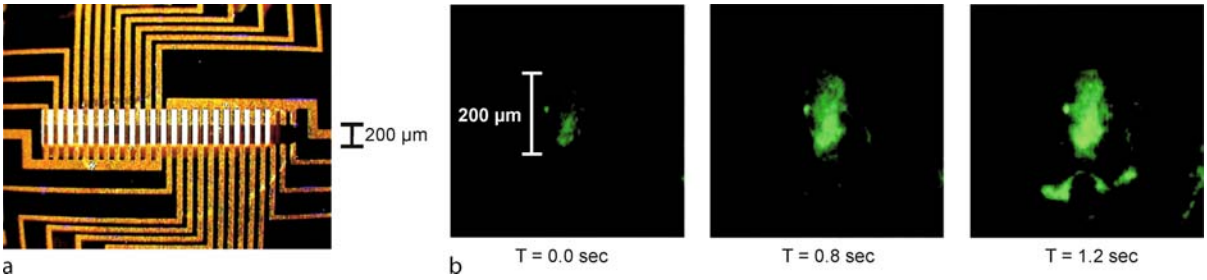
Cell Adhesion and Detachment, Figure 6 Cell detachment using the thermally responsive polymer PNIPAM. A surface coated with the polymer is seeded with human keratinocytes cells which form a sheet-like layer at 37°C (**a**). When the temperature is lowered to 20°C, the cells are released from the surface (**b**) as a sheet. Taken from [9]

Key Research Findings

The use of silane chemistry and coupling with GMBS was recently applied to the attachment of antibodies to the surfaces of glass/PDMS microfluidic devices by Murthy et al. [5]. These antibodies were selected based on their known affinity for two sub-types of white blood cells, T and B lymphocytes. The anti-CD5 antibody was selected based on its affinity for the T lymphocytes used in this work, and the anti-CD19 antibody was chosen based on its affinity for B lymphocytes. In addition to the antibody, Murthy et al. further functionalized their microfluidic devices with PEG to eliminate non-specific cell binding. Starting with mixed suspensions containing varying concentrations of each cell type, these investigators observed high purity capture ($> 97\%$) of the target cells, namely T lymphocytes in anti-CD5-coated devices and B lymphocytes in anti-CD19-coated devices (Fig. 3).

This design concept was further refined by Cheng et al. in the development of a microfluidic system designed to count T lymphocytes expressing the CD4 antigen for HIV diagnostics [6]. In HIV-positive patients the number of T lymphocytes expressing CD4 drops dramatically, and counting the number of CD4-positive T lymphocytes per unit volume of blood forms the basis of standard tests for HIV infection. The microfluidic system developed by Cheng et al. is a portable, point-of-care diagnostic device that requires only 10 µl of a blood sample for an accurate diagnostic measurement. Another example of a microfluidic diagnostic device based on antibody-mediated capture of cells has been described by Du et al. [7]. This device is designed to capture cervical cancer cells that are known to express the α6-integrin receptor by attachment to antibodies bound to the microfluidic device surface.

More recently, Plouffe et al. reported how peptides bound to the surface of a microfluidic device can be utilized



Cell Adhesion and Detachment, Figure 7 Biomolecule release within a microfluidic device using PNIPAM films and microfabricated heaters (**a**). The release of fluorescently labeled protein from a PNIPAM-coated region within the device when the heaters are turned off and the temperature falls below 37°C (**b**). From [10]

to selectively capture smooth muscle cells and endothelial cells from mixed suspensions containing both cell types along with fibroblasts [8]. The peptides used in this work were the sequences valine-alanine-proline-glycine (VAPG) and arginine-glutamic acid-aspartic acid-valine (REDV). VAPG is known to bind preferentially to smooth muscle cells and REDV is known to bind to endothelial cells. Smooth muscle cells and endothelial cells were captured by adhesion on the device surface with purity levels as high as 86 %. The captured cells remained viable after the flow and capture process, over a range of shear stresses between 1.3 – 4.3 dyn/cm^2.

The use of electroactive molecules to release cells was demonstrated by Yeo et al. [3] with the RGD peptide and fibroblast cells. The RGD peptide, which consists of three amino acids, arginine, glycine, and aspartic acid, linked together, is a ligand that binds to many different types of cells. Yeo et al. created a monolayer of alkanethiolate molecules on a gold surface. These molecules have a sulfhydryl group at one end which forms a bond with the gold surface; these molecules *self-assemble* on the surface to form a layer that is only one molecule thick (i. e. a *monolayer*). The other end of these molecules usually contain functional groups that can be utilized in subsequent reactions or processes, such as electroactive quinone groups connected to RGD units. As shown in Fig. 4, upon application of a −700 mV potential, the quinone groups undergo reduction to lactone, with the release of the RGD groups. Figure 5 shows the attachment of fibroblasts to a surface modified such that the left half contains RGD units tethered to a non-electroactive alkanethiolate monolayer. The right half of the surface contains RGD units attached to an alkanethiolate monolayer via electroactive quinone groups. In the absence of any electrical potential, fibroblasts do not distinguish between the two types of monolayers, perceiving only the RGD units and therefore becoming adhered to the surface. When the electrical potential is applied, the RGD units on the electroactive monolayer (right hand side of the surface) detach, causing detachment of the fibroblasts. This transition can be clearly seen by comparing Fig. 5a and Fig. 5b.

An example of cell detachment using the thermally responsive polymer PNIPAM has been described by Yamato et al. [9]. These investigators created a layer of PNIPAM by irradiating a polystyrene surface with an electron beam and allowing PNIPAM molecules in solution to bind covalently to the activated surface. A layer of human keratinocytes was cultured on this surface at 37°C. As shown in Fig. 6, lowering the temperature to 20°C resulted in detachment of the keratinocytes from the surface. The authors further observed that the keratinocytes detached as sheets, indicating that the cell detachment was uniform throughout the PNIPAM region.

The use of PNIPAM films within a microfluidic device has been described by Huber et al. [10]. This device, shown in Fig. 7a, consist of an array of microfabricated heaters over which a layer of silicon oxide and PNIPAM are deposited. Figure 7b shows the progressive release of fluorescently labeled protein from a location on this device. Initially, the PNIPAM is held at a temperature of 37°C and allows adsorption of the protein (the fluorescence is restricted to the PNIPAM-coated region). At the 0 s time point, the heaters are turned off, and as the PNIPAM cools, the protein is progressively detached, producing a fluorescent smear as it spreads away from the PNIPAM-coated region. Although this study by Huber et al. examined the release of protein molecules, the work of Yamato et al. suggests that a similar design concept could be utilized to detach cells within a microfluidic device.

Future Directions for Research

The ability to selectively adhere cells of different types within microfluidic devices is well developed. Knowledge of specific ligand-receptor interactions unique to any given cell type can readily be extended to a microfluidic applica-

tion, as illustrated in the examples above. However, more work needs to be done to better understand the mechanisms of cell-ligand interactions within the context of microfluidic systems. For example, it is known that the number of receptors on a cell may change based on exposure to fluid shear stress; such a change would impact the adhesion characteristics of the cells. In the area of cell detachment, future research must be directed at finding biologically specific release strategies that can be implemented easily within microfluidic devices.

Definition

A *cell assay* is defined as measurement and analysis of cellular response to chemical and/or physical stimulus. Cellular responses are diverse: alterations of intracellular and extracellular biochemistry, cell morphology, motility, and growth properties. These responses characterize the cell *phenotype*, and are typically monitored in a culture dish or a multiwell plate, while more recently microfluidic devices have been employed. A cell assay performed in a microfluidic device is sometimes termed an *on-chip* assay.

► High throughput screening (HTS) is a class of analytical techniques in which many different assays are performed in parallel, or very rapidly in succession. Currently, there is great interest in performing cell assays in a HTS format.

Overview

Introduction to Cell Assays

The cell is the irreducible element of life and is often studied as a living model of complex biological systems. Some studies, such as analysis of cell morphology and growth, can only be evaluated by means of cell assays. Other studies, such as the analysis of cellular biochemistry, can also be performed by simpler, molecular assays, that is, measuring molecular interactions in cell-free systems. Molecular assays are faster and less complicated to perform but can result in misleading conclusions as it is impossible to mimic the complex and unique properties of the intracellular environment (organelle compartmentalization of reagents, spatially localized receptors, varying temporal expression, etc.). Thus, cell assays are preferable for study of living systems. Nevertheless, they have several disadvantages, including being expensive, time-consuming, and much more complex than other kinds of analyses. An additional drawback is that many cells, such as mammalian cell culture lines, require strict adherence to sterile operating conditions.

Cell assays are conventionally performed in culture dishes or in multiwell plates (plastic trays containing 96, 384, etc. wells). While culture dishes require milliliter volumes of media and reagents, multiwell plates contain microliter volumes and enable simultaneous analysis of multiple cell types or stimuli. Cell responses in microwell plates are often evaluated using microplate readers, which are specialized optical detection instruments designed to rapidly analyze all of the samples on a plate, making use of techniques such as fluorescence intensity and polarization, luminescence, or absorbance. Multiwell plates and plate readers have become the standard means for medium- and high-throughput screening in cell and biomolecular assays. In these experiments, the plates, the plate reader, the fluid handling apparatus, and other miscellaneous equipment are typically integrated in a robotic analysis platform. Two major drawbacks of robotic platforms are the expense of the instrumentation (over $500,000), and the cost of experimental consumables (e. g., plates, pipette tips, reagents, and cells), which can be prohibitive. (This is true in general, but even more so for cell assays). Hence, applications requiring high-throughput cell assays are out of reach of all but the wealthiest of laboratories.

Miniaturization of Cell Assays in Microfluidics

Microfluidics, a technology characterized by devices containing networks of micron-dimension channels, enables integration of multiple processes on a single platform while reducing reagent consumption and analysis time. As such, microfluidics has been touted as a solution for the challenges inherent in conducting cell assays in HTS format [1].

In addition to the potential for facilitating HTS, microfluidic devices are advantageous for cell assays for a variety of reasons, the most obvious of which is the similarity in dimensions of cells and microchannels (10 – 100 μm widths and depths). Another important advantage is flow: channels with this size are characterized by laminar flow where diffusion is the only source of non-axial mass transport. Although diffusion-based transport is slow for delivering reagents across long distances, in microchannels, diffusion enables rapid and repeatable reagent delivery. In addition, the combination of laminar flow and diffusion makes possible the formation of highly resolved chemical gradients across small distances; this feature is particularly useful for cell assays as such gradients are common in living systems but difficult to implement in macroscale setups. A fourth advantage of microfluidic devices is the increased surface-to-volume ratio which facilitates

favorable scaling of heat and mass transfer, as well as favorable scaling of electrical and magnetic fields that are often used in cell analysis. A final consequence of the size regime is in concentration of analytes: as cells in microchannels are confined in sub-microliter volumes, relevant analytes do not become too dilute and can thus be more readily detected.

Microfluidics does have some disadvantages for cell assays. One limitation is the difficulty inherent in controlling many reagents simultaneously. A potential solution to this limitation is the use of *digital* or droplet-based microfluidics (▶ digital microfluidics). A second limitation is that the high surface-to-volume ratio of microchannels enhances the adsorption of molecules onto channel walls, reducing the effective concentration of reagents, and potentially causing problems related to cross-contamination. Finally, a major challenge for microfluidic applications in general is the macro-to-micro interface. To take a full advantage of the reduced scale, new technologies are needed to enable delivery of very low volumes of cells and reagents into microfluidic devices.

Key Examples

Li and Harrison carried out the first cell assay in microchannels [2]. This seminal work made use of electrokinetically driven flow (electroosmosis and electrophoresis) to transport bacteria, yeast, and mammalian cells in channels and to implement low-volume chemical lysis (cell death). This theme of microfluidics-based cell transport, sorting, and lysis, has continued to be a popular application, as well as related work in using microfluidics to culture cells and to pattern them into structures. We acknowledge the utility of these methods (and note that they are featured in several good reviews – see El-Ali et al. [1] and other entries in the *Encyclopedia*), but focus here on describing microfluidics-based cell assays that fit the definition described above – application of a stimulus and measurement of a response. These assays fall into four broad themes sorted as a function of the type of response to be measured: intracellular biochemistry, extracellular biochemistry, mechanical properties, and electrical properties. Prior to discussing these kinds of assays, we describe the basic methodology common to all forms of cell assays in microfluidics devices.

Basic Methodology

Cell Culture

In a microfluidic device for cell-based assays, adequate culture conditions must be maintained for the duration of the experiment, which can span hours or days. While being cultured, cells must be continuously perfused with nutrients and oxygen; in addition, constant temperature and pH must be maintained. Cell populations exist either in suspension (dispersed in liquid media) or as adherent layers grown on surfaces presenting an appropriate matrix, (Fig. 1a). In practice, adherent cells must be detached from culture flasks and seeded into a microfluidic device while sufficient time has to be allowed to achieve proper cell attachment and reduction of stress induced by the transfer [3]. Mobile cells in suspension are easier to handle and require less time to adapt to the new environment.

Cell assays are either performed on cell populations or on single cells. Being naturally heterogeneous, cell populations are more physiologically relevant and observation of populations allows for analysis of intercellular signaling. However, some cell phenotypes are not observable in an averaged signal produced by the population, so these assays can only be implemented by studying single cells. This chapter deals mainly with analysis of cell populations in microfluidic devices; we refer the reader to other entries of the *Encyclopedia* that discuss single cell analysis (▶ single-cell analysis in microfluidics).

Microflow Design

With typical flow rates usually smaller than 10 μl/min, a microflow has to be capable of continuous and uniform perfusion of media as well as steady culturing conditions. The flow must have a distribution such that adherent cells are not exposed to significant shear stress. Cells in suspension are either assayed while carried by bulk microflow or, more often, after immobilization in the chip. Common immobilization techniques are hydrodynamic trapping [4, 5] and adsorbing cells to a chemically treated surface [6].

Microflow is realized either as electroosmotic flow (EOF) or pressure driven flow. EOF is in many cases not suitable for transport of cell media due to its high ionic strength; additionally, the electrical fields may cause adverse effects on a cell population. Thus, pressure driven flow generated by off-chip or on-chip pumps is preferable for cell assays. On-chip pumps are particularly convenient – of note, pumps formed by multilayer soft-lithography have been applied to analyzing T-cell behavior in microfluidic devices [4].

Materials

Microchannels are generally fabricated in silicon, glass or poly(dimethyl siloxane) (PDMS). Glass and PDMS provide transparency for optical monitoring, and the latter is also permeable to the oxygen and carbon dioxide that is

(Image reproduced, with permission, from [11])

necessary for cell culture. For long-term assays, thorough sterilization of channels is recommended to prevent cell contamination [3]. Assays involving adherent cells require microchannel walls to be pretreated usually by attaching extracellular matrix proteins (e. g., fibronectin, collagen, or laminin) to enhance adhesion. On the other hand, when transporting cells in suspension, channel walls are often coated with bovine serum albumin (BSA) to prevent non-specific adhesion [4].

Types of Stimuli

Stimuli used for cell assays in microfluidic devices can be categorized into two main groups:

- chemical stimuli, including drugs and other reagents, antibodies and gene transfection agents, and
- physical stimuli, including topographical features and other mechanical and electrical forces.

Both kinds of stimuli are translated by cell signaling networks into a diverse range of responses, including growth and proliferation, migration, activation of metabolic pathways, production and release of proteins and other biomolecules, and the initiation of apoptosis (programmed cell death).

Detection Methods

Cell responses to physical or chemical cues are measured in microfluidic devices primarily via optical or electrochemical means. Fluorescence is the most widely used optical detection technique, because absorbance detection (commonly used for macro-scale assays) is of limited value in microchannels because of the short path lengths. Fluorescence detection, characterized by its unparalleled sensitivity, is easy to implement in microfluidic systems. Chemiluminescence and bioluminescence also offer low detection limits and have less background noise than fluorescence [6]. Electrochemical detectors are even more easily integrated with microfluidic devices and often are much less expensive than optical systems. However, fabrication of electrodes is a technical challenge and the electrical fields used in detection can interfere with on-chip processes such as electrophoresis. Electrochemical techniques include potentiometry, amperometry and con-

ductometry. Recently, mass spectrometry detectors and nuclear magnetic resonance detectors have been interfaced with microfluidics as well.

Key Research Findings

Cell assays in microfluidics can be classified into four themes: intracellular biochemistry, extracellular biochemistry, mechanical properties, and electrical properties.

Intracellular Biochemistry

Intracellular biochemistry assays were the first, and continue to be the most common cell assays performed in microfluidic devices. Controllable and highly resolved delivery of reagents to cells and facile integration with optical and electrochemical detection techniques has sparked research in many areas, ranging from metabolism to gene expression analysis. We categorize these assays in terms of the type of chemical stimuli (homogeneous vs. heterogenous), as well as by assay duration and throughput.

Homogeneous Stimuli

In the most straightforward form of intracellular biochemistry assays, a homogeneous stimulus is applied to cells, after which various indicators of metabolism or signaling are measured. Wheeler et al [4] performed cell viability assays and measured intracellular Ca^{2+} flux in Jurkat T-cells and U937 cells. A suspension of cells was hydrodynamically manipulated and focused onto a dock at a T-junction stagnation point (Fig. 1b). The integrated device, which relied on multiple on-chip valves and pumps, enabled a high degree of control of reagent delivery while facilitating complete solution change in approximately 100 ms.

Heterogeneous Stimuli

While homogeneous stimulus-response assays are more straightforward, a particularly useful kind of assay relies on heterogenous stimuli in the form of chemical gradients. A device for creating controlled linear, parabolic and periodic concentration gradients was developed by Dertinger et al. [7], employing diffusive mixing in a complex network of serpentine microchannels (Fig. 1c). This kind of structure has been exploited widely in microfluidic cell-based assays. For example, Thompson et al. [8] stimulated HeLa S3 cells with 8 different concentrations of the inflammatory cytokine TNF-α (an intercellular chemical messenger protein), and monitored the resulting dynamic expression of the NF-κB transcription factor with a fluorescent reporter. Another promising application of controllable concentration gradients was reported in studies of stem cells [9] – this is particularly relevant, as stem cell differentiation is highly dependent on microenvironmental cues.

In addition to forming gradients, multiple laminar streams can provide stimuli selectively to subcellular domains. In a striking example of this phenomenon, Takayama et al. [10] delivered a fluorescent dye specific for mitochondria to a designated portion of a cell. After staining, the migration of labeled mitochondria was observed within few hours. In the same study, local cytoskeletal structures were similarly effected by delivering latrunculin A (an agent that promotes dissolution of actin filaments), which resulted in localized disruption of cell morphology (Fig. 1d). Similarly, different temperature stimuli were applied using laminar streams to deliver fluid to immobilized *Drosophila* embryos (Fig. 1e) [11]. Posterior and anterior parts of embryos treated in this manner exhibited different development as a function of the different temperatures applied.

Long-Term Assays

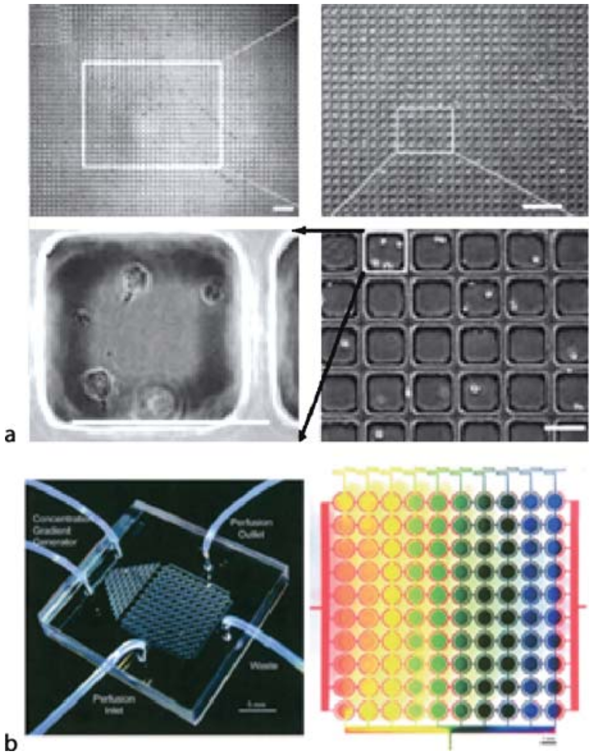
Most of the aforementioned work describes short-term assays that were largely independent of cell response to the microfluidic environment. A thorough investigation of a microfluidic system for long-term experiments was performed by Davidsson et al. [3] using luciferase (an enzyme that catalyzes bioluminescent reactions) reporter gene activity in the cell line HFF11. Cells were immobilized on silicon chips at 37 °C (Fig. 1a), incubated in CO_2-independent cell media, and monitored for up to 30 hours. The authors observed that cell stress and consequent non-specific gene expression were caused by

- detachment and transfer of adherent cells from culture flask to the chip,
- a change of environment from static to flow, and
- changes in chemical environment (e. g., addition of fresh cell media.)

By allowing cells to incubate and adapt to new conditions for several hours, non-specific gene expression decreased to a low, steady level.

HTS Assays

Although a few studies have described medium-throughput microfluidic cell assays, the potential of this application has not yet been fully realized. Quake and coworkers [12] developed a device comprising hundreds of reaction chambers, a complex network of microchannels, and multiplexed valves. The utility of the device was illustrated by detecting a recombinant cytochrome c peroxidase (an enzyme used for chemiluminescent detection) expressed in *E. coli*. This device, which houses 256 725 nL chambers, demonstrates the potential for high-throughput



Cell Assays in Microfluidics, Figure 2 (**a**) Microfabricated array of cell chambers for high-throughput screening. (Image reproduced, with permission, from [13]) (**b**) Microfluidic array for high-throughput cell assays with concentration gradients formed across ten columns. (Image reproduced, with permission, from [14])

cell assays with minimal reagent use. A similar platform was developed by Chin et al. [13], and contains 10,000 microwells (Fig. 2a). Rat neural stem cells were seeded in the wells and enclosed in a microfluidic system such that all cells shared the same media, including any chemicals secreted by the cells. Proliferation of over 3,000 individual cells was monitored over period of days in single-, two- and three-cell-per-well assays. Hung et al. [14] developed a device for conducting cell assays in 100 chambers (Fig. 2b). In addition to perfusing cells with fresh media and assay reagents, the device was capable of passaging cells, i.e., growing multiple generations after cell division. Although these studies are promising, microfluidic systems capable of achieving throughput similar to conventional robotic platforms have not yet been realized.

Extracellular Biochemistry

Cells secrete signaling molecules (e.g., hormones and neurotransmitters), growth factors, and metabolic products. Measurements of the secreted molecules are required for studying cell–cell communication and regulation of cell secretory processes. Conventionally, these measurements are implemented by perfusing cells with chemical stimuli, collecting the perfusate, and analyzing it by *immunoassays* or other means. Integration of these processes on-chip enables continuous, automated monitoring and analysis of cellular secretion with high temporal resolution. This capacity is required to observe a complete secretion profile of system with complex kinetics. For example, insulin secretion goes through several phases, including initial burst, plateau and oscillations, all within seconds.

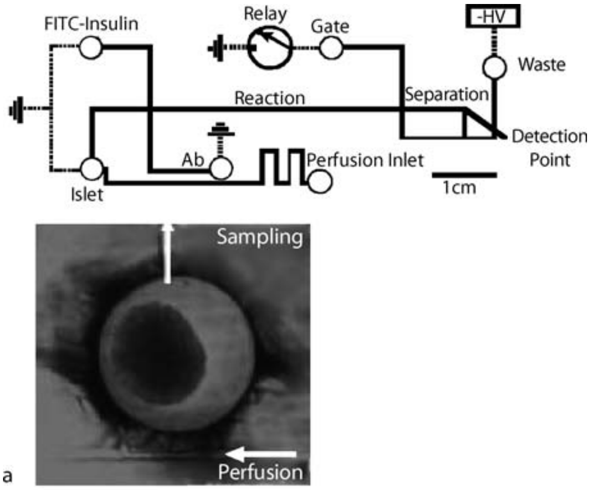
Understanding the mechanism of insulin secretion is tremendously important in diabetes research. In response to this challenge, an on-chip system for monitoring insulin secretion from islets of Langerhans (groups of pancreatic beta cells) was developed by Kennedy and coworkers [15]. The device enables a fully integrated cell assay with continuous on-chip cell perfusion, sampling of secretions, downstream mixing of labeling reagents, and separation and analysis with high temporal resolution (Fig. 3a). Islets were stimulated with glucose and extracellular fluid was sampled and analyzed every 6 s by means of an electrophoresis-based immunoassay having a 0.8 nM detection limit. Cells exhibited no morphological changes during the two-hour assay.

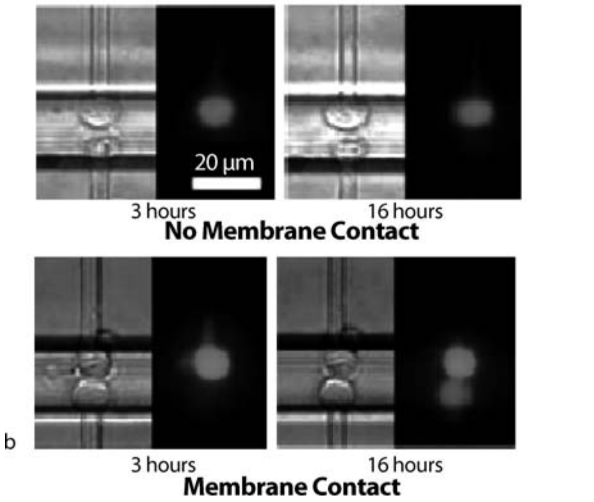
While the methods and devices developed by the Kennedy group for analysis of insulin secretion are the most comprehensive of this type, several on-chip methods have been reported for other analytes. For example, Davidsson et al. [6] designed a system for quantitative analysis of secreted glucose and ethanol. The allergic response of rat leukemia cells was monitored in a microfluidic device [16] by measuring fluorescence from a dye released along with histamine after stimulation. Lee et al. [5] investigated cell–cell communication via gap junction interactions on single cell pairs. The authors trapped two different mouse fibroblast populations at opposite sides of a microchannel and detected the interaction between cells by monitoring dye transfer between them. If the trapped cells were in contact, the dye was transferred within 16 h (Fig. 3b).

As these studies demonstrate, microfluidic devices are a useful and in some cases unique platform for dynamic, high-resolution measurements of cell secretory profiles. Relative to conventional tools, these on-chip methods enable superior control of perfusion, high-frequency analyte sampling, and integration of various processes on a single device.

Mechanical Response

Mechanical responses of cells to physical or chemical stimuli include cell growth patterns, morphology, adhesion and motility. Many mammalian cells grown in culture are adherent. For such cells, the adhesive interactions with the





Cell Assays in Microfluidics, Figure 3 (**a**) Schematic of a device for continuous perfusion of pancreatic cell islets and stimulation with glucose, and monitoring of insulin release (top). Perfusion chamber with an islet (bottom). (Image reproduced, with permission, from [15]) (**b**) Microfluidic device for monitoring cell–cell communication via gap junctions. Fluorescent dye transfers from one cell to another only when cells are in contact. (Image reproduced, with permission, from [5])

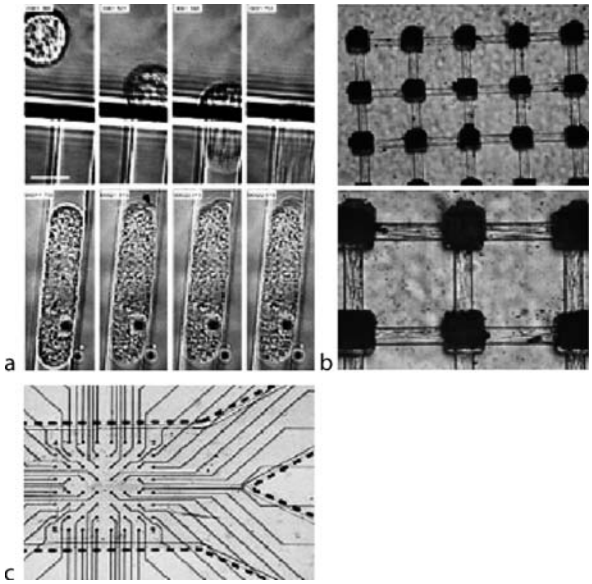
physical environment (extracellular matrix or other cells) are a critical determinant of their biochemistry and behavior. Microfluidics has become a useful tool for studying these interactions. Many of these studies are reviewed elsewhere (▶ cell adhesion and detachment), so we focus here on assays that evaluate the effects of physical or chemical cues on cell morphology or motility.

Cell Morphology

Cell morphology, or shape, is important for survival, differentiation and migration. A few microfluidic cell assays have been conducted to characterize cell elongation, contraction and other morphological changes in response to mechanical forces and chemical cues. Gray et al. [17] studied endothelial cell shape in microchannels under static and dynamic flow conditions. Under both conditions significant cell elongation in the direction of a microchannel/flow was observed after 12 h. In other study, Li et al. [18] used a microfluidic platform and an acoustic wave sensor to monitor contractions of heart muscle cells. In addition to the effects of chemical stimuli, alterations in contractions were observed to be a function of electrode size, presence of the microchannel plate, and liquid loading onto the sensor.

Cell Motility

In cell motility and migration studies, special attention has been paid to chemotaxis, or migration of cells in response to gradients of chemicals known as chemokines. Chemotaxis of human neutrophils (immune cells that migrate to sites of infection or injury) was evaluated in seminal work by Jeon et al. [19]. Complex gradients of the chemokine interleukin-8 were generated in microchannels and maintained at a steady state using the pyramidal branched microchannel structure [7] described above. Others have noted that when generating chemokine gradients, care should be taken to moderate flow rates as a bias in cell migration is observed under high shear flow [20]. Beebe and coworkers [21] monitored neutrophil chemotaxis under concentration gradients formed statically, i. e., without flowing fluid. Chemical species diffused into a cell microchamber through a membrane which imposed high fluid resistance to minimize convective flows. In this manner, soluble cues including autocrine factors (secreted by a cell itself) and paracrine factors (secreted by other cells) were not washed away with a laminar flow but rather accumulated in the microenvironment. This design allows for examining the influence of cell–cell communication on chemotaxis or on other cell responses to chemical stimuli. While movement of cells in response to chemical factors has been a popular research topic, only a few studies have evaluated the effects on cell motility of mechanical stimuli. In one important study [22], neutrophil morphology, rheology and viscoelasticity were monitored when cells were seeded in microchannels of smaller dimensions than cell diameter (Fig. 4a). An important observation was made in that mechanical deformation of neutrophils is not passive, but rather active, as migration capabilities are enhanced through the formation of pseudopods and a reduction in cell stiffness. Undoubtedly, these findings encourage further research in this field.



Cell Assays in Microfluidics, Figure 4 (**a**) A neutrophil flowing into a microchannel and becoming deformed. After entering the channel, the cell forms a pseudopod (arrow) that facilitates movement. (Image reproduced, with permission, from [22]) (**b**) Neurons seeded in chambers on top of patterned electrodes, with cell structures protruding into microchannels. (Image reproduced, with permission, from [24]) (**c**) Microfluidic channel (dashed lines) fabricated on top of patterned electrodes for recording neuronal activity. (Image reproduced, with permission, from [25])

True cell mechanical stimuli can hardly be implemented in macro-scale assays. Therefore, most of the work prior to the advent of microfluidics was focused on cellular response to chemicals or soluble signals. In contrast, as illustrated by the studies above, microfluidic devices are capable of mimicking in vivo physical conditions including topography and shear stress, which enables new research focused on mechanical response of cells to mechanical stimuli in combination with chemical cues.

Electrical Response

Electrical measurements on cells are discussed in other entries in the *Encyclopedia* (►cell electrical measurements, ►patch-clamp measurements on-chip). We focus here on the basic cell electrical responses assayed in microchannels, most of which have been developed in the context of cell-based biosensors. These studies typically evaluate cell action potential which is a net electrical change in cells resulting from changing concentrations of intracellular ions. Action potentials are important physiologically because they result in the transmission of signals between nerve cells and contraction of muscle cells. These electrogenic cells are very sensitive to chemical changes in the cell microenvironment and changes in action potential are detectable much sooner than any morphological changes.

DeBusschere and Kovacs [23] developed a portable microfluidic platform integrated with a complementary metal-oxide semiconductor (CMOS) chip which enables control of temperature as well as the capacity to measure action potentials in cardiomyocytes. When cells were stimulated with nifedipine (a calcium channel blocker), action potential activity was interrupted. Morin et al. [24] seeded neurons in an array of chambers in a microfluidic network integrated with an array of electrodes (Fig. 4b). The electrical activity of cells triggered with an electrical stimulus was monitored for several weeks. Cells in all chambers responded asynchronously to the stimulus. This device illustrates the utility of microfluidic tools that can investigate structure, function and organization of biological neural networks. A similar study probed the electrical characteristics of neurons as they responded to thermal stimulation [25] in a microfluidic laminar flow. Neurons were seeded on an array of electrodes (Fig. 4c) which allowed for measurements of variations in action potentials when cells were exposed to different temperatures.

By combining facile electrical measurements with controllable physical and chemical stimuli at the micron level, microfluidic devices are developing into a versatile platform for cell-based biosensors, drug discovery, genetic analysis and diagnostics.

Future Directions for Research

The studies summarized here were selected to demonstrate the potential of microfluidics for use in cell-based assays. We do note that the majority of the methods described are in a proof-of-principle stage. For real-world application in both academic and industrial research, a few hurdles must be overcome including device reliability, integration and automation, throughput, and macro-to-micro interfacing. We believe these challenges are solvable, and given the trajectory of interest and innovation in this area, we speculate that microfluidic cell assay tools will soon become irreplaceable in biosensing, diagnostics, drug screening and other biomedical applications.

On-Chip Cell Culture; Cell Culture on a Chip

Definition

Cell culture on chip is defined as those methods to cultivate biological living cells on two- and three-dimensional (2D and 3D) chip devices. Microchip techniques can provide many advantages for cell culture systems because the scale of the cultivated environment inside the microchip is fitted to the size of the cells. The integration of microfabrication and cell culture technologies promises great advances in basic biological research, diagnostics, biosensors, high-throughput drug screening, and so on.

Overview

Cultivating cells in vitro is one of the cornerstones of modern biology. Cell culture is an essential tool in biological science and clinical analysis, with some applications such as drug screening and biosensors. Many advances have been made in developing automated high-throughput cell culture systems. However, high cost and large size limit their application. It is therefore highly desirable to produce a miniaturized, inexpensive platform for *cell-culture-on-a-chip* to enable high-throughput cell experiments.

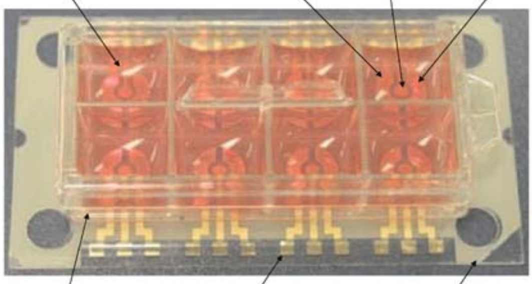
In their normal physiological environment, cells are subject to multiple cues varying in time and space. Here a cell or cell layer is a complex system with appropriate response to a variety of external physical and chemical excitations from neighboring cells and extracellular matrix. Microfabrication technology creates new opportunities for the spatial and temporal control of cell growth and stimuli by combining surface modification and microfluidic transportation methods. Microfabricated systems can present cells with different cues in a controllable and reproducible fashion that cannot easily be achieved by standard macroscopic cell culture methods. They can also be used to integrate cell culture with analytical devices to probe cellular behavior. Further integration with other analytic microsystems results in multifunctional platforms for basic biological research and cell-based biosensors. Among existing cell culture microsystems, some simply represent miniaturized versions of conventional laboratory techniques, whereas other devices exploit the advantages of small scales and low Reynolds numbers. Stable long-term cell culture is necessary and difficult in the realization of microchip-based cellular systems.

The integration of cell culture and microfabrication technologies provides some advantages for cell culture microsystems, because microfluidics allow the creation of culture systems on a size scale similar to the characteristic size of biological objects and their local in vivo environment. Much cell culture microsystems research takes place within a *Lab-on-a-Chip* or *micro total analysis system* (μTAS) framework that seeks to create microsystems incorporating several steps of an assay into a single system. Microfluidics can provide suitable environments for cell culture because of the large surface-to-volume ratio and fluidic behavior similar to the environments in vivo. Such microfluidic environments are now used to investigate cell–cell interactions and behaviors in vitro, emulating situations observed in vivo. Compared to traditional culture tools, microfluidic platforms should provide much greater control over cell microenvironments and rapid optimization of media composition using relatively small numbers of cells. The ability to perform multiple steps of a biological cell assay on a single self-contained microchip promises significant advantages in analysis speed, separation efficiency, cost reduction, reduced sample/reagent consumption, elimination of contamination, fewer wasted reagents, more detailed control of the cellular environment, and faster response time. Automated high-throughput experiments may be performed in a large number of repeating functional microstructures fabricated on a single chip. These microsystems can also monitor the time course of the release, which is difficult to measure by conventional batch cell culture methods.

Basic Methodology

Cells and the Extracellular Matrix

Cellular patterning using microfabrication techniques is essential for most on-chip cell culture methods. It is possible to reproducibly create a cell microenvironment at cellular resolution. Recent advances in microfabrication and microfluidics have allowed highly controlled cellular micropatterning, high-density sample characterization, and multiple experiments on one array. Surface patterning of microscale features allows micrometer-sized control over cell and extracellular matrix interactions, and the generation of ensembles of cells with defined geometry. Lam-



Cell Culture (2D and 3D) on Chip, Figure 1 Configuration of the microfabricated cell culture chip integrated with the electrochemical impedance measurement method. The cell chip consists of an eight-well cell culture chamber incorporated with a three-electrode system on each well. The gold electrode for impedance measurements is fabricated by sputtering on polycarbonate film

ination, molding, and photopolymerization techniques all allow fabrication of 3D scaffolds with feature sizes in the sub-micrometer range. The cellular micropatterning techniques have been employed to understand fundamental cell biology, especially cell–cell, cell–surface, and cell–medium interactions.

Among a large number of surface-patterning techniques available, the photolithographic technique is highly developed and has been widely used to control cell–cell interactions in co-cultures by using specific and nonspecific adhesion. In the microcontact printing method, the size and shape of a cell-adhesive region can be manipulated on the surface of a cell culture substrate. Consequently, the size and shape of the cells can be controlled by manipulating the adhesive regions, which affect many aspect of cellular activity such as protein secretion, cell growth, apoptosis, and differentiation. The microfluidic patterning technique using microchannels can generate patterns of thin lines containing various ligands on the cell culture substrate. With this technique, cell adhesion and spreading are spatially controlled on patterned lines containing specific peptides. The stencil method can be used for patterning virtually any adherent cell type on various materials, ranging from polystyrene Petri dishes to a microelectrode circuit or a gel.

Cellular micropatterning techniques have been used to understand questions in fundamental cell biology. The precise control of the cellular environment has been made possible by microtechnology, which provides new opportunities for understanding biochemical and mechanical processes responsible for changes in cellular behavior. Adhesive extracellular matrix patches can also be designed so that the shape of patterned cells can be controlled.

2D Cell Culture on Chip

2D Cell Culture on Patterned Surfaces

Patterned surfaces are widely used in 2D cell culture methods, where some receptor proteins or extracellular matrix are patterned on a surface for subsequent cell docking. Many microfabrication techniques described above can be used to form patterned surfaces. They allow a high degree of geometrical control over microscale features of a substrate. Micropatterned cell cultures are ideal to address fundamental issues of cell–cell and cell–surface interactions in confined geometries, as well as subcellular processes.

2D Cell Microarray

2D cell microarray technology is widely used in high-throughput cell-based research such as biosensors and drug screening. Surface patterning, soft lithography, and photolithography have been used to realize cell microarrays.

3D Cell Culture on Chip

Cell Culture in Microchambers

Microchamber-based cell culture is a common 3D cell culture method where cells are cultivated in a microscale chamber structure. This microchamber can easily be fabricated using existing microfabrication technology. It is similar to a miniaturized model of a traditional macroscopic cell culture well (Fig. 1). Microchambers are used for long-term culture and monitoring of extremely small populations of cells with single-cell resolution.

Agar Microculture Chip

A cell culture system based on photothermal etching has been developed for on-chip cultivation of living cells using an agarose microchamber array. The method can be used to flexibly change the chamber structure by photothermal etching, even during the cultivation of cells, depending upon the progress in cell growth. By using photothermal etching with adequate laser power, narrow tunnel-shaped channels can easily be fabricated between the microchambers at the bottom of the agar layer (Fig. 2). Photothermal etching occurs only in the area where an absorbing material is used, which means that it is possible to photothermally etch lines without damaging the cells in the microchambers. The advantages of this system are that it can control the positions and numbers of cells for cultivation by using agar-based microchambers, and it can change the tunnel network between adjacent chambers during cultivation by photothermal melting a portion of agar at the

focal point of an infrared laser beam. The results suggest that the agar–microchamber cell culture system in combination with photothermal etching can potentially be used for the next stage of single-cell culture including the real-time control of the interaction of cells during cell culture.

On-Chip Single-Cell Culture

Most current on-chip culture methods are carried out in a batch mode, without keeping tracking of a single cell, and only for adherent cells. Dynamic monitoring of a single cell is important for individual cell analysis without the influence of neighboring cells in independently controlled environments. Thus, single-cell culture chips are attracting wide attention. An ideal microchip for single-cell experiments should allow one to culture cells, to select any desired single cell from a group, to retain the cell for convenient cellular signal detection, and to deliver any buffer or reagent directly to the cell at any time during continual detection and observation. Most importantly, any negative impact on the live cell should be minimized.

Cell Culture on 3D Surfaces

Cell culture on 3D surfaces is similar to that on 2D surfaces despite the former being more complex surfaces. Cell patterning on 3D surfaces is rather difficult. Some microfabrication methods have been developed for 3D surface patterning. For example, a plasma-based dry etching method enables patterned cell culture inside microfluidic devices by allowing patterning, bonding, and sterilization steps to be carried out in a single step. This plasma-based dry etching method is used to pattern cell adhesive and non-adhesive areas on glass and polystyrene substrates. The surface patterning method offers a convenient way of micropatterning biomaterials for selective attachment of cells on substrates, and enables cultivation of patterned cells in microchannels.

One important application of cell culture on 3D surfaces is microtissue engineering. It is increasingly important to control cell growth into and within artificial scaffolds. Tissues such as skin, blood vessels, and cartilage have multilayer structures with different cells in each layer. With the aid of microfabrication technology, scaffolding methods for biodegradable polymers such as polylactic acid, polyglycolic acid, and the copolymer poly(lactide-*co*-glycolide) are developed to construct 3D multilayer microfluidic tissue scaffolds. Construction of complex microfluidic structures within and across the layers of multilayered scaffolds is demonstrated for modulation of cell growth.

Cell Culture in Microchannels

Microchannel systems can be used to generate continuous gradient of some growth factors in order to study the optimal proliferation and differentiation conditions of some cells. They can also be used to micropattern the cell culture surface area. Cells cultivated in microchannels are used to study cellular properties within fluidic environments, especially the impact from shear stress. For example, the geometry of the microchannel affects cell growth, orientation, and phenotype control of vascular smooth muscle cells. Smooth muscle cells cultured in wider microchannels (80 – 160 μm wide) switch from fibroblast morphology and random orientation to spindle-shaped morphology, and align along the direction of the microchannel nearing confluence at common cell density. They proliferate at low cell density and shift from a synthetic to a more contractile phenotype and random to unidirectional cellular orientation at high cell density nearing confluence. The wider microchannels also allow cells to grow to a higher cell density comparable to that of flat surfaces compared to narrower microchannels (10 and 40 μm wide).

3D Cell Microarray

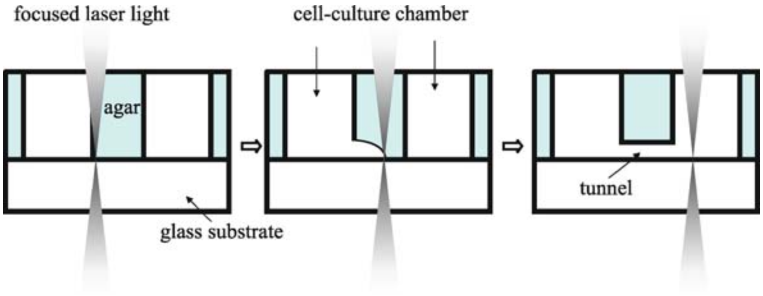
A 3D cell microarray is similar to a 2D cell microarray except that cells are cultivated in arrays of microchambers. Cells in a 3D microarray can live longer than those in 2D culture style for medium perfusion and a temperature control unit can be integrated in this system. The microfluidic cell culture array can potentially offer an affordable platform for a wide range of applications in high-throughput cell-based screening, bioinformatics, synthetic biology, quantitative cell biology, and systems biology. As for the mono-microchamber cell culture style, detection components such as microelectrodes can also be fabricated in microchamber arrays for on-chip cellular analysis.

Cell Culture on Microcarrier Beads

In this mode, cells are grown on microcarrier beads and kept thermostatted while their metabolism is probed in real time. Several microanalytical systems are integrated in this cell culture device for real-time measurement of cellular activity.

Continuous Perfusion Cell Culture

Cultivating cells up to higher density and larger numbers is one of the most important tasks to achieve physiologically meaningful functions. It is also required for tissue engineering. To reach this goal, continuous nutrition



Cell Culture (2D and 3D) on Chip, Figure 2 A schematic of photothermal etching. First, an infrared laser beam is focused on the chromium layer on the glass slide; second, the focused beam is moved to the agar wall and a portion of agar at the spot-heated point melts and diffuses into water; finally, after the heated spot has been moved, two microchambers are connected by a tunnel

and oxygen supply and waste removal through the culture medium have to be ensured. Another important physiological function of cultivated cells is the secretion of chemical products. A variety of chemicals are released from cells, including signaling molecules such as hormones or neurotransmitters, trophic factors, and metabolic products. Temporally resolved measurements of materials released from cells are important in studying the regulation of the secretory process as well as technological pursuits such as drug development. Such measurements are typically performed by perfusing cells, collecting fractions, and then performing off-line analysis by immunoassays or other appropriate methods. Perfusion cell culture is believed to provide a stable culture environment due to the continuous supply of nutrients and removal of waste. However, the culture scales used in most cases are large, where the culture conditions cannot be regarded as homogenous because of chemical gradients. To improve this, the concept of miniaturization is applied to 3D cell culture. The development of a microfabricated device that can miniaturize and automate such measurements will be valuable in physiological studies. With the help of recent advances in microfabrication and μ-TAS, a continuous perfusion cell culture system can be miniaturized into a microfluidic device, which not only largely minimizes the chemical gradients existing in culture environments and cultured constructs, but also provides better control over the microenvironment of cells. It also reduces the required cell numbers, the volumes of culture medium, and the need for costly reagent. As a combination of microchamber and microchannel cell culture method, it uses a microscale perfusion system to provide a relatively stable culture environment, because of the continuous supply of nutrients and removal of waste, to realize longer-term cell culture.

Continuous-perfusion cell culture results in some advantages: it can allow one obtain truly dynamic measurements of secretion because the secreted products do not like those within traditional chamber-based methods where they continually increase in concentration; it can allow rapid raising and lowering of concentration of drugs or secretagogues on the cell as required for many experiments; and it can continually provide fresh nutrients to the cells, which decides the time that cells can be viable on the chip. The continuous-perfusion cell culture system can also enable vastly improved temporal resolution for monitoring, facile control of the cellular environment, and compatibility with longer-term measurements. A microfluidic system provides accurate control of the perfusion rates and biochemical composition of the environment surrounding the cells. It can serve as an improved in vitro model for studying muscle cell differentiation and for characterizing extracellular molecules and mechanisms involved in neuromuscular differentiation. Reliable fluidic control is particularly paramount for perfusion-based cell differentiation studies because differentiation processes are biochemically delicate and they take several days to complete. Thus, some elaborate micropumps and microvalves have been used in these systems for accurate fluidic control. Long-term viability is of great interest not only for differentiation studies but also for a variety of applications encompassing cell-based biosensors, high-throughput assays, and basic cell biology research. Long-term perfusion at low flow rates does not interfere with cell differentiation and is not observed to affect cell morphology or growth.

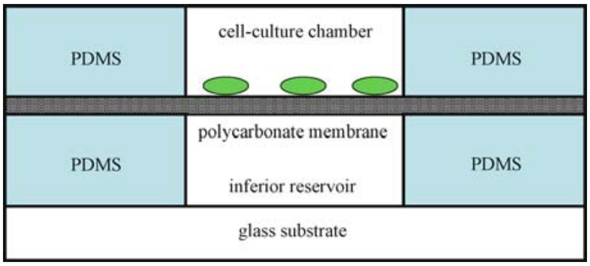
Key Research Findings

In 2D cell culture on chip, cell adhesion has been extensively studied on patterned surfaces for it is critical to cellular functions. Micropatterns have been used to study the cellular interactions with various materials such as metals, polymers, self-assembled monolayers, extracellular matrix proteins, cell-adhesion peptides, and other bioactive molecules. The physical and chemical proper-

ties of a substrate affect the attachment and growth of cells on it, and many studies have demonstrated that different topographical features of a surface affect cell attachment. Glass, silicon, and polydimethylsiloxane (PDMS) are widely used as substrate materials of cell culture microchips. The influence of these materials on the attachment and growth of several different types of cells has been studied. For example, PDMS substrate often requires oxidation of the surfaces to seal the device irreversibly. These hydrophilic surfaces may result in poor initial attachment, and detachment of certain cell types. In some cases, excess curing agent in the polymer may cause detachment of certain types of cells and prevent cells from reaching confluence. Some surface modification of PDMS substrate such as fibronectin coating is suitable for culturing various types of cells. There are many advantages of fabricating devices made of PDMS rather than conventional materials such as glass, silicon, and polystyrene.

Recently, cell spheroid microarrays have become a hotspot in cell microarray research. A 2D microarray of spherical multicellular aggregates (spheroids) are fabricated on a PDMS chip by a photolithography-based technique, which consists of thousands of cylindrical microcavities. Most cells on the PDMS chip gradually gather and subsequently form a single spheroid in each cavity until several days of culture. A part of the spheroid is attached to the bottom or wall surface of the microcavity, and the spheroid configuration is maintained for long-term culture. Spheroid microarrays can also be microfabricated on hydrogels. Photo-crosslinkable chitosan is synthesized and utilized for fabricating hydrogel microstructures through a micromolding process. The chitosan surface is initially cell repellent but becomes increasingly cell adhesive over time. By using this unique property of chitosan hydrogels, it is possible to generate patterned co-cultures of spheroids and support cells. This spatially controlled spheroid co-culture system can potentially provide a useful tool for fabricating biomimetic cellular microenvironments, for studies of cell–cell interactions, and for tissue engineering applications. Another spheroid culture device with an array of pyramid-like microholes is constructed in a silicon chip that is equipped with elastomeric microchannels. A cell suspension is introduced via the microfluidic channel into the microstructure that comprises silicon microholes and elastomeric microwells. A single spheroid can be formed and localized precisely within each microstructure. Since the culture medium can be replaced via the microchannels, a long-term culture is available on the chip.

Nanoporous polycarbonate membrane, which is used for macroscopic cell tissue culture and measurements, can be sandwiched between two structured wafers (silicon, glass, or PDMS) for cell patterning and culture. This method allows cell nutrition and exposure to various chemicals from either side of the membrane (Fig. 3). To realize a more efficient assay, a local temperature control device is designed and fabricated to keep different optimum temperatures in different areas on a microchip. Some detection methods such as electrochemical impedance or potential measurement electrodes can be integrated in microchambers for on-chip cell analysis (Fig. 1). Surface plasmon resonance (SPR) can also be integrated on microchamber cell culture devices for real-time monitoring of express proteins. As the surface patterned cell culture method, surface-modified PDMS is widely used in cell cultivation chambers. It has excellent air permeability, and air can be directly delivered to a PDMS microchamber without any external air supplying system. The microchamber can easily be integrated with other microfluidic components to form a whole cell-Lab-on-a-Chip.



Cell Culture (2D and 3D) on Chip, Figure 3 Schematic cross-section of a cell culture microchamber device showing the PDMS sandwiched nanoporous polycarbonate membrane, assembled with top and bottom microfluidic reservoirs

In a single-cell culture chip model, a zero-speed point is controlled to retain the cell for 3D cell balancing and cell scanning in order to prevent damage of the cell by mechanical force. A dispersive flow delivers reagents at a high speed to very near the cell and provides them to the cell at a low speed. No force stronger than its gravitational force is exerted on the cell, which can be balanced on different positions on an arc-sloping wall, thus minimizing any negative impact on the cell due to strong liquid flows.

Protoplasts in a PDMS channel showed cell division and microcolony formation within several weeks. In embryo culture study, the results suggest that the microchannel culture systems may provide a culture environment that more closely mimics the in vivo environment. The microfluidic systems can enhance assisted reproduction efficiencies. The flow rate affects the cellular behavior of myoblasts, as well as differences in cell density of undifferentiated myoblasts and differentiation patterns. Shear stress brings some effects on hepatocyte activity. The shear flows cause hepatocytes to change morphology and functions accord-

ing to their exposed value of shear stress. The metabolic activities of hepatocytes under higher shear stress are lower. Morphologic observation reveals that hepatocytes change their shape like vascular endothelial cells do.

Microscale blood vessels can also be modeled by microfluidic channels. This work may be applicable to studies of blood vessels and endothelia. As in the microchamber cell culture method, detection devices such as microelectrodes can be fabricated in microchannels for on-chip cellular analysis.

In a 3D stem cell culture microarray platform, a high-density array of microwells is integrated into a fluidic chamber to guide deposition of adult neural stem cells and confine their progeny. This platform enables parallel, automated, long-term, live-cell microscopy of single cells in culture; tracking of individual cell fates over time; and correlation of differentiated progeny with founder clones. Using this microarray platform, one can further interrogate the response of distinct stem cell subpopulations to microenvironmental cues (mitogens, cell–cell interactions, and cell–extracellular matrix interactions) that govern their behavior. It enables parallel, quantitative analysis of stem cell proliferation and differentiation. In addition, unlike multiwell plate platforms, large numbers of live cells may be observed using conventional microscopy and correlated with differentiated progeny by high-magnification immunofluorescence in a rapid and efficient manner. In some cases, some drug containers can be integrated in 3D cell culture microarrays for high-throughput drug screening. This realizes a simultaneous evaluation of the effects of multiple chemical stimuli on the cells arrayed in the chip. Another novel platform technology creates arrays of microwells on chips for hosting cells in a local microenvironment characterized by controlled shape and surface chemistry. This 3D cell culturing combining 2D chemical patterning with topographical microstructuring presents to the cells a local 3D host structure. Using the inverted microcontact printing method, the plateau surface between the microwells is successfully passivated to block adsorption of proteins and prevent cell attachment by transfer of a graft copolymer. This novel platform is useful for fundamental cell biological studies and applications in the area of cell-based sensing.

A perfusion microbioreactor has been developed based on mass transport simulation to find out reasonable culture scales with relatively low chemical gradients. Here a PDMS surface is treated with surfactant solution to reduce nonspecific serum protein adsorption, which keeps the culture conditions steady. As described above, to achieve physiologically meaningful functions in vitro, a culture with a larger number of cells and higher density must be obtained. This will require bioreactors with larger surface areas for cell attachment and sufficient amounts of oxygen and nutrition supply. For these purposes, this bioreactor is fabricated by stacking tens of PDMS layers together. Several cell culture microchambers are fabricated on each PDMS layer. The high gas permeability of PDMS allows oxygen supply to the microfluidic channels through the thin walls. Consequently, by stacking single culture chambers and oxygen chambers in between, one can realize a microfluidic bioreactor for large-scale cell cultures. Continuous-perfusion microdevices can easily be integrated with other microfluidic analytical methods such as electrophoresis. Cellular activity under shear stress can also be monitored using continuous-perfusion systems. In some cases, a polymer membrane is used as scaffold for the attachment of cells in the perfusion system.

Future Directions for Research

Many cell culture microsystems available today are still in the proof-of-concept phase. Typical on-chip cell growth has been demonstrated, but robust approaches to fabrication, integration, and packaging remain major research areas. Integration and automation are important goals that also remain considerable hurdles. The rationales for integration include greater accuracy and reproducibility, smaller sample sizes, and higher throughput. Though on-chip cultivated cells can live longer and longer, long-term cell culture and perfect preservation of cellular activity are still very difficult. The growing emphasis in molecular biology on single-cell analysis derives from increasing and accurate appreciation of phenotypic heterogeneity among cells in a population. Physicochemical modeling of biological processes also demands single-cell data, or at least information about the distributions of key parameters. Thus, single-cell manipulation will be a future research hotspot. Although significant challenges face routine applications of *cell culture on chip*, tremendous advances have been realized over the past decade, and a future in which chips effectively compete with laboratory-scale technologies in the analysis of complex biological phenomena is clearly in sight. Highly integrated microdevices will find application in basic biomedical and pharmaceutical research, whereas robust and portable point-of-care devices will be used in clinical and point-of-care analysis.

Definition

Cell patterning is a process to position cells on a substrate, especially in a microfluidic chip, with defined spatial selection and in turn to keep stable cell growth on the substrate.

Overview

Predefined patterning or network of cells is important for cellular/tissue function and neuronal activities. Cell patterning has a wide range of applications such as tissue engineering, wound healing, biosensors, and cell migration studies.

Early studies for patterning cells were reported in 1914 [1] in which the interaction between spiders' webs and embryonic cells was studied. Similarly, other artificial microstructures used for cell patterning have been reported. These structures include grooved structures, micro-stamps, and micro-agarose chambers. Another approach is to use patterned surface coatings, e. g. metal, self-assembled monolayer, protein, or other chemicals, to guide cell growth. These coatings either promote or inhibit cell adhesion so that a cell pattern is defined. The search for competent coating material is not trivial for a specific cell type. Therefore studies of biocompatible polymers, extracellular matrix protein, and new coating materials have regularly been reported. An alternative patterning approach that *actively* confines cells is to utilize dielectrophoresis force to trap cells near electrodes.

For all of the above approaches, the transfer of an artificial pattern onto a cell growth substrate is commonly accomplished by photolithography or laser director writing. Recently even ink-jet printers have been utilized for pattern transfer. Using a layer-by-layer approach, a microfluidic chip has been able to generate three-dimensional cell patterns [2].

Synonyms

Cell separation; Cell fractionation

Definition

Cell sorting is defined as the separation of a heterogeneous mixture of cells into purified fractions of homogeneous cells. In this context it will also include the isolation of individual cell types from a heterogeneous mixture of cells. In this context *cell* refers to prokaryotic and eukaryotic cells.

Overview

Methods for processing microliter samples containing cells are in high demand for a wide range of applications in areas such as biomedical research, clinical diagnostics, counter-terrorism, environmental analysis, and biotechnology. Development of a cell-based screening assay often requires identification and isolation of particular cells from a mixture of various kinds of cells in various stages of development. Moreover, in order to obtain reproducible data on cells, reliable and nondestructive purification of cells is essential. However, the efficient separation of cells is a nontrivial task. In addition to the typical difficulties inherent to any analytical separation, the process is often further complicated by the physical and chemical heterogeneity and complexity of both the cells and the sample matrix. Cells, human cells in particular, are mechanically more fragile and more deformable than other cells. They are also biologically more sensitive and quicker to respond to changes in their environment.

Efficient and rapid sorting of cells on the macroscale has been accomplished with techniques such as flow cytometry, differential centrifugation, and filtration, but these conventional methods for sorting cells often result in dilution and dispersion and have disadvantages with regard to their cost, efficiency, response speed, resolution, and adaptability. Efforts to reduce volume and power requirements for particle separation have resulted in a number of miniaturized devices that take advantage of microfluidics and microfabrication. Advantages offered by microfluidic cell sorting techniques include more precise control over cellular microenvironments; significantly less reagent volumes and shorter reaction times in biochemical cell assays which in turn reduces space requirements and operational costs; single cells or rare cells can be manipulated in a non-invasive manner; massively parallel configurations with very high throughputs using arrays of microfluidic channels are possible; automation is more easily achieved; and processes are more easily integrated with further analysis steps.

This article highlights the most commonly used methods to perform cell sorting in microfluidic devices. Some of the microfluidic techniques presented here are a miniaturized version of conventional laboratory analysis techniques and devices, and take advantage of the reduced sample volumes and increased speed of analysis. Many other types of devices have successfully exploited the novel effects that arise in a microfabricated environment that are not evident on the macroscale.

Basic Methodology

Flow Cytometry

Flow cytometry is a conventional technique for counting, examining, and sorting microscopic particles suspended in a stream of fluid. It allows simultaneous multi-parametric analysis of the physical and/or chemical characteristics of single cells flowing through an optical and/or electrical detection apparatus. State-of-the-art conventional flow cytometry systems provide rapid and reliable analytical capacities; however, they are bulky, expensive, mechanically complex, and require trained dedicated staff, multiple sample pre-treatment steps, and a high volume of the sample. These facts have all motivated efforts to take advan-

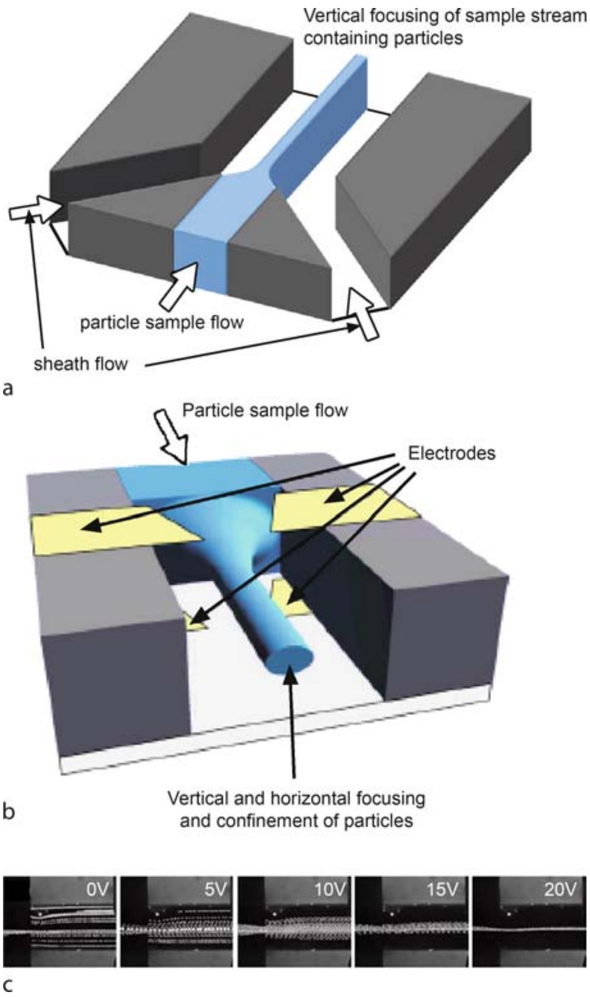
tage of microfabrication technologies and microfluidics to achieve smaller, simpler, more innovative and inexpensive instrumentation. An excellent review of microfluidics for flow cytometry was recently published by Huh et al. [1].
Flow cytometry works in the following way. Specific cells in a sample are labeled with antibodies, fluorescent dye, or magnetic label. The cells are then focused to flow one by one in a single line passing the detection region. Particle focusing can be achieved using two approaches: passive focusing uses converging channels to confine cells without additional energy sources and active focusing using hydrodynamic, electrical, magnetic, or acoustic forces to confine the sample stream. Hydrodynamic focusing is a commonly used method for focusing the sample stream. Typically, the sample fluid stream is driven along the central channel of a cross-shaped channel. As the sample enters the intersection the three fluid streams meet and the sample stream is focused into narrow stream. The main advantage of this technique is that particle velocities are independent of the fluid composition or particle properties and the channel material. The disadvantages of hydrodynamic focusing are that accurate control of differential fluid flow rates or pressure on each channel is necessary to ensure efficient focusing; focusing acts on the fluid rather than the particles and therefore small particles and molecules can diffuse from the sample stream into the sheath fluid; however, it requires supplementary buffer inlets and precise flow control. Maintaining focusing whilst switching fluids into different channels is also problematic.

An alternative method is electrokinetic focusing, which uses a direct current electric field (at high voltages of $\sim$1 kV) to focus particles and liquids into a narrow stream. Typically, the sample fluid stream is driven along the central channel of a cross-shaped channel. As the sample enters the intersection, three fluid streams meet and the sample stream is focused into narrow stream. Dielectrophoresis (DEP) can also be used for sample focusing. DEP is the movement of polarized particles in a nonuniform electric field. This phenomenon is explained further in the next section. The main advantage of this method is that the focusing force acts on the particles rather than on the fluid, allowing particles to be focused within a single stream, and addition side streams are not necessary for focusing.

Targeted cells are then deflected or sorted from the sample stream for subsequent analysis. This cell sorting is commonly achieved by the active control of either the fluid flow or the particle/cell motion itself. The switch of flow is implemented by either electrokinetic or hydrodynamic means or by a combination of the two. In addition to this cell motion can be control by optical forces.

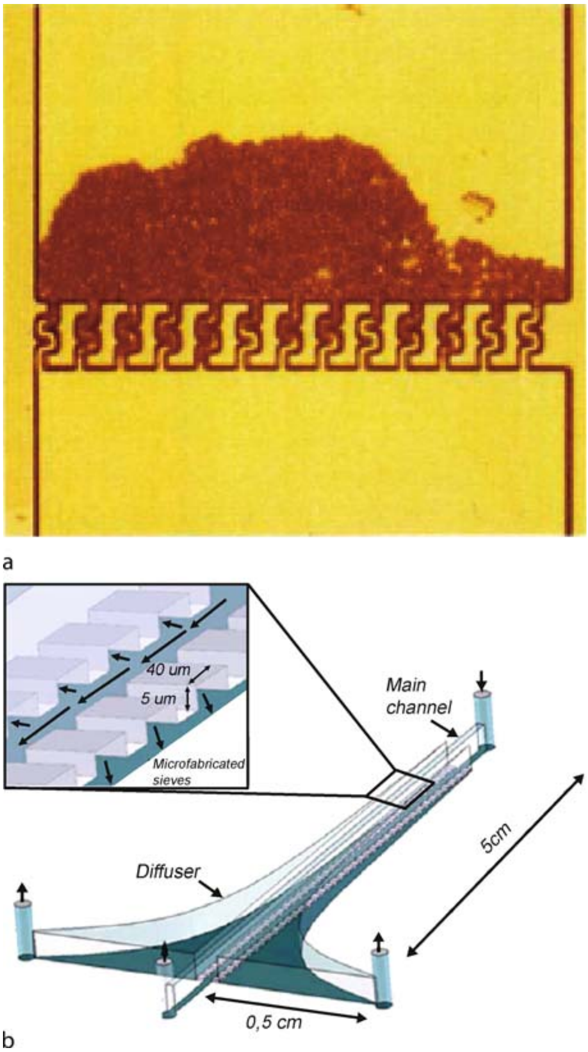
Filtration

This is another conventional technique which can be successfully miniaturized. Microscale filters work on the same principle as macroscale filters in that they separate cells based on size. Using microfabrication techniques, arrays of posts, comb-shaped filters, weir-type filters, and membranes (Fig. 2a) have been fabricated for mechanical filtration of heterogeneous cell samples. An advantage



Cell Sorting, Figure 1 (**a**) Schematic diagram showing the principle of one-dimensional hydrodynamic focusing. The input particle stream is confined on both sides by sheath flow resulting in a focusing of the sample stream, and, as a result, of the suspended particles. (**b**) Schematic diagram showing how DEP can be used to focus particles in two dimensions. Thin microelectrodes on the top and bottom of the channel push the particles into the centre of the channel. The electrodes do not influence the fluid flow. (**c**) Sequence showing how increasing the applied voltage causes the particles to focus into a tight band at 20 V, with significantly poorer focusing at lower voltages. The dark region on the left of each image is the electrodes, which obscure the particles. (Adapted from [7])

of microfiltration is that it does not require specific buffer conditions. However, fabrication of microfluidic filtering components is not trivial. Trapping of the cells tends to be irreversible and clogging of filter and pressure build up is very common as operation time or sample volume is increased. Attempts have been made to overcome filter clogging using a filter parallel to the fluid flow as shown in Fig. 2b. The cell sample or feed stream flows down the center of the device. Smaller particles are transported into the lateral stream through the filtration barriers by high tangential rates, while larger particles will be still suspended in the feed stream. This dramatically avoids the problems of clogging. However, even after removing the problem of clogging due to the heterogeneity of cell size and deformability, the separation specificity of this filtration technique can be poor.



Cell Sorting, Figure 2 (**a**) Filtration of 5.78 μm diameter beads in 500 μm wide channel by a filter with 5 mm spacings. This device has also been used to separate blood cells. (Adapted from [8]) (**b**) Schematic of a microfluidic diffusive filter for cell enrichment. (Adapted from [9])

Electric Forces

Electrical forces that are used for cell sorting applications at the microscale include electrophoresis and DEP. Electrophoretic forces arise from the interaction of a cell's charge and an electric field, whereas DEP arises from a cell's polarizability [2]. Both forces can be used to create microsystems that separate cell mixtures into their component cell types. The advantage of using electric forces is that electrodes can be created in a microdevice using the standard microdevice fabrication techniques and they can be easy controlled using low-cost high-voltage power supplies which are often programmable. Electrophoresis enables the charge-based separation of suspended particles. This method has been used to separate and characterize bacteria and mammalian cells and has proven to be very useful for some applications. However, mixtures of different cell types or live and dead cells could not always be successfully separated since separation is solely based on the charge to size ratio. DEP was first described by Pohl [3] and a good review of its application in microfluidics was written by Hughes [4] DEP is the electrokinetic motion of dielectrically polarized particles in non-uniform electric fields. When particles approach a field gradient, they experience a selective force owing to DEP that is proportional to the particle volume and the difference in complex conductivity of the particle and the fluid. Unlike electrophoresis which depends primarily on the charge to size ratio of the particle, DEP depends on a set of both structural and chemical properties of the particle itself and the conductivity of the suspension media. This enhances selectivity and sensitivity of the technique. Depending on the relative magnitude of the particle conductivity and that of the fluid, the DEP force can act to drive particles towards regions of either high electric field strength or low electric field strengths. These types of DEP are termed positive and negative, respectively. Since most biological cells behave as dielectric particles in an external electric field, the generated DEP forces allow the manipulation of the cells in a liquid suspension.

There are two forms of DEP being used in the micro-/nanofluidic community. Most commonly, DEP is driven by electric field non-uniformities arising from multiple electrodes embedded throughout a fluidic system. Recently considerable interest has been shown in insulator-based dielectrophoresis (IDEP), an alternative approach to conventional DEP. IDEP has also been called *electrodeless*

DEP or *multigradient DEP*. In IDEP, insulating structures (i. e. packing material, posts, ridges, oil droplets) result in gradients in a local electric field (Figs. 3a and c), which is imparted using electrodes located only at the channel inlet and channel outlet. If the applied field has a DC component, this field can also produce an electrokinetic flow through the channel so external forces for fluid flow are not required.

The most popular mode of DEP operation for sorting cells in microsystems is in batch mode. DEP forces are used to trap and hold the cells of interest while allowing other cells and particles to pass through the device (Figs 3a and b). The trapped cells can then be released for further handling. However, operation in a batch mode can make the fluidic control of the microsystem and further cell processing difficult. Therefore, a great effort has been put into the development of continuous cell sorting techniques. Methods for continuous mode DEP are shown in Figs. 3c–e. In Fig. 3c native DEP mobilities of cells are used for separation of particles. In an alternative approach, Fig. 3e uses DEP labels to sort rare *Escherichia coli* that display a specific surface marker from an excess of nontarget bacteria of the same species. The label in this case is a polymeric bead with an antibody for the specific marker. Another commonly used method of continuous separation is called dielectrophoretic field flow fractionation (DEP-FFF). Cells are injected into a carrier flow that passes through the separation chamber where a DEP force is applied perpendicular to the flow. Negative DEP levitates flowing cells into different regions of a parabolic flow profile, achieving a spatial dispersion reflecting the dielectric properties of the cells. Negative DEP has also been used to deflect cells traveling in one laminar flow into another, or into side channels.

DEP is very attractive for sorting and separating cells of interest because the DEP force is created using electrode components without any moving parts. It can handle large numbers of cells and lends itself particularly well to cell handling since comparatively low voltages can produce significant and contactless forces. However, the main advantage of DEP is that it allows for label-free separation of cells allowing cells to remain in their native states. An important disadvantage to using DEP is that low-conductivity buffer is required so solvent exchange or dilution of sample is often necessary.

Magnetic Forces

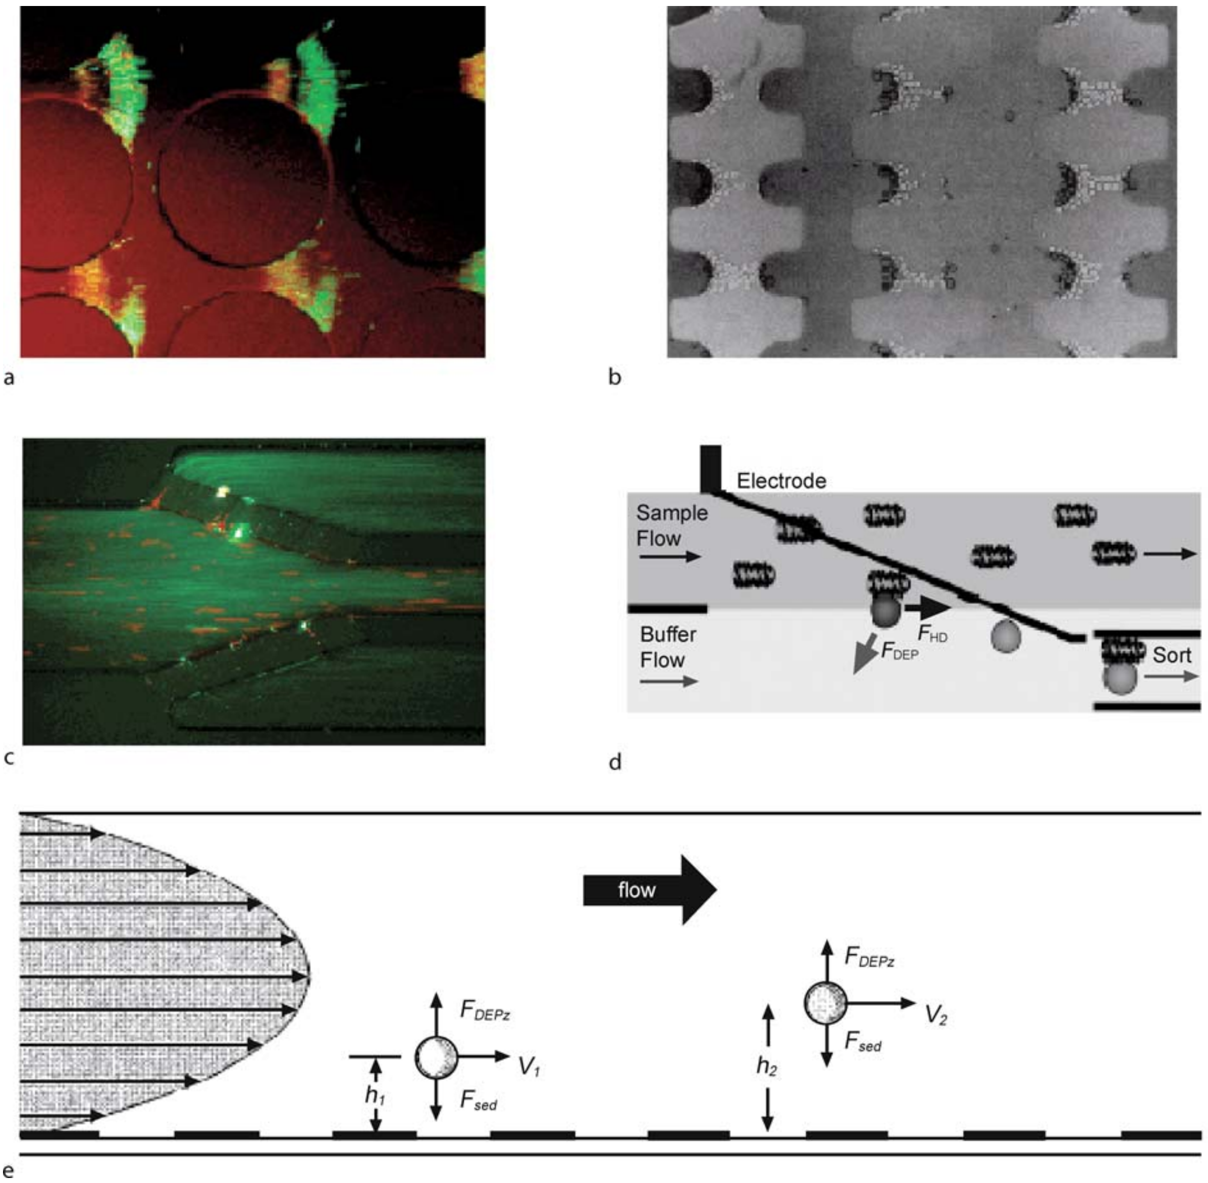
Magnetoquasistatic fields are used to manipulate cells either due to an intrinsic magnetizability, such as the iron in red blood cells, or by attaching magnetic materials to the cells for magnetically activated cell sorting. The use of magnetic particles has attracted considerable interest since many functionalized magnetic beads (an iron oxide core surrounded by a polymer shell) are now commercially available. Magnetophoresis, the separation of particles based on different magnetic susceptibility, has the important attribute of being highly specific because the vast majority of material does not respond strongly to magnetic fields. Like DEP, magnetophoresis can be operated in batch and continuous mode. On application of a magnetic field the magnetically labeled cells can be retained in the reaction vessel while the remainder of the sample mixture is removed. Alternatively magnetic forces can also be used to create immunocapture beds to isolate cells as shown in Fig. 4a. The advantage of this technique is that beds can be formed and then released into large channels that do not clog easily. Continuous flow separation involves the application of an inhomogeneous magnetic field perpendicular to the direction of laminar flow, which forms a magnetic field gradient over the separation chamber. A mixture of magnetic particles and nonmagnetic particles can be injected continuously into the system through the sample inlet channel. The nonmagnetic particles are not influenced by the magnetic field and leave the chamber at the exit opposite the sample inlet. Magnetic particles, however, become magnetized and are hence dragged into the inhomogeneous magnetic field. Particles that are either different in size, or different in their magnetic susceptibility, will be deflected from the direction of laminar flow to a different degree and it is therefore possible to separate particles.

Ultrasonic Forces

Ultrasonic standing wave (USW) manipulation is a simple and useful method for handling, separating, and concentrating large groups of cells. An USW creates a pressure node that will attract particles or cells. As with DEP, a cell can experience either an attractive or repulsive acoustic force depending on its material parameters. This can be used either to trap objects locally over an ultrasonic transducer, concentrate them within a fluidic channel, or separate different types of objects from each other. Successful separation of human erythrocytes from human lipid vesicles has been reported (Fig. 5).

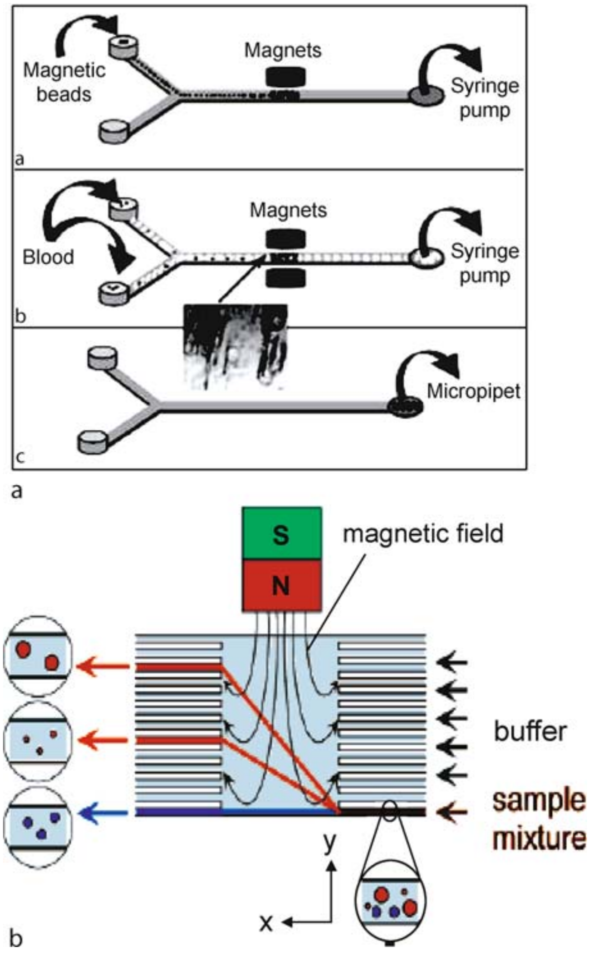
Optical Forces

Optical tweezers were developed by Ashkin and coworkers in the 1970s [5, 6]. Optical tweezers use the radiation pressure from a focused laser beam to trap, hold, and manipulate a particle or cell. The trapped object can be translated with extremely high precision, by rapidly scanning the laser beam between different positions and several

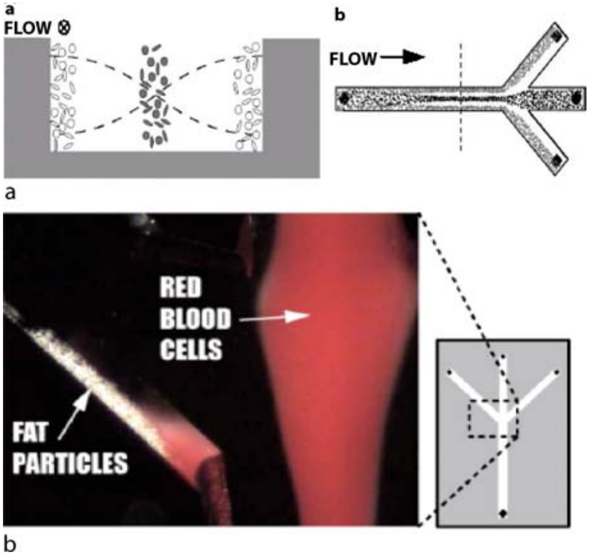


Cell Sorting, Figure 3 (**a**) Differential trapping of live and dead *Escherichia coli* cells using IDEP is shown by two separate bands of different color. Live cells (green) are trapped at the wider regions between the circular posts (negative DEP) and dead cells (red) exhibit less negative DEP since they are trapped at the narrower regions between circular posts. (Adapted from [10]) (**b**) Cancer cells, human breast cancer cell line MDA231, remain on the electrode tips after blood cells had been swept downstream. (Adapted from [11]) (**c**) Two-component sample of *Bacillus subtilis* and 200 nm particles; *Bacillus subtilis* cells are confined to the central channel due to the dielectrophoretic force created by ridges. (Adapted from [12]) (**d**) Schematic of rare cells separated from bulk cell sample. Cells entering in the sample stream are only deflected into the collection stream if they are labeled with a dielectrophoretically responsive label. (Adapted from [13]) (**e**) DEP-FFF principle and experimental setup. A thin, rectangular chamber was constructed with microfabricated, interdigitated electrodes on its bottom wall. Different cell types were levitated to different equilibrium heights under the influence of the opposing DEP (F_{DEPz}) and sedimentation (F_{sed}) forces. With a flow-velocity profile established in the chamber from the injection syringe pump, the cells at different heights ($h_2 > h_1$) were carried through the chamber at different velocities ($V_2 > V_1$) and thereby separated. Cells exited the chamber from the bottom outlet port and were detected and counted by an on-line flow cytometer. (Adapted from [14])

particles or cells can be held by a single laser beam. The use of optical forces for cell sorting is extremely attractive in that it is a noninvasive, noncontact, label-free technique. The nature of the interaction between a particle and the light field depends on the particle's size, shape, composition, and refractive index giving a range of criteria



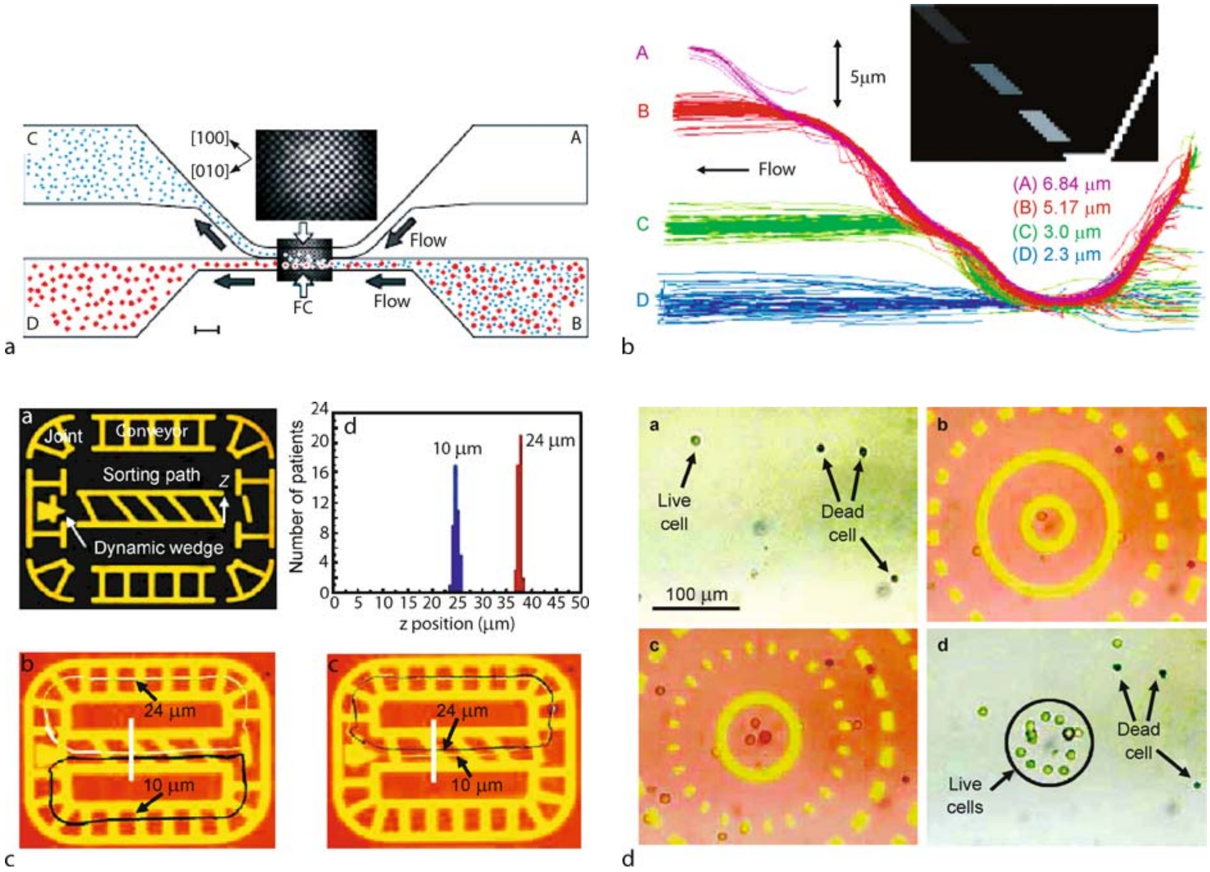
Cell Sorting, Figure 4 (**a**) Immunomagnetic separation of T cells: (a) syringe pump draws protein A/anti-human CD3 magnetic beads into the channel for capture with a magnet; (b) blood samples are introduced from both channels, T cells are captured with magnets above and below, then washed with RPMI 1640; (c) magnets were removed and captured cells and magnetic beads were transferred from the outlet with a micropipet. Inset shows T cells captured by beads in a magnetic field. Beads show as dark streaks, cells as translucent circles. (Adapted from [15]) (**b**) Concept of free-flow magnetophoresis. Magnetic particles are pumped into a laminar flow chamber; a magnetic field is applied perpendicular to the direction of flow. Particles deviate from the direction of laminar flow according to their size and magnetic susceptibility and are thus separated from each other and from nonmagnetic material. (Adapted from [16])



Cell Sorting, Figure 5 (**a**) Two particle types positioned, by acoustic forces, in the pressure nodal and anti-nodal planes of a standing wave. (Cross-section of the channel in (b), dashed line.) (b) Top view of a continuous separation of two particle types from each other and/or a fraction of their medium. (Adapted from [17]) (**b**) Human lipid particles separated from human erythrocytes at the trifurcation of 350 mm separation chip with ultrasound turned on. (Adapted from [18])

to sort a particle solely by tailoring the interference pattern to the particles one wishes to sort. The throughput is low since only a limited number of cells can be processed at one time, scale-up is difficult, and the position of the cell needs to be known in advance. Optical tweezers are custom built instruments usually starting with a commercial optical microscope with extensive modifications. The laser and optics required are very expensive. These instruments require specialized personnel to run. In addition one of the main concerns for laser tweezers is the cell viability/damage due to high laser power in long-term operation. In order to overcome the problems of throughput there has been a lot of interest in creating multiple optical traps using a single laser. This can be achieved using a diffractive beamsplitter which converts a single input beam into several beams, each of which forms a separate optical trap. The diffractive beamsplitter can be a computer-generated hologram, and therefore in the literature this technique has been coined *holographic optical tweezers* (HOT). These HOT devices can control hundreds of optical traps in a three-dimensional microscopic volume. Individual traps may be independently translated, eliminated, and created, but even a static array of traps is useful for particle separation as shown in Fig. 6a. Another approach has been to use a scanning laser beam while the light intensity levels were varied (as shown in the grayscale inset in Fig. 6b). Initial results showing the separation of polystyrene spheres were promising; however, the separation of cells has yet to demonstrated.

Another approach called optoelectronic tweezers shows great promised for cell sorting. Optoelectronic tweezers use direct optical images to create high-resolution DEP electrodes. The optoelectronic tweezers are constructed by assembling a ground layer (indium tin oxide (ITO)-



Cell Sorting, Figure 6 (**a**) Without an actuator all particles from chamber B would flow into chamber D. Chamber A would typically introduce a blank flow stream. The three-dimensional optical lattice into the fractionation chamber (FC) selectively deflects one species of particle into the upper flow field. The reconfigurability of the optical lattice allows for dynamic updating of selection criteria. The scale bar is 40 μm. (Adapted from [19]) (**b**) Separation of particles based on size using optical forces. (Adapted from [20]) (**c**) (a) Integration of virtual components, including an optical sorter path, conveyors, joints, and a wedge. The motion of different components is synchronized. (b, c) Two polystyrene particles with sizes of 10 μm and 24 μm pass through the sorter path and are fractionated in the *z*direction owing to the asymmetrical optical patterns. The particle trajectories can be switched at the end of the sorter path by the optical wedge. (d) Optical sorting repeatability test. The white and black loops in (b) and (c) represent the particle traces after 43 cycles. The trace broadening at the white bar has a standard deviation of 0.5 μm for the 10 μm bead and 0.15 μm for the 24 μm bead. (Adapted from [21]) (**d**) Selective collection of live cells from a mixture of live and dead human B cells. (a) Randomly positioned cells before OET. (b, c) Cell sorting. The live cells experience positive OET, trapping them in the bright areas, and pulling the live cells into the pattern's centre. The dead cells (stained with Trypan blue dye) leak out through the dark gaps and are not collected. The optical pattern appears light, while weak background scattered light results in a darker hue in the non-patterned areas. (d) Sorted cells. (Adapted from [22])

coated glass), a liquid chamber, and a photoconductive layer (glass substrate coated with an aluminum layer, photoconductive amorphous silicon layer, and silicon nitride layer). An electrical bias is applied between the top (ITO) and bottom (aluminum) electrodes. In the dark state, most of the voltage drops across the photoconductor due to its high electrical impedance. This results in a very weak electric field in the liquid layer. When the light source is focused on the photoconductive layer, the local photoconductivity in the illuminated region is greatly increased. This light-defined microelectrode creates a highly non-uniform field in the liquid layer. Since the field is non-uniform field, a DEP force is created and can be used to manipulate particles.

The main advantages of optoelectronic tweezers over optical tweezers is that the required optical power is orders of magnitudes lower (since light is used to switch the voltage drop between the photoconductive layer and the liquid layer and not to directly trap the particles) than that of conventional optical tweezers. This allows the use of a digital optical projector with an incoherent light source or light emitting diodes. As a result one can take advantage of projected real-time moving images which in turn produce addressable or moving electrodes. This has

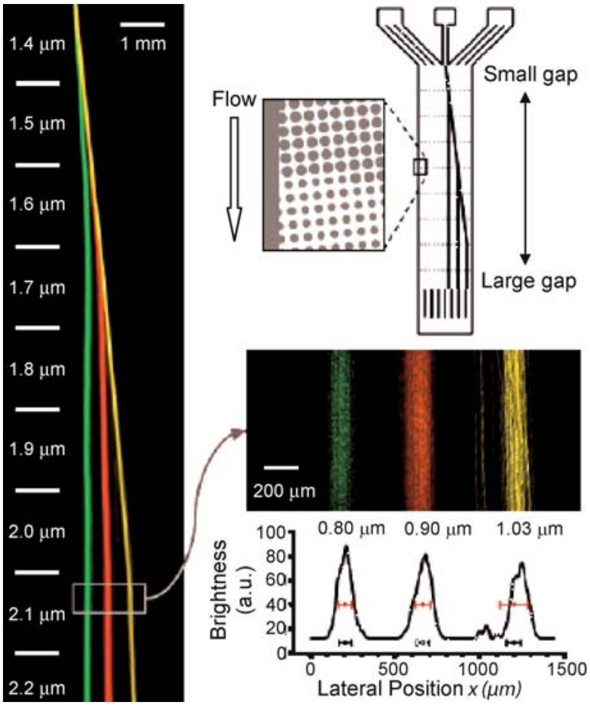
allowed the creation of conveyor belts, moving deflecting wedges and shrinking circles (Figs. 6c and d). This makes the system very adaptable and vastly less expensive than optical tweezers.

Hydrodynamic Forces

A system that does not require outer field controls or any moving parts is an attractive option for cell sorting. The first attempts to used hydrodynamic forces for cell separation were based on macroscale separation using chromatographic media. Microfabrication techniques were used to create microscale *lattices* and *asymmetric obstacles* which would act to exploit the diffusion variation of particles of different size (Fig. 7). The devices were shown to be effective at separating blood into its separate components. Recently, there have been a few reports concerning continuous and hydrodynamic particle separation in microfluidic devices using only the laminar flow profile and channel geometry. This technique has been called *hydrodynamic filtration*, *pinched flow fractionation*, and *asymmetric pinched flow fractionation*. The principle of hydrodynamic particle movement is that small particles can be present near the inner surface of a microchannel, while large particles cannot fully access the low flow rate region near the surface. The most basic form of these devices (Figure 8a) allows particle streams to be separated according to their size using sections of different widths. Two fluid streams with/without particles a pumped through the narrow or "pinched" channel segment. The stream containing particles is focused on one sidewall in the narrow segment by controlling flow rates from both inlets. At the intersection between the narrow and wide segments the particles feel a force that is dependent on their size. The slight difference of the particle positions in the pinched segment is significantly amplified in the broadened segment, so the particles are separated perpendicularly to the flow direction according to their sizes. Larger particles are confined to the center of the microchannel due to the spreading flow profile. Smaller particles, however, are deflected towards the sidewall. The technique was further advanced to incorporate side channels which allow the particle collection as shown in Figs. 8b–d.

Key Research Findings

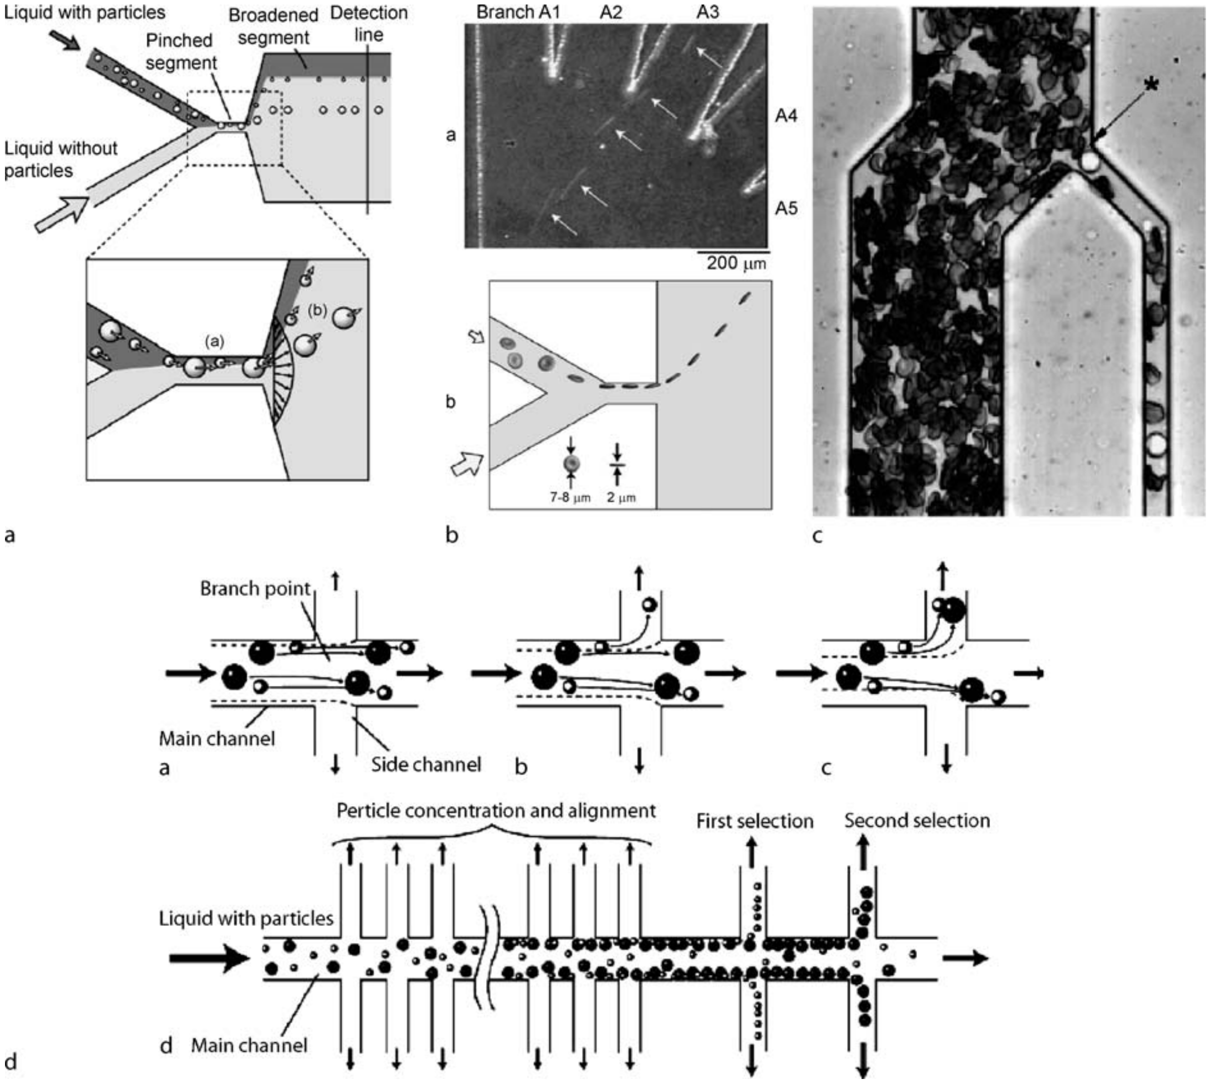
It is clear from examination of the literature that microfluidic techniques have advanced the field of cell sorting. Several macroscopic methods such as flow cytometry and filtration have been successfully miniaturized to give enhanced separation performance with a reduced sample volume. For example, in conventional macroscale sorting,



Cell Sorting, Figure 7 High-resolution separation of fluorescent microspheres with diameters of 0.80 µm (green), 0.90 µm (red), and 1.03 µm (yellow), with a matrix of varying gap size. (Adapted from [23])

using hydrodynamic focusing, a large amount of sheath liquid (of the order of liters) is necessary to processing a small amount of sample (of the order of milliliters) which has prevented a further reduction in the size and volume of the whole system. Microfluidic techniques have reduced the volume or even the need for a sheath fluid. In addition microfabricated filters have reduced the problems with clogging in conventional filters using laminar diffusion and microfilters parallel to the sample flow. However, macroscale cell sorting, using flow cytometry, remains faster (50,000 cells per second) than microfluidic cell sorting ($\leqslant$ 14,000 cells per second).

It is important to note at this point that cell sorting performance should not be judged solely on speed. Conventional flow cytometers are very expensive to purchase and operate, and are therefore only found in large research facilities or hospitals. Microfluidics has demonstrated that cell sorting, in multiple formats geared for tailored applications, can become available to all researchers and clinicians since these devices can be made cheaply and configured with commercially available instrumentation. In addition many of the microfluidic technologies allow for disposability which reduces the problem with sample cross-contamination, sterility, and biosafety (when



Cell Sorting, Figure 8 (**a**) Principle of pinched flow fractionation. (a) In the pinched segment, particles are aligned to one sidewall regardless of their sizes by controlling the flow rates from two inlets; (b) particles are separated according to their sizes by the spreading flow profile at the boundary of the pinched and the broadened segments. The dark-colored liquid contains particles. (Adapted from [24]) (**b**) Separation of erythrocytes. (a) A photograph of separated erythrocytes, indicated by white arrows. (b) Schematic diagram of the erythrocyte alignment and separation. (Adapted from [25]) (**c**) Leukocyte enrichment from whole blood. As smaller, more flexible erythrocytes seek the faster flow region in the center of the channel lumen, collide with leukocytes forcing them to migrate toward the sidewalls. Therefore, before the first bifurcation is reached, the leukocyte distribution across the channel changes considerably, with most of the leukocytes traveling near the channel sidewalls (Adapted from [26]) (**d**) Principle of hydrodynamic filtration. (a–c) Schematic diagrams showing particle behavior at a branch point; the relative flow rates distributed into side channels are (a) low, (b) medium, and (c) high. handling pathogenic samples). Microdevices also compare favorably with conventional techniques on cell purity and have shown increased cell viability which is very important when further analysis is necessary or long-term experiments are performed. In addition to this, entirely novel microdevices and techniques have been developed using acoustic, optical, dielectrophoretic, and hydrodynamic forces to sort cells. These forces cannot be harnessed on the macroscale. This has led to the ability to sort particles based on a widening set of parameters including size, charge, conductivity, shape, deformability, and life stage. An array of these devices operating in parallel will allow an increase in quantitative measurements which could allow the discovery of entirely new subpopulations

of cells from heterogeneous populations. These capabilities are very important in the realm of clinical diagnostics, presymptomatic disease detection, and biomedical applications.

Finally the most important point to be noted is that microfluidic techniques should be judged as complementary to rather than a replacement for conventional techniques which will continue to have a significant role in cell sorting. Most of the successful examples in adapting microfluidic devices for cell sorting have been those in which the microfluidic device is used as either sample preparation module or downstream processing and detection module after the conventional technique has processed the sample.

Future Directions for Research

It is clear that, great progress has been made in the field of cell sorting. However the key issues still to be addressed are parallelization, throughput, and integration. Parallelization will lead to higher throughput which at times is necessary because large sample volumes have to be processed such as in the sorting of rare cells, e. g. circulating tumor cells or in water analysis. Also as stated previously parallelization will allow multi-parameter sorting. Issues such as transport of cells to downstream analysis and how different cells types might be identified will also have to be addressed.

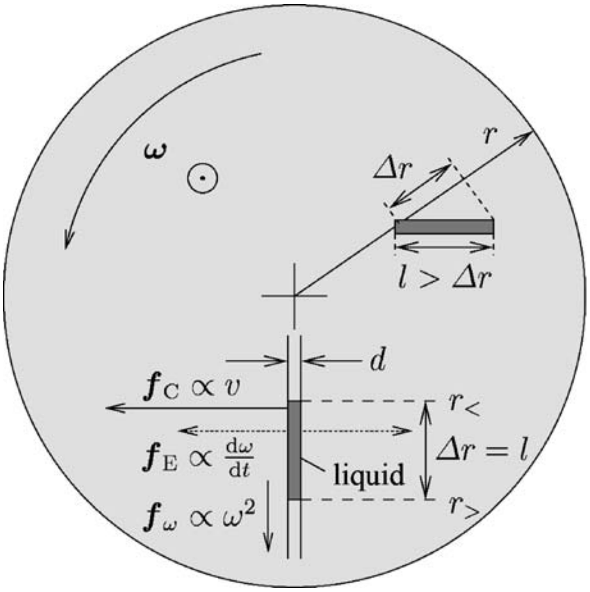
Definition

Centrifugal microfluidic technologies use the inertial pseudo forces experienced in a rotating reference frame to transport and manipulate fluids, overwhelmingly liquids, through networks of microchannels and chambers on substrates which are often in the format of a disk. These density-dependent pseudo forces are the centrifugal force scaling with the square of the frequency of rotation, the Euler force which is associated with an accelerated rotational motion and the Coriolis force acting on flows through rotating channels. Unit operations such as valving, routing, metering and mixing often results from the interplay of the rotational forces, capillary flow control and/or siphon-like structures. Centrifugal microfluidic systems typically comprise a polymeric substrate with the size of a compact disk incorporating a planar microchannel network and an actuation unit exhibiting a rotational drive, a detection unit and/or a dispenser. Most applications aim for the process integration, automation, parallelization and miniaturization of analytical, diagnostic and preparative protocols in life sciences.



Centrifugal Microfluidics, Figure 1 Geometry and forces on a disk spinning at the angular velocity vector $\boldsymbol{\omega}$ pointing out of the paper plane towards the reader. The radial coordinate is given by r. The liquid plug of diameter d and absolute length l extends between its inner and outer radial positions $r_<$ and $r_>$, respectively, with $\Delta r = r_> - r_<$ and $\bar{r} = 0.5(r_< + r_>)$. For a radially oriented plug, $\Delta r = l$, otherwise $\Delta r < l$. The liquid traveling at a speed $\boldsymbol{v}$ down the channel is exposed to the centrifugal force density $\boldsymbol{f}_\omega \sim \omega^2$ (2), the Euler force density $f_{\mathrm{E}} \sim d\omega/dt$ (3) and to the Coriolis force density $\boldsymbol{f}_{\mathrm{C}} \sim \boldsymbol{v}$ (4)

Overview

Hydrodynamic Equation of Motion

In centrifugal microfluidic systems, the Navier–Stokes equation is most conveniently expressed within the reference frame where the substrate rotating at a frequency $\omega = 2\pi\nu$ is at rest (Fig. 1). Due to the non-inertial nature of this frame of reference, the centrifugal force density f_ω, the Euler force density f_{E} and the Coriolis force density f_{C} additionally appear in the hydrodynamic equation

of motion

$$\varrho\left[\frac{\partial}{\partial t}\boldsymbol{v}+(\boldsymbol{v}\cdot\nabla)\boldsymbol{v}\right]=-\nabla p+\eta\nabla^2\boldsymbol{v}\underbrace{-\varrho\boldsymbol{\omega}\times(\boldsymbol{\omega}\times\boldsymbol{r})}_{f_\omega}$$
$$\underbrace{-\varrho\frac{\mathrm{d}\boldsymbol{\omega}}{\mathrm{d}t}\times\boldsymbol{r}}_{f_\mathrm{E}}\underbrace{-2\varrho\boldsymbol{\omega}\times\boldsymbol{v}}_{f_\mathrm{C}} \quad (1)$$

where $\boldsymbol{r}$ denotes the radial position, ϱ the mass density and $\boldsymbol{v}$ the velocity of the fluid. For the common situation where the vector $\boldsymbol{\omega}$ is perpendicular to the vectors $\boldsymbol{r}$ and $\boldsymbol{v}$, the absolute values of the densities of the three pseudo forces in (1) reduce to

$$f_\omega=\varrho\omega^2 r \quad (2)$$

for the centrifugal force (density),

$$f_\mathrm{E}=\varrho r\frac{\mathrm{d}\omega}{\mathrm{d}t} \quad (3)$$

for the Euler force (density) and

$$f_\mathrm{C}=2\varrho\omega v \quad (4)$$

for the Coriolis force (density).

Centrifugal Flow

We consider the analytically simple case of a centrifugally driven flow through straight channel with round cross section of diameter d. A continuous liquid plug of length l within the channel possesses menisci at the radial positions $r_<$ and $r_>$ at its upstream and downstream end, respectively. The channel exhibits a mean radial position

$$\bar{r}=\frac{r_>+r_<}{2} \quad (5)$$

and covers a height

$$\Delta r=r_>-r_< \quad (6)$$

in radial direction.

To investigate the flow, we consider stationary conditions, discard fringe effects at the boundaries of the plug and look at the quasi-static case where ω is constant and the product $\boldsymbol{v}\omega$ is small so the Euler force f_E and the Coriolis force f_C can be neglected in (1). Further excluding external pressure differences $\Delta p=0$ between the inlet and the outlet, we can solve the Navier-Stokes equation (1) to obtain a parabolic flow profile exhibiting a mean velocity

$$\bar{v}=\frac{\varrho}{32\eta}\frac{\Delta r}{l}\bar{r}d^2\omega^2 \quad (7)$$

peaking at the center of the tube. For a radially oriented channel, Δr equals l to eliminate their ratio $\Delta r/l$ and hence, contrasting pressure-driven flows, the average flow velocity $\bar{v}$ becomes independent of the channel length l. Apart from the scaling with the properties of the liquid, we obtain $\bar{v}\sim\bar{r}d^2\omega^2$.

Using the material properties of water ($\varrho\approx 1000\,\mathrm{kg\,m^{-3}}$, $\eta\approx 1\,\mathrm{mPa\,s}$), a typical channel diameter $d=200\,\mu\mathrm{m}$, $\Delta r=l$ and a mean position of the liquid plug $\bar{r}=3\,\mathrm{cm}$, a scaling

$$\bar{v}\approx(\nu[\mathrm{Hz}])^2\cdot 1.48\times10^{-3}\mathrm{ms^{-1}} \quad (8)$$

is derived. At a frequency $\nu=30\,\mathrm{Hz}=1800\,\mathrm{rpm}$, the flow velocity $\bar{v}\approx 1.3\,\mathrm{m\,s^{-1}}$, implying a residence time of about 1.5 ms, only, in a 2 cm long radial channel which can easily be accommodated on a disk of the size of a standard Compact Disc™ (CD). Note that due to the parabolically shaped laminar flow, the residence time distribution varies across the channel.

The overall discharge

$$Q=\bar{v}A=\frac{\pi\varrho}{128\eta}\frac{\Delta r}{l}\bar{r}d^4\omega^2 \quad (9)$$

of the centrifugal flow scales with the mean radial position $\bar{r}$ and the square of the rotational frequency ω. Similar to a pressure driven Poiseuille flow, the discharge Q is proportional to the square of the channel cross section $A=\pi d^2/4$ and inversely proportional to the viscosity η. Note that similar to $\bar{v}$ in (7), the discharge Q is independent of the length of the liquid plug flowing through the channel as long as $\Delta r=l$.

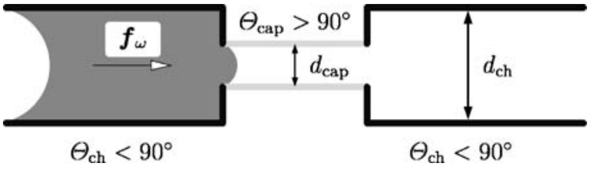
For the liquid characteristics of water, a microchannel with a lateral extension of $d=200\,\mu\mathrm{m}$ and a mean radial plug position of $\bar{r}=3\,\mathrm{cm}$, we obtain a discharge

$$Q\approx(\nu[\mathrm{Hz}])^2\cdot 2.72\times10^{-3}\mathrm{ml\,min^{-1}} \quad (10)$$

yielding $Q\approx 2.45\,\mathrm{ml\,min^{-1}}$ at $\nu=30\,\mathrm{Hz}=1800\,\mathrm{rpm}$. This means that, for instance, a single disk featuring about hundred channels in parallel can process more than 100 ml per minute!

Also an equivalent (external) pressure head

$$\Delta p_\omega=\varrho\bar{r}\Delta r\omega^2 \quad (11)$$



Centrifugal Microfluidics, Figure 2 A capillary barrier in made up of a geometrical constriction from the channel diameter d_{ch} to a narrow capillary of diameter $d_{cap} \ll d_{ch}$. In a hydrophobic barrier, the contact angles are $\Theta_{cap} > 90° > \Theta_{ch}$. The capability to stop the flow up to a certain frequency threshold ω^* (15) is determined by the capillary pressure Δp_Θ (14) scaling with the curvature d^{-1} as well as the inertia of the impinging flow

can be defined which would establish the same discharge Q as a centrifugal flow at an angular frequency ω. Note that in contrast to Q in (10), Δp_ω scales with the radial length of the plug Δr (6). Inserting again typical numbers for the liquid (water) and the geometry ($\bar{r} = 3$ cm, $\Delta r = 2$ cm), we arrive at

$$\Delta p_\omega \approx (\nu[\text{Hz}])^2 \cdot 2.4 \times 10^{-2}\,\text{kPa} \tag{12}$$

yielding a hydrostatic pressure head of $\Delta p_\omega \approx 21.6\,\text{kPa} \approx 0.2\,\text{atm}$ for $\nu = 30\,\text{Hz} = 1800\,\text{rpm}$.

In order to study secondary components of the centrifugal flow field, it is also interesting to look at the ratio

$$\frac{f_\omega}{f_C} \approx \frac{16\eta}{\varrho d^2}\frac{1}{\omega} \tag{13}$$

between the (radial) centrifugal force density f_ω and the (transversal) Coriolis force density f_C using $\bar{\nu}$ from (7) as the characteristic velocity. The scaling of the ratio with ω^{-1} implies that a threshold frequency exists beyond which f_C supersedes f_ω. Setting the ratio (13) to unity and inserting again the liquid characteristics of water for a channel measuring $d = 200\,\mu\text{m}$, f_ω already balances f_C at rather moderate centrifugal frequencies of about $64\,\text{Hz} \approx 3820\,\text{rpm}$.

Capillary Flow Control

Valving is an important unit operation in microfluidics. To assure a cost-efficient manufacturing, the substrate in centrifugal microfluidics ought to be made of passive components, only. Flow control is therefore commonly implemented by capillary forces. While a global hydrophilization of the substrate assures self-priming of narrow channel networks, selective hydrophobization of constrictions can generate a pressure difference opposing the further progression of a liquid meniscus (Fig. 2).

This capillary pressure

$$\Delta p_\Theta = 4\sigma\left[\frac{1}{d_{ch}}\cos\Theta_{ch} - \frac{1}{d_{cap}}\cos\Theta_{cap}\right] \tag{14}$$

depends on the surface tension σ of the liquid as well as the diameters d_{ch} and d_{cap} and the contact angles Θ_{ch} and Θ_{cap} at the channel and at the capillary constriction, respectively. For water ($\sigma \approx 10^{-1} Nm^{-1}$), a narrow constriction ($d_{cap}/d_{ch} \ll 1$) with $d_{cap} = 20\,\mu\text{m}$ and $\Theta_{cap} = 120°$, a pressure difference $\Delta p_\Theta = 0.2/d = 10\,\text{kPa}$ is found.

Setting Δp_Θ (14) equal to Δp_ω (11), such a capillary barrier breaks at frequencies

$$\nu\,[\text{Hz}] = \frac{1}{\pi}\sqrt{\frac{\sigma\,|\cos\Theta_{cap}|}{\varrho\bar{r}\Delta r d}} \tag{15}$$

resulting to roughly $\nu \approx 20$ Hz for the above specified conditions. A capillary barrier can be regarded as a high-pass valve with respect to the frequency of rotation ω.

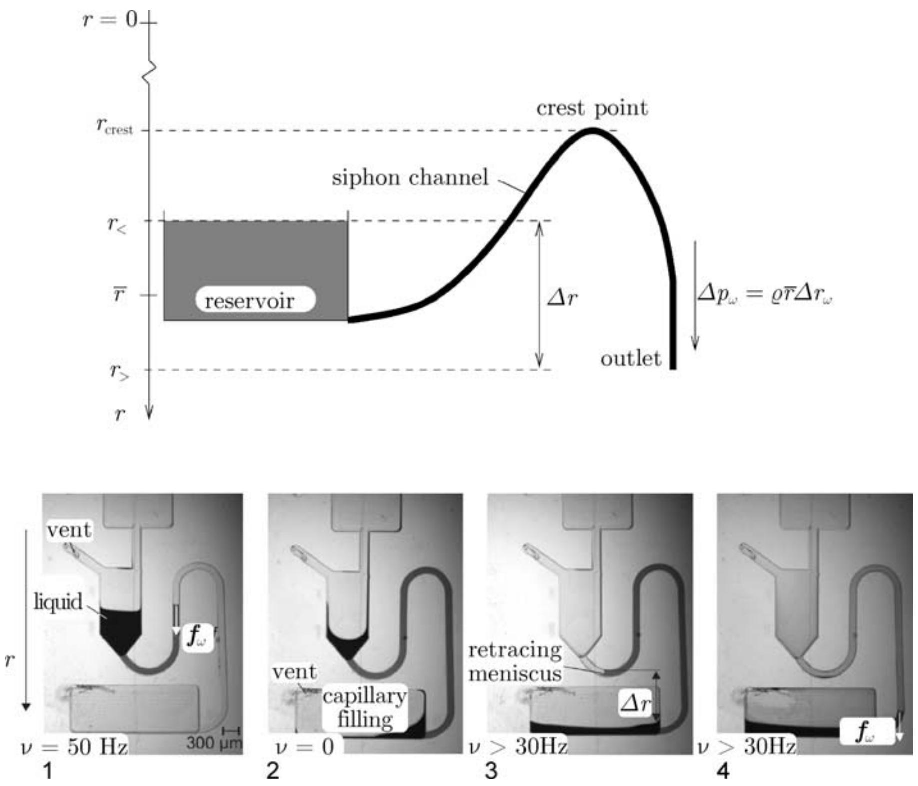
Siphoning

The centrifugal field can also be deemed an artificial gravity with an acceleration $g = r\omega^2$. Therefore, also the siphoning effect can also be applied as sketched in Fig. 3. As long as the siphon tube which is submerged in the liquid within the reservoir stays empty, the liquid is retained at all frequencies ω. Once the tube is filled with a continuous liquid column and the liquid meniscus at $r_>$ has protruded farther outside than the liquid level in the reservoir at $r_<$, a hydrostatic pressure Δp_ω develops according to (11).

The flow out of the reservoir ceases as soon as $r_< = r_>$ or air disrupts the continuous columns, e. g. in case the reservoir is entirely empty. The priming of the tube can either proceed by adding water to the reservoir until its liquid level exceeds the crest point r_{crest} or by capillary action enabled by a hydrophilized inner surface of the tube. In contrast to the capillary barrier, the siphon represents a low-pass filter with respect to the frequency of rotation ω.

Sacrificial Valves

The previously introduced capillary and siphon-based valve structures are switched by the frequency of rotation ω. However, some applications demand vapor-proof valves for long-term liquid storage or programmability of the valves independent of the frequency of rotation ω.



Centrifugal Microfluidics, Figure 3 A siphon structure consists of a reservoir and an outlet which are connected by a completely filled tube passing the crest point r_{crest}. The radial boundaries of the liquid volume are $r_<$ and $r_>$. For $\Delta r = r_> - r_< > 0$, a flow propelled by the hydrostatic pressure $\Delta p_\omega \sim \Delta r$ (11) drains from the reservoir over the crest point to the outlet without an external pump

In these cases, sacrificial valves may be employed. These valves are characterized by a disposable physical barrier such as a foil or polymer structure which is typically installed during manufacturing. For opening, these normally closed valves are, for instance, destroyed by punching with a spike or by laser ablation. Also regenerative valves, e. g. based on UV-polymerization, have been shown in Lab-on-a-Chip systems.

Sedimentation

A density difference between a liquid and suspended particles leads to a sedimentation in a centrifugal field (Fig. 4). The speed of sedimentation in radial direction

$$v_r = Sr\omega^2 \tag{16}$$

is governed by the centrifugal acceleration $g = r\omega^2$ as well as the sedimentation coefficient

$$S = \frac{m}{\bar{f}}\left(1 - \frac{\varrho_{\text{liquid}}}{\varrho_{\text{part}}}\right) \tag{17}$$

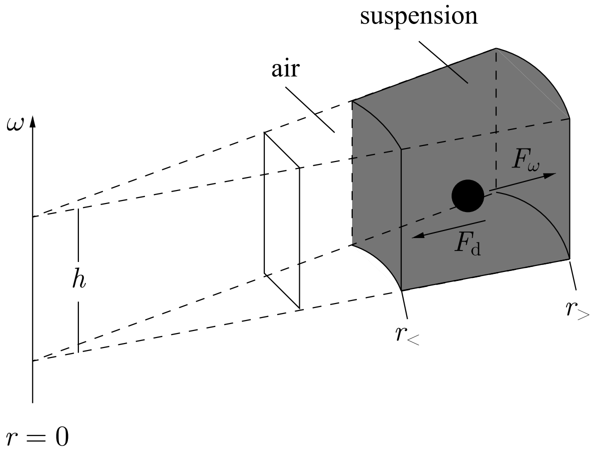
depending on the mass of the particle m, its hydrodynamic friction coefficient $\bar{f}$ and the ratio of the densities of the liquid ϱ_{liquid} and the particle ϱpart. This means that the speed of sedimentation v_{r} (16) is highest for heavy particles displaying a low drag coefficient $\bar{f}$ and a much higher density ϱ_{part} than the suspending liquid ϱ_{liquid}.
In an initially homogeneously distributed suspension, a shock interface forms traveling at a radial speed

$$r(t) = r_< \,\mathrm{e}^{S\omega^2 t} \tag{18}$$

from the inner liquid surface located at $r_<$. At a given instance in time t, the space between $r_<$ and r is cleared of particles.

System Aspects

Most present centrifugal microfluidic systems are networks of chambers communicating via interconnecting channels. Discrete liquid volumes are transferred between the chambers as the system seeks the hydrostatic equilibrium in the artificial gravity set by the frequency of rotation ω.



Centrifugal Microfluidics, Figure 4 Sedimentation of a particle suspended in a liquid volume under the impact of a centrifugal field f_ω (2). The volume of height h is confined by the inner and outer radial boundaries $r_<$ and $r_>$, respectively. The motion of the particle follows the buoyancy corrected force f_ω accounting for the mass difference Δm between the particle and the displaced liquid volume. The centrifugal motion is counteracted by the viscous drag F_d

In the majority of centrifugally controlled systems, the liquid handling proceeds in a pseudo-hydrostatic fashion governed by statically defined overflow, siphon and capillary principles. Highly dynamic break-up phenomena which are common, for instance, in contact-free liquid dispensers, are also possible, but rarely used. This means that the liquid handling performance can be made widely independent of the flow properties, in particular the viscosity of the processed liquid. Within the chambers, centrifugally induced buoyancy efficiently supports the removal of gas bubbles from the liquid bulk.

Furthermore, the ability to supersede capillary and surface tension related forces by raising the frequency of rotation ω also means that undesirable effects can virtually be 'switched off'. This refers the transient suppression of unwanted capillary filling as, for example, implemented by a hydrophilically primed siphon (Fig. 3). Also the surface-tension induced bending of surfaces may be compensated by a strong centrifugal field, thus allowing to shape flat menisci. The liquid handling performance may hence be made widely independent of the surface tension σ.

Another ubiquitous topic in Lab-on-a-Chip technology is the parallelization of processes. The centrifugal field suggests to replicate identical structures according to the rotational symmetry in a spoke-wheel like pattern. While such a highly symmetric layout has also be used in a pressure driven approach with a single pump pressurizing a central feed channel, only the centrifugal force transmission suppresses *hydrodynamic cross talk* between the parallel channels, e. g. the increase of the flow rate due to the clogging of a neighboring channel.

In summary, the quasi-hydrostatic implementation of liquid handling under the impact of the frequency controlled centrifugal field makes processes widely independent of the liquid properties. The symmetry as well as the volume force nature of the centrifugal field also improve the parallelization of processes.

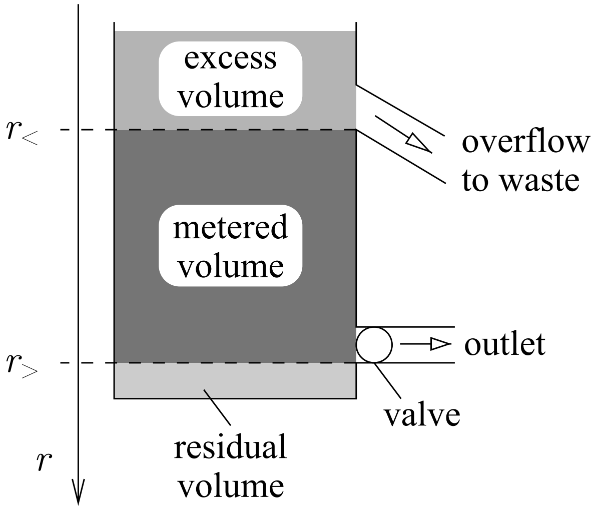
Basic Methodology

Volume Metering

Most centrifugal microfluidic systems are networks of vessels and interconnecting channels performing assays, chemical synthesis or preparative protocols at the downstream end. To provide quantitative results, a metering of the volumes is required. However, an accurate and precise metering is not only essential for the chemistry, but it is also of key relevance for the centrifugal flow control via the radial coordinates $r_<$, $r_>$ and $\bar{r}$ of the volume within the channel network, see for instance (7), (9), (11) and (13).

Volume metering is predominantly realized by overflow principles. If, for instance, an excess volume is filled into a bucket, the liquid level lowers to its upper edge, thus metering the initial volume to the geometrically defined (smaller) volume of the bucket. In centrifugal microfluidics, the overflow corresponds to an outlet connected to a radially inward position (Fig. 5).

To interface with succeeding process steps, the volume often has to be forwarded to another chamber. To this end, another outlet channel located radially below than the first 'hole' is connected to the metering chamber. To avoid



Centrifugal Microfluidics, Figure 5 Metering by an overflow connected at a radially inward position $r_<$. As long as the valve blocking the exit channel at $r_>$ is closed, excess liquid depletes via the overflow to a waste. After the liquid surface has reached $r_<$, the valve is opened and a volume geometrically defined by $\Delta r = r_> - r_<$ is forwarded via the outlet to downstream structures. The valve can, for instance, be represented by a hydrophobic constriction (Fig. 2) of a hydrophilic siphon (Fig. 3)

depletion of liquid during the metering phase, the passage is blocked by a capillary barrier (Fig. 2) or a siphon (Fig. 3) yielding upon changes of the rotational frequency ω.

Volume Splitting

In case an initial volume has to be split into several (metered) aliquots, a hydrophilic zigzag structure with hydrophobic patches confining the conduits connected to each jag has been used (Fig. 6). The upper jags are vents avoiding underpressure during the exit phase of the liquid. The outward pointing jags forward the geometrically defined volume retained in each V to the downstream areas. Key factors for a proper functioning are a complete initial capillary filling of the zigzag, the compensation of boundary effects at the two laterally outermost Vs, as well as synchronous *cutting* of the liquid column at the upper edges.

Batch-Mode Mixing

As in other microfluidic devices, strictly laminar conditions prevail at experimentally reasonable operating conditions. While smaller volumes of roughly a few nanoliters allow *spontaneous*, merely diffusive mixing within seconds and below, an efficient mixing of larger volumes, e. g. on the microliter range, requires an active reduction of diffusion distances and a simultaneous increase or interfacial surface area, also known as chaotic advection.

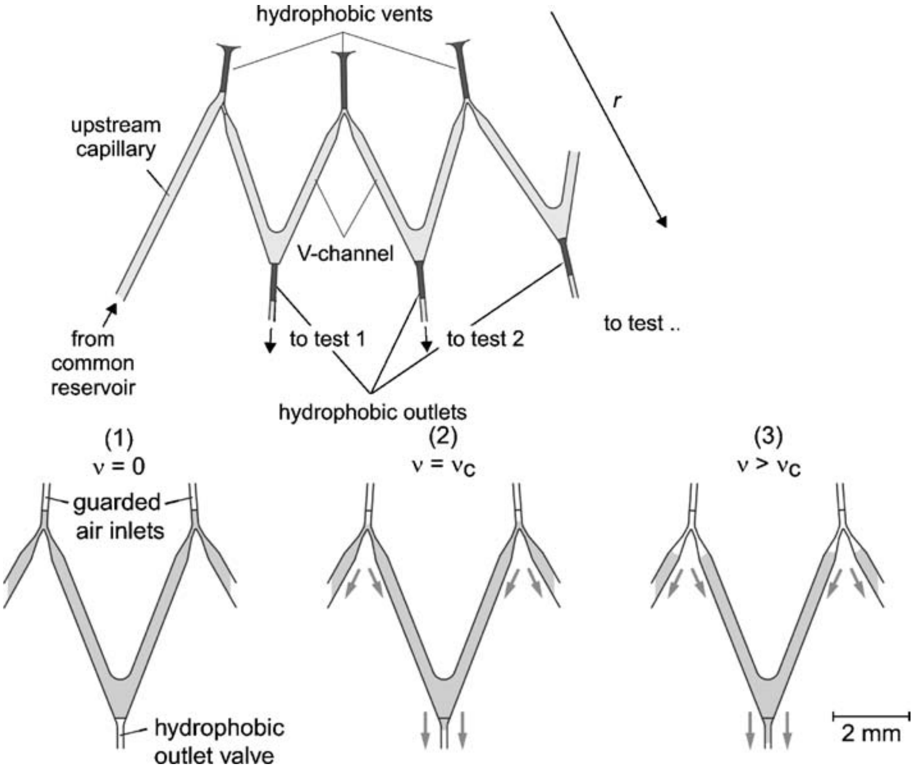
A broad scope of passive and active mixing schemes for Lab-on-a-Chip systems has been published in the literature. Many of these schemes may also be applied to centrifugal microfluidic systems. However, due to the technical and economical burden imposed by integrating active components onto the rotating, typically disposable substrate, passive mixing schemes are preferred. In this contribution we focus on schemes that make explicit nature of the rotational motion.

In a rotating chamber, mixing can be induced by rapid changes of the speed of rotation. The resulting the Euler force $f_E \sim d\omega/dt$ (3) leads to internal advection currents which accelerate mixing (Fig. 7, left). The efficiency of the mixing process is governed by the steepness and the magnitude of the frequency ramps $\omega(t)$ as well as by the shape and the size of the chamber. Due to the competition between favorable inertial effects and counteracting viscous dampening, chambers exhibiting aspect ratios near unity and containing large liquid volumes are preferable for this *shake-mode* mixing. By introducing paramagnetic beads which are deflected by stationary permanent magnets aligned with alternating polarization along the orbit of the chamber, a reversed *magnetic stirring* can be realized (Fig. 7, right).

Mixing of Flows

In case large *macroscopic* volumes have to be mixed which cannot be contained in a single chamber or when the volumes are too small for implementing mixing effects based on the Euler force f_E (3), continuous-flow mixing schemes may be applied. The aim is to contact the reagents with a large interfacial contact surface and short diffusion distances. A plethora of schemes to optimize micromixing between concurrent streams has been presented the literature for pressure driven flows. These schemes have often been enhanced by imposing secondary, transversal flow components or turbulent flow, e. g. via bends, impeller walls, grooves or stationary phases. The particular choice depends on parameters like the Reynolds number during operation and the constraints on the manufacturability and the durability of the system.

Due to the similarity of the flow profiles, most of these passive, continuous-flow schemes can, in principle, also be adopted for centrifugally driven flows. In addition, the availability of the Coriolis pseudo force f_C (4) offers an intrinsic means for the generation transversal flow components, even in straight radial channels exhibiting a constant cross section (Fig. 8). Due to the scaling of forces $f_\omega/f_C \sim \omega^{-1}$ (13), the Coriolis-force induced mixing is most efficient towards high frequencies of rotation ω, i. e. high flow rates Q (9).



Centrifugal Microfluidics, Figure 6 (Top) Schematic of the structure for parallel metering comprising a zigzag channel which features hydrophobically blocked valves and vents. (Bottom) By elevating the rotational frequency above the burst frequency of the outer hydrophobic barriers, the volume contained in each V is released into attached test units. The precision of metering is linked to the symmetry of the break-up process [8]

Routing

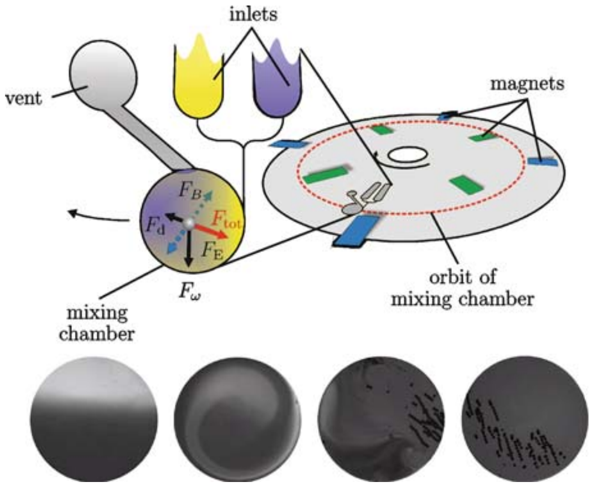
The routing of a sequence of discrete volumes to designated outlets is a common task, e. g. in preparative protocols where sample, wash and elution buffers have to be directed to the waste or a receiving vessel after passing a common stationary phase. While different strategies such as flow focusing concepts have been pursued for Lab-on-a-Chip systems, we here consider on concepts connected to the rotational motion of centrifugal microfluidic systems.

In the first approach in Fig. 9, the incoming liquid stream disintegrates at the orifice on the upper left side of a large chamber. The individual droplets preferentially stick to the left hand wall where the centrifugal field guides them towards a hydrophobic patch at the entry of the first outlet channel. At high frequencies of rotation ω, the droplets overcome the capillary barrier. At lower frequencies ω, the interfacial force supersedes the centrifugal field to deflect the droplet towards the second outlet at the right hand side of the chamber.

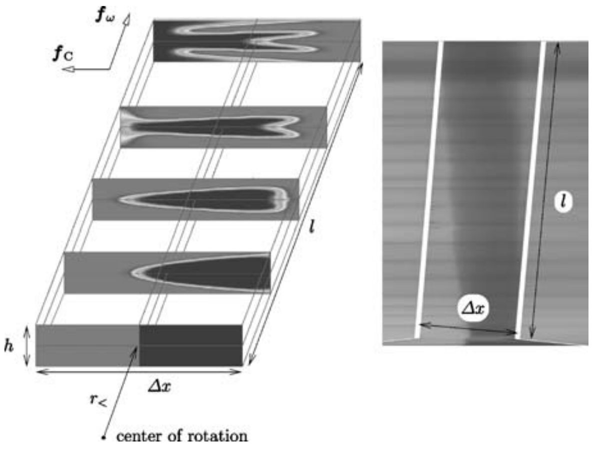
Another routing scheme presented in Fig. 10 is primarily based on the Coriolis force f_C (4). In an inverse Y-channel geometry, the common radial inlet splits into two symmetric outlets. As the Coriolis force f_C prevails the centrifugal force ω towards elevated frequencies of rotation f_ω (13), a critical frequency ω^* exists above which binary switching occurs. Ideally, individual droplets pass the chamber interspersed between the inlet and the outlets in a free flight. The performance of this *Coriolis switch* is tightly linked to the dimensions and surface properties of the channels and the chamber. Attachment to the upper and lower walls by capillary forces tends to deteriorate the performance of binary switching. Note that a similar switching behavior could also be achieved by (solely or additionally) using the Euler force f_E (3).

Control of Flow Rate

The centrifugally driven flow rate Q (9) is governed by the mean radial position $\bar{r} \sim [r_< + r_>]$ (5) of the liquid volume and the frequency of rotation ω. In typical assay protocols, a metered volume such as a reagent or a wash buffer is driven from an upstream chamber by the centrifugal force through a stationary phase such as a biosensitive layer immobilized on the channel wall, aggregated beads or a membrane.



Centrifugal Microfluidics, Figure 7 (Top) Concept of the rotating microfluidic disk and the forces acting on a paramagnetic bead: a set of permanent magnets is aligned in the lab-frame at radial positions which are positioned inbound and outbound relative to the mean orbit followed by the rotating mixing chamber (dashed circle). Thus, a confined magnetic bead experiences an alternating radial driving force F_B which deflects the bead and induces advection via the viscous drag force F_d. The centrifugal force F_ω constantly points away from the center of rotation. Rapid changes of the sense of rotation lead to a Euler force F_E (3) on the bead and the liquid. (Bottom) Flow patterns induced by F_{tot} and f_E in the mixing chamber [7]

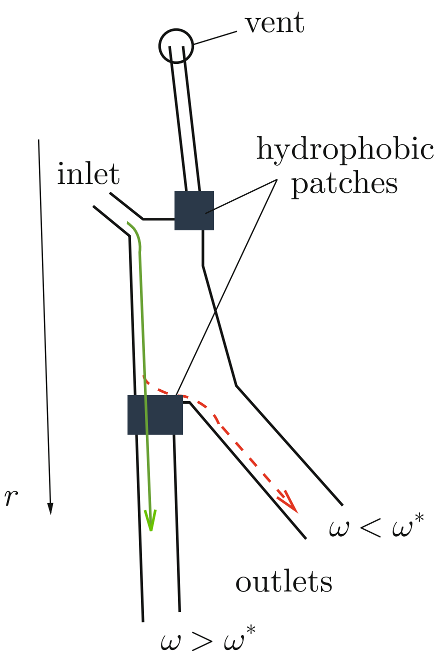


Centrifugal Microfluidics, Figure 8 Lateral spreading of two concurrent centrifugal flows A (clear) and B (dark) due to the Coriolis force f_C (4) for an angular frequency $\omega = 300\ \text{rad}\,\text{s}^{-1}$ in a rectangular radial channel of length $l = 2.1$ cm, height $h = 65\ \mu\text{m}$ and width $\Delta x = 320\ \mu\text{m}$ starting at $r_< = 3$ cm. The right hand side shows a top-view photography of the lateral spreading in the corresponding experiment. (Note that different length scales apply to the x- and y-axis.)

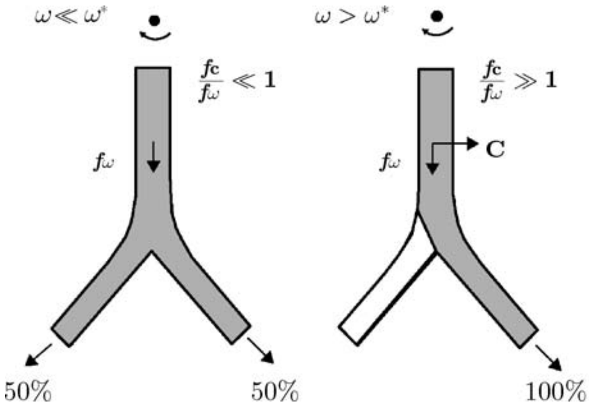
In many cases, the variation of the flow rate Q due to changes in $\bar{r}$ during the depletion of the upstream chamber ought to be minimized to homogenize incubation times. Looking at (9), the flow rate Q can be stabilized by an online adjustment of ω. Such a dynamic adjustment of ω either requires a very well reproducible flow behavior or a closed loop control of $\bar{r}$, e. g. via continuous tracking of the transient positions of the menisci $r_<$ and $r_>$.

An alternative to the adjustment of ω is to pinpoint $r_<$ and $r_>$ as far as possible during the flow interval. Regarding the downstream end at $r_>$, the continuous liquid column can, for example, be disrupted at a hydrophobic orifice leading into a large receiving vessel (Fig. 11). The fixed radial position of the orifice then coincides with $r_>$. For the upstream meniscus, the radial change of the inner meniscus $r_>$ can be minimized by maximizing the lateral dimensions of the issuing reservoir.

For other applications such as the simultaneous sedimentation at large ω (17), the overall minimization of the flow rate Q may be required. Resorting again to (9), we can also reduce the quotient $\Delta r d^4/l$ to throttle the flow rate. This geometric factor reflects the ratio of the hydrostatic pressure head ($\sim \Delta r$) to the hydrodynamic resistance ($\sim l/d^4$). So a radially shallow channel with a high tilt angle between the channel axis and the radial direction, i. e. $\Delta r \ll l$, diminishes Q (Fig. 1). A further reduction of Q can be accomplished by increasing the flow resistance, e. g. by a narrow, meander-like flow channel with an embedded stationary phase.



Centrifugal Microfluidics, Figure 9 Liquid router. Liquid is introduced via the upper left inlet and follows the left hand chamber walls towards a hydrophobic region at the entrance of the first outlet. Depending on the centrifugal field and thus the frequency ω, the droplet can either pass the capillary barrier or proceed to the second outlet [5]



Centrifugal Microfluidics, Figure 10 Flow through a symmetric, inverse Y-structure. (Left) At low frequencies ω where the Coriolis force f_C (2) is still negligible compared to f_ω (3), the flow is symmetrically divided between both outlets. (Right) The Coriolis force f_C dominating beyond a critical frequency ω^* (13) diverts 100% of the flow into an outlet addressed by the sense of of rotation [9]

Particle Sedimentation

As the rotary drive offers the function of a customary centrifuge, also sedimentation processes can be enforced, see, for instance, the hematocrit measurement in Fig. 12. However, in typical applications based on centrifugal microfluidics, the sedimentation usually only constitutes one upstream unit step in an integrated process chain to which the supernatant has to be forwarded.

Figure 13 shows an integrated sedimentation structure based on hydrophobic valving for the initial, overflow based metering, a radially flat and narrow transfer channel to throttle the flow such that the suspension has sufficient time to sediment in the separation chamber before pure supernatant is passed on to the plasma chamber. From there, the plasma can, for instance, be forwarded downstream structures by a hydrophilic capillary while halting the rotation.

Fabrication

Compared to other Lab-on-a-Chip systems, similar criteria apply to the selection of the fabrication process. Usually a master is made by conventional microstructuring or, in particular during prototyping, by well-established *soft lithography*. Polymer replication of smaller lots is often done by hot embossing while mass fabrication can resort to injection molding. After the structuring of the bulk material, postprocessing such as surface modification (e. g. hydrophilic, hydrophobic, biosensitive, anti-fouling), sealing (e. g. thermal bonding, gluing), integration of stationary phases (e. g. aggregated beads, membranes) and reagent loading (e. g. lyophilized, liquid storage in pouch) may be required.

The main distinction to common, credit-card sized Lab-on-a-Chips is the high lateral extension of the substrate, e. g. with a diameter of 12 cm when using CD-like formats. Across such a large surface area, it is usually harder to guarantee homogeneity of all microstructuring and post-processing steps. In addition, the substrate has to be mechanically balanced to minimize the load of the spindle. As for most microfluidic substrates, the transfer from prototyping technologies to mass fabrication may be accompanied by significant deviations in the performance. These deviations often root in the change of the replication process, resulting in significant differences in the surface characteristics, e. g. affecting its texture or chemical composition. This may directly influence the behavior of capillary flow or the resistance to bio-fouling, but it may also alter the adherence of coatings and the sealing process.

Device Technology

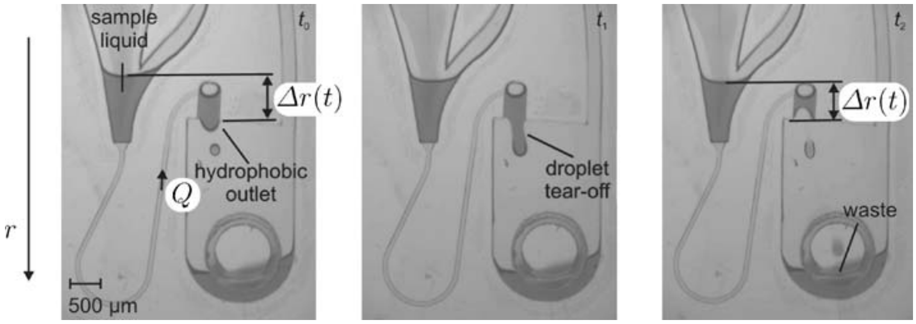
The core element is a frequency-controlled motor and a holder for the rotating substrates (e. g. disks). Depending on the application, liquid, optical and possibly electrical interfacing between rotating *on-board* components and stationary *lab-frame* components such as dispensers or detection units have to be incorporated. A process control software has to synchronize events such as liquid handling or optical readout to the periodic motion of the substrate. Figure 14 shows device concept of the LabCD™ platform.

Development Tools

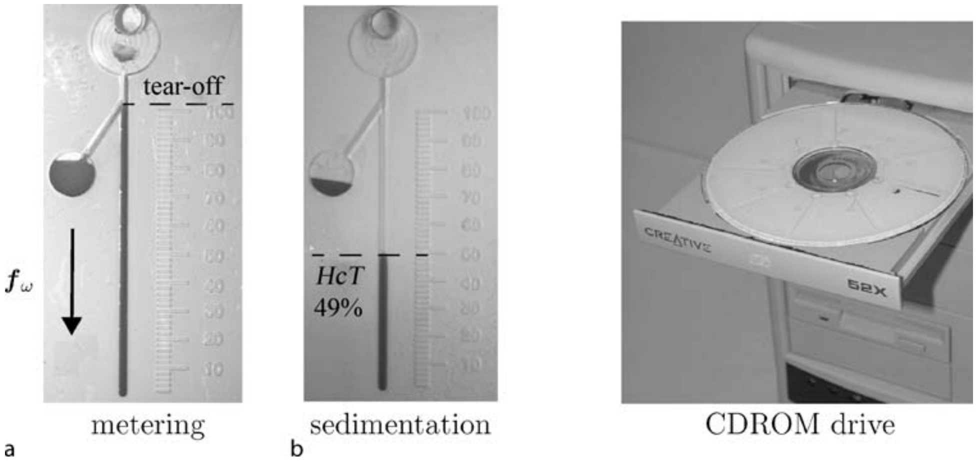
For the development of centrifugal microfluidic technologies, it is very useful to capture the dynamic processes during high-speed rotation. This is commonly done by a stroboscopic measurement setup comprising a microscope mounted CCD camera with a short exposure time and a flash light which are synchronized to the rotational motion (Fig. 15). Regarding simulation, the majority of commercially available computational fluid dynamic (CFD) packages is able to cope with rotating channels.

Key Research Findings

Since the early 1990s, several commercial and academic groups have launched activities to port various analytical or preparative protocols on centrifugal microfluidic systems. Companies such as Abaxis, Gyros, Gamera/Tecan, Eppendorf and SpinX have developed proprietary substrate formats and corresponding workstations incorporating actuation, liquid interfacing and detection units as well as various means for quality control. First full-fledged products have been available on the market.



Centrifugal Microfluidics, Figure 11 Course of liquid break-off at the hydrophobic outlet of the drain channel in a structure designed to stabilize the flow rate Q (9). The liquid tears off into a waste reservoir. This way, the outer radial position of the liquid plug $r_>$ is kept constant and is fluidically decoupled from the filling height in the waste reservoir and other parasitic effects. The variation of inner plug position $r_<$ is minimized by the large lateral extension of the upstream chamber [8]



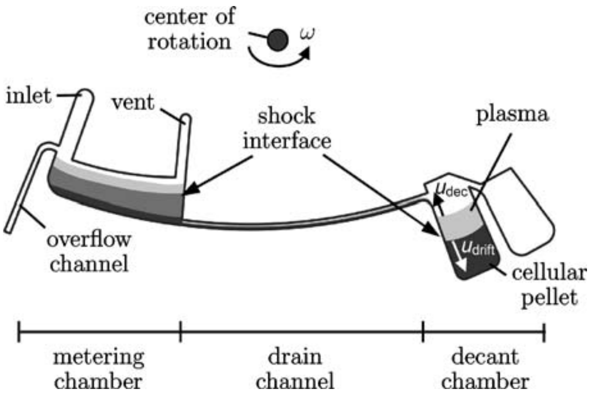
Centrifugal Microfluidics, Figure 12 (**a**) After an unmetered volume of whole blood is applied to the inlet reservoir, the capillary is primed and a precise volume of whole blood is metered during rotation. (**b**) Following sedimentation, the absolute hematocrit can be determined with the calibrated scale imprinted along the channel [7]

The present emphasis is put on general chemistry testing and immunoassays based on absorption, agglutination or fluorescence detection. Also the preparation of protein samples for subsequent analysis by MALDI-MS has been commercialized. For the rapidly emerging field of nucleic acid testing, key steps such as cell lysis, DNA isolation and thermocycling for polymerase chain reaction (PCR) have been demonstrated. In the mid-term future, it seems feasible to integrate an entire process chain comprising all steps between the take-up of real-world samples to displaying the analytical result on a centrifugal microfluidic nucleic acid workstation.

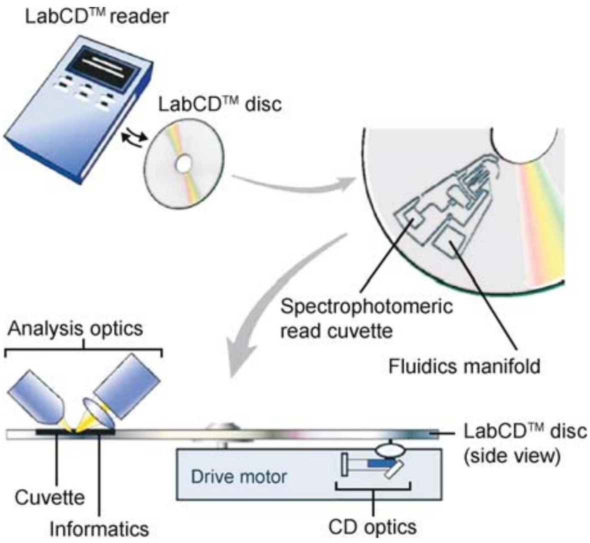
Another branch of centrifugal microfluidics forks into the field of micro process engineering. By making designated use of the frequency dependent artificial gravity conditions and the pseudo forces on the rotating substrate, applications such as ultra-fast mixing at high discharges, e. g. for chemical reacting, have been demonstrated. Also the centrifugally induced generation of multiphase systems such as highly monodisperse emulsions, segmented liquid-liquid and gas-liquid flow and air-to-liquid sampling has been shown.

Future Directions for Research

Most conventional Lab-on-a-Chip technologies may, in principle, be transferred to the *Lab-on-a-Disk*, in particular when they are active only while halting the rotation. The feasibility of the incorporation of these technologies to the rotating platform will be a trade-off between an enhancement of process integration, automation, control and variety of application protocols on the one side, and the increased complexity of the device (‘overengineering’) on the other.



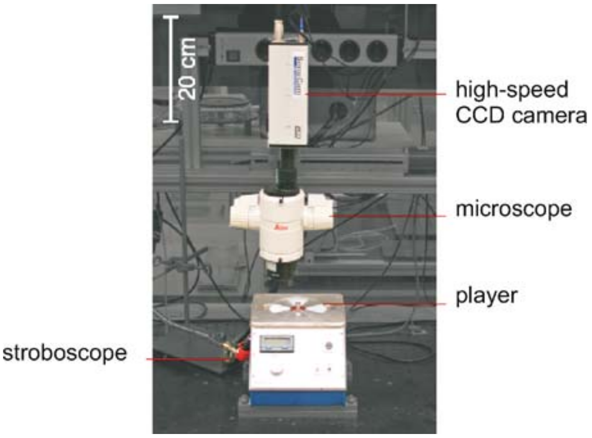
Centrifugal Microfluidics, Figure 13 Flow scheme of a decanting structure for plasma separation from whole blood. A metered volume of the blood sample is defined between hydrophobic stop and overflow channel. Upon breaking the outlet valve, a metered volume flows via the drain channel into the decant structure. A shock interface separating plasma from the cellular pellet builds out in all parts of the network and proceeds radially outwards at a speed u_{drift}. The filling height of the decant chamber rises at counter-current speed u_{dec} before the plasma overflows into the plasma collection chamber. The speed u_{dec} of the filling height in the cell reservoir is adjusted by the hydrodynamic resistance of the drain channel so that only purified plasma advances to the plasma reservoir [8]



Centrifugal Microfluidics, Figure 14 LabCD™ instrument and disposable disk. Here, the analytical result is obtained through reflection spectrophotometry [3]

Future initiatives ought to start out with a look at the inherent advantages of centrifugal microfluidic systems:

- Modular setup
  - Centrifuge drive – passive microfluidic substrate
  - Easy exchange of disposable cartridge
  - Flexibility of substrate formats (disk, slide, ...)



Centrifugal Microfluidics, Figure 15 Centrifugal test and development stand [7]

- Centrifugal field
  - Pulse-free pumping
  - No pressure-tight interfaces needed
  - Low pressure load on lids
  - Standard operation in sample prep
  - Robust liquid handling widely decoupled from viscosity and surface tension
  - Intrinsic, buoyancy-based bubble removal
  - Coriolis force manipulates flows
- Rotational symmetry
  - Replication of identical process channels
  - Simultaneous processing of parallel channels
  - Sequential channel-by-channel processing
- Full process integration and automation

and carefully weigh them against potential drawbacks such as

- Interfacing with lab-frame components
  - Pipettes and dispensers
  - Quality control units
  - Detection units
- On-board components
  - Exposure to centrifugal force
  - Need for mechanical balancing
  - Difficult wiring, e. g. for electrical power, liquids and signal transmission

which are primarily associated with the rotating motion of the substrate.

On behalf of research, the scope of unit operations should be extended. A key factor constitutes the availability of on-board detectors which will enable a truly continuous monitoring of processes taking place along the entire orbit to appreciable enhance the sensitivity. A similar effect may

be achieved by lab-frame optical systems which are able to track rotating reaction chambers.

Also an on-board electrical power supply, e. g. by photovoltaic cells or thermogenerators connected to a lab-frame irradiation source, would introduce additional, frequency independent degrees of freedom, enabling a multi-force manipulation of the processed liquids. Another extension of present centrifugal systems is the (wireless) data communication with the lab-frame workstation for an improved process control and analysis.

Regarding commercialization, it is expected that researchers will continue to further augment the level of process integration, automation, parallelization and miniaturization. Multi-purpose workstations which can run a set of different applications, each represented by a designated substrate (disk), will certainly be a strong selling point. The largest markets for centrifugal microfluidic technologies are expected for decentralized systems for medical diagnostics and (bio-)chemical analysis as well as research tools for pharmaceutical drug discovery.

Apart from reliability, sensitivity, interfacing with established standards and regulatory issues, the main hurdle to pass for a successful commercialization is clearly the price per assay or preparation compared to presently established or other emerging technologies. This concerns the polymer substrate as well as the device for which important lessons may, for instance, be learnt from the massive cost erosion of Compact Disc™ technology over the last decades. Patients autonomously performing complex diagnostic assay protocols by simply introducing a body liquid into a $1 disk which is automatically 'played' by a $10 discman remains a truly tantalizing vision for centrifugal microfluidic technologies.

Turbulent flows; Turbulence

Definition

There is no universally recognized definition of chaotic flows. Flows with properties that are neither constant in time nor presenting any regular periodicity are normally referred as chaotic. Fluid turbulence is generally found to be chaotic. It is also random, dissipative, and multiple scaled in time and space. It is a complex system of infinite degrees of freedom.

Overview

Noises are due to random thermal fluctuations or other environmental factors and can be completely unpredictable except for statistical sense. Chaos arises from deterministic systems [1, 2]. Normally the nonlinearity in the system can produce high sensitivity to the initial state of the system such that even a small error will be exponentially amplified as the system evolves in time.
A simple differentiable dynamical system of dimension n can be written as

$$\frac{\mathrm{d}\boldsymbol{x}(t)}{\mathrm{d}t} = f(\boldsymbol{x}(t)) \text{ where } \boldsymbol{x} \in R^n$$

The solution of the system produces a time series of the value of $\boldsymbol{x}$ in time t with the initial value of $\boldsymbol{x}$ given at time $t = 0$ or $\boldsymbol{x}(t = 0) = \boldsymbol{x}_0$. The space $\boldsymbol{x}$ (R^n) with t as a parameter is termed a phase space. The function f determines the time evolution of the system. The dynamic system is nonlinear with nonlinear term in the function f. One example in fluid dynamics is the Navier–Stokes equations for Newtonian fluids. The nonlinearity of the system comes mainly from the convective motion of the fluid flow. The fluid motion can develop unpredictable, yet observable behavior with the proper choice of the initial conditions.
One example of such a system is the Lorenz system [3] with $n = 3$. The system can be written as

$$\frac{\mathrm{d}x}{\mathrm{d}t} = -\sigma x + \sigma y$$

$$\frac{\mathrm{d}y}{\mathrm{d}t} = -xy + rx - y$$

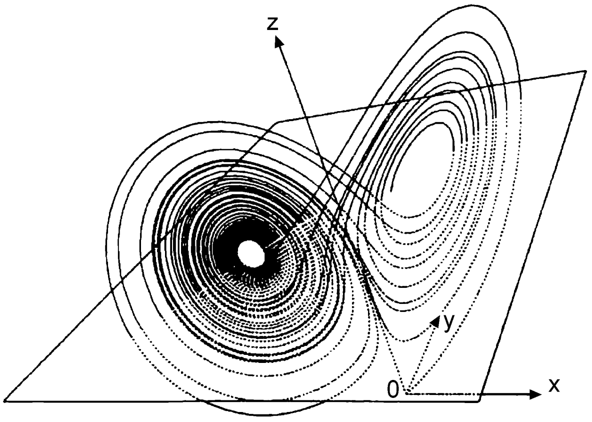
$$\frac{\mathrm{d}z}{\mathrm{d}t} = xy - bz$$

The system is a simplified form of the Navier–Stokes equations. The solution of the system ($x(t)$, $y(t)$, $z(t)$) in the phase space or trajectory with an initial condition near (0, 0, 0) and $\sigma = 10$, $r = 28$, $b = 3/8$ is shown in Fig. 1 [4].
Discrete equations, such as finite difference equations, can also produce chaos. Henon [5] proposed a system of discrete time evolution equations

$$x(t + 1) = y(t) + 1 - a[x(t)]^2$$

$$y(t + 1) = bx(t)$$

which exhibits the same essential properties as the Lorenz system for certain values of the parameters in the equations.
In practice, the identification of chaos is difficult. The noise of a physical system interferes with the dynamics that are determined by the governing equations. The components in a measurement device will also present noise. Several possible measures of chaos include the use of the power spectrum, the Poincare map and the Liapunov number.
The power spectrum is probably the most frequently used measure. The power spectrum decomposes a complex time



Chaotic Flows, Figure 1 Trajectory of the Lorenz system

series or system behavior into a series of sine waves of a range of frequency. The power spectrum of a chaotic time series is normally a continuous power spectrum. The power associated with a particular frequency is the square of the amplitude of that sine function. A time series is chaotic with a broad band of continuous frequency with appreciable power.

A Poincare map is established by cutting across the trajectories in a certain region in the phase space, say with dimension n, with a surface that is one dimension less than the dimension of the phase space, $n-1$. One such cut is also shown in Fig. 1. The equation that produces the return to the crossing the next time is a discrete evolution equation and is called the Poincare map. The dynamics of the continuous system that creates the Poincare map can be analyzed by the discrete equation. Therefore, chaotic behavior of the Poincare map can be used to identify chaos in the continuous system. For example, for certain parameters, the Henon discrete evolution equation is the Poincare map for the Lorenz systems.

The Liapunov number can be used as a quantitative measure for chaos. The connection between chaos and the Liapunov number is through attractors. An attractor is a set of points S such that for nearly any point surrounding S, the dynamics will approach S as the time approaches infinity. The steady state of a fluid flow can be termed an attractor with dimension zero and a stable limit cycle dimension one. There are attractors that do not have integer dimensions and are often called strange attractors. There is no universally acceptable definition for strange attractors. The Liapunov number is determined by the principle axes of the ellipsoidal in the phase space, which originates from a ball of points in the phase space. The relationship between the Liapnuv number and the characterization of chaos is not universal and is an area of intensive research.

Fluid turbulence has had many descriptions. It is random, chaotic, dissipative, and multiple scaled. The turbulent flows describable by the Navier–Stokes equations present these properties when the nonlinear terms, which represent the convective effect of fluid motion, become relatively large compared with the other terms, such as the viscous forces. The Reynolds number can be regarded as one such measure for the ratio. At small Reynolds numbers, or when the viscous effects dominate the nonlinearity in the system, the solutions of the Navier–Stokes equations are regular and smooth, a state commonly referred to as laminar flow. Chaotic time series of the flow begins to appear as the Reynolds number increases, or when the nonlinearity becomes dominant. As the time series of the behavior at large Reynolds number can present quite large oscillations, methods using averaging have been applied so that the smooth, averaged flow behaviors are more amendable to studies. This process, however, naturally produces additional unknowns that do not have the corresponding unaveraged quantities in the Navier–Stokes equations. This is referred to as the turbulence closure problem.

Basic Methodology

The averaging method for a turbulent flow divides the time series into an averaged value and a fluctuation with respect to that average [6]. Or,

$$u = U + u'$$

$$\text{where } U = \bar{u} = \lim_{(\zeta_b - \zeta_a)\to\infty} \frac{1}{\zeta_b - \zeta_a} \int_{\zeta_b}^{\zeta_u} u d\zeta$$

The quantity U can be obtained in a few different ways. The average can be taken over time or space variables. It can also be obtained by ensembling. When the three averaging procedures lead to the same result, the system is ergodic. The equations for the averaged quantities can be obtained by exercising the averaging procedure on the Navier–Stokes equations. u' represents the deviation of the time series from the average value, or fluctuation. The intensity of the fluctuation or $|u'|$ is a measure of the deviation. The decomposition or averaging has facilitated the development of most of the current understanding of turbulent flows theoretically, experimentally, and numerically. However, as described earlier, the averaging also introduces the closure problem. For example, for a and b being turbulent flow quantities, or $a = A + a'$, $b = B + b'$ the nonlinear convective terms of the averaged Navier–Stokes equations produce terms like

$$\overline{ab} = \bar{a}\,\bar{b} + \overline{a'b'}$$

The second-order correlation of the fluctuations $\overline{a'b'}$ is not known and does not appear in the Navier–Stokes equations. Additional equations need to be provided, therefore giving rise to the closure problem. The closures are provided for an area called turbulence modeling for RANS (Reynolds-averaged Navier–Stokes) and LES (large eddy simulation) methodologies.

With the exponential increase of computing speed, numerically solving the Navier–Stokes equations has been conducted for turbulent flows of increasingly high Reynolds numbers. This belongs to a subject called direct numerical simulation or DNS.

In micro- and nanoscaled devices, the particle nature of fluid becomes important. For a gaseous fluid, the ratio of the molecular mean free path λ and the system length scale

L is termed the Knudsen number Kn:

$$\mathrm{Kn} = \lambda/L$$

For micro- and nanoscale gaseous flows with large Knudsen number, say 0.1, the equilibrium assumption inherent in the Navier–Stokes equations becomes invalid and a discrete approach has to be used. This is also true for liquids, although the Knudsen number is not an appropriate parameter to measure deviation from continuum for liquid flows. Given the observations made from macroscaled devices and the known fluid properties, the Reynolds numbers for the flows in micro- and nanoscaled devices are very small due to the small length scales.

Key Research Findings

Arguably the most significant finding that has redirected turbulent flow research is the identification of the so-called coherent structures in experiments and in numerical studies. They are observable by using conditional sampling or phase averaging, particularly in flows that are somewhat excited. The structures are generally coherent in their appearance and vorticity. The structures are often of large scale, for example of the same order as that of the mean flow. They have been found to be responsible for mechanisms that relate to the transport and the production in almost all commonly observed turbulent flows. Findings show the existence of the underlying orderliness in the apparent chaos of turbulent flows and have fostered many modifications to the traditional thinking of turbulence, such as the turbulent gradient transport hypothesis. Weakly nonlinear analysis has been shown to reproduce the large-scale phenomena in simple flows.

Future Directions for Research

Chaotic flows remain one of the most challenging problems in sciences and engineering. At micro- and nanoscales, the behaviors of fluid flows are yet to be fully investigated. On the other hand, nano- and microscaled devices have brought new opportunities to the study of chaotic flows. Molecular tagging and many other new techniques are emerging every day. They also bring possibilities of new control methodologies of chaotic turbulent flows.

Definition

Due to the small characteristic dimensions of a microfluidic channel, flow in a microfluidic channel has a small Reynolds number. For aqueous solutions, this leads to laminar flow which is not conducive to mixing flow streams, particularly in the passive mixing approach. However, the viscoelasticity of fluids can be exploited to enhance mixing. Aqueous solutions, which are Newtonian fluids, could be made viscoelastic by the addition of a small amount of high molecular weight polymers to the solutions. These solutions with polymeric additives are known as non-Newtonian viscoelastic fluids. Through proper design of the microfluidic channels to exploit the viscoelastic nature of these fluids, flow instability and chaotic flow can be induced. This chaotic flow behavior will lead to efficient mixing. Viscoelastic mixing, can lead to efficient mixing even at small Reynolds number and large Péclet number.

Overview

Chaotic and turbulent flow instabilities are recognized as effective mechanisms for mixing. However, the microscale dimensions of microfluidic devices lead to small Reynolds numbers (small ratio of inertial to viscous forces). This impedes turbulent flow instabilities and promotes laminar flow due to the domination of viscous effects. For liquid flows in a microchannel, interaction between a fluid

and the channel wall will dominate, and the surface to volume ratio increases tremendously compared to that at macroscopic-length scales. For laminar flow, the primary means of mixing multiple streams in microfluidic channels is through the molecular diffusion mechanism. However, diffusion is small over the timescales of interest. Therefore mixing enhancement is one of the key challenges for microfluidic devices. Generally, passive mixers, which include lamination micromixers and chaotic advection mixers, rely on the diffusive mixing mechanism. They require long and complicated channels, and relatively slow flow rates. Although active mixers might be employed, they require external actuators [1]. Both approaches lead to complex and expensive fabrication processes. A different approach that bypasses the low Reynolds number limitation yet provides efficient mixing will be a significant improvement for microfluidic system design.

It is known that a viscoelastic fluid, e. g., a solution with a trace amount of highly deformable polymers, can lead to elastic flow instability at Reynolds number well below the transition number ($\mathrm{Re} \approx 2000$) for turbulence flow. Such chaotic flow behavior has been referred to as elastic turbulence by Tordella [2]. Indeed, the proper characterization of viscoelastic flows requires an additional non dimensional parameter, namely the Deborah number, De, which is the ratio of elastic to viscous forces. Viscoelastic fluids, which are ► non-Newtonian fluids, have a complex internal microstructure which can lead to counterintuitive flow and stress responses. The properties of these complex fluids can be varied through the length scales and timescales of the associated flows [3]. Typically the elastic stress, by shear and/or elongational strains, experienced by these fluids will not immediately become zero with the cessation of fluid motion and driving forces, but will decay with a characteristic time due to its elasticity. Therefore, through the high deformation rates achievable in microlength-scale devices, strong viscoelastic effects can be generated even in dilute aqueous polymeric solutions.

Hitherto little attention has been paid to microfluidic flow involving viscoelastic fluids with the notable exception of ink-jet printing. Ink-jet printing applications, whose typical dimensions are on the order of 50 μm or less, utilize aqueous fluids containing low concentrations of high molecular weight polymers. A prototypical geometry that captures a number of features in an ink-jet print head is the converging entry flow through abrupt contraction–expansion geometry. This geometry has been used extensively to study the nonlinear flow phenomenon associated with *non-Newtonian fluid* elasticity in converging flows at macrolength scales. The recirculating flow vortices have been comprehensively documented for a large number of polymeric solutions and polymer melts [4]. Lately, distinct similarities in these early works at macrolength scale were demonstrated qualitatively in a microlength-scale planar contraction by Rodd et al. [4], and in flip-flop memory devices by Groisman et al. [5].

Much less research has been conducted on the enhancement of mixing through viscoelastically induced flow instability in microfluidic devices. Groisman and Steinberg [6] have presented the use of a polymeric liquid for enhanced mixing in small geometries of millimeter scale. Moderate shear rates were generated in small channels to induce elastic flow instabilities. Using repeated half-ring flow geometry with a uniform cross-section, mixing was achieved with a relatively long mixing path at a moderate flow rate.

Indeed, to exploit effectively the viscoelasticity of fluids for chaotic flow instability, and thus mixing, sharper and smaller geometries should be employed. Stress singularities developed at such corners have been the source of elastic instabilities in many macroscale experiments [3], while rounded corners tend to suppress elastic behavior. From a practical standpoint, it is necessary to understand the rheological nature of such flow in order to optimize the use of viscoelastic effects in microfluidic mixing applications. The complex interplay that arises between the elasticity and viscosity of the fluids, and the ratio of contraction of the channel is the key to efficient mixing of fluid streams in microfluidic channels.

Basic Methodology

In the last few decades, understanding and controlling contraction flow or entry flow behavior has been one of the classical problems of fluid mechanics. Reviews of investigations published prior to 1987 can be found in Boger [7] and White et al. [8], and a brief summary of more recent works is given in Rodd et al. [4].

Dimensionless Parameters

For mixing in laminar flow, diffusion is an important mechanism. The Péclet number, Pe, indicates the relative importance of advection to diffusion, and is given by

$$\mathrm{Pe} = \frac{\bar{v} L_{\mathrm{char}}}{D} \tag{1}$$

where $\bar{v}$ is the average velocity, L_{char} is the upstream channel width and D is the diffusion coefficient. The higher the Pe, the less significant is the diffusion.

For an aqueous or a viscous solution, the onset of flow instability can be characterized by the Reynolds number, Re, which measures the relative importance of inertial and

viscous effects in a fluid flow. It can be defined as

$$\mathrm{Re} = \frac{\rho \bar{v} d_\mathrm{c}}{\mu_0} \qquad (2)$$

where d_c is the characteristic dimension of the geometry. ρ and μ_0 are the fluid density and viscosity, respectively.
For a given geometry, the viscoelastic effects of a fluid flow can be characterized by the Deborah number, De. The Deborah number is a dimensionless parameter which typifies the relative importance of the elastic stresses of the fluid with the timescale of the flow system [3]. Generally, a smaller dimension results in a higher characteristic deformation rate for the same flow rate, resulting in higher elastic effects and a higher De.
Based on the characteristic shear rate, the Deborah number can be expressed as

$$\mathrm{De} = \lambda \dot{\gamma}_\mathrm{char} = \lambda \left(\frac{2\bar{v}}{d_\mathrm{c}} \right) = \frac{2\lambda \bar{v}}{d_\mathrm{c}} \qquad (3)$$

The characteristic shear rate may be expressed as $\dot{\gamma}_\mathrm{char} = (\bar{v})/(d_c/2) = 2\bar{v}/d_c$, where λ is the *relaxation time of the viscoelastic fluid* measured in shear.
It should be noted that for some problems, more than one characteristic time for the flow can be identified [3]. Thus, a second dimensionless group, the Weissenberg number, Wi, is sometimes used in polymeric fluid dynamics. It can be defined as

$$\mathrm{Wi} = \lambda \kappa \qquad (4)$$

where κ is a characteristic strain rate in the flow. For problems where there is only one identifiable characteristic time, the Deborah number should be preferred. Indeed, in a steady channel flow De and Wi are interchangeable. However, there are debates about the most appropriate terminology for more complex flows that are associated with the unsteadiness of the process, see Bird et al. [3] and Metzner et al. [9] for further discussion of this topic.
A smaller channel has a smaller flow characteristic length and time. Thus, Re is smaller and it is difficult to have inertia/viscous flow instability. Conversely, De becomes larger and it is easier to have elastic/viscous instability. The relative dominance of elastic to inertial effects is typified by the Elasticity number, El, i. e., the ratio of fluid elasticity to fluid inertia. El is expressed as

$$\mathrm{El} = \frac{\mathrm{De}}{\mathrm{Re}} = \frac{2\lambda \mu_0}{\rho d_\mathrm{c}^2} \qquad (5)$$

El is a function of the given fluid and geometry. It is dependent on the fluid properties and the inverse of the characteristic cross-sectional area.

The contraction ratio (α) is another key parameter in determining the entry flow behavior. It is defined as

$$\alpha = \frac{W}{d_\mathrm{c}} \qquad (6)$$

where W is the upstream channel dimension and d_c is the characteristic dimension of the contraction channel.
However, in general the rheological properties of a viscoelastic fluid are shear rate ($\dot{\gamma}$) dependent. Thus the various dimensionless parameters are also shear rate dependent. For example, the Elasticity number El is now dependent on the change in shear rate $\dot{\gamma}$, which could be written as

$$\mathrm{El}(\dot{\gamma}) = \frac{2\lambda(\dot{\gamma})\mu(\dot{\gamma})}{\rho d_\mathrm{c}^2} \qquad (7)$$

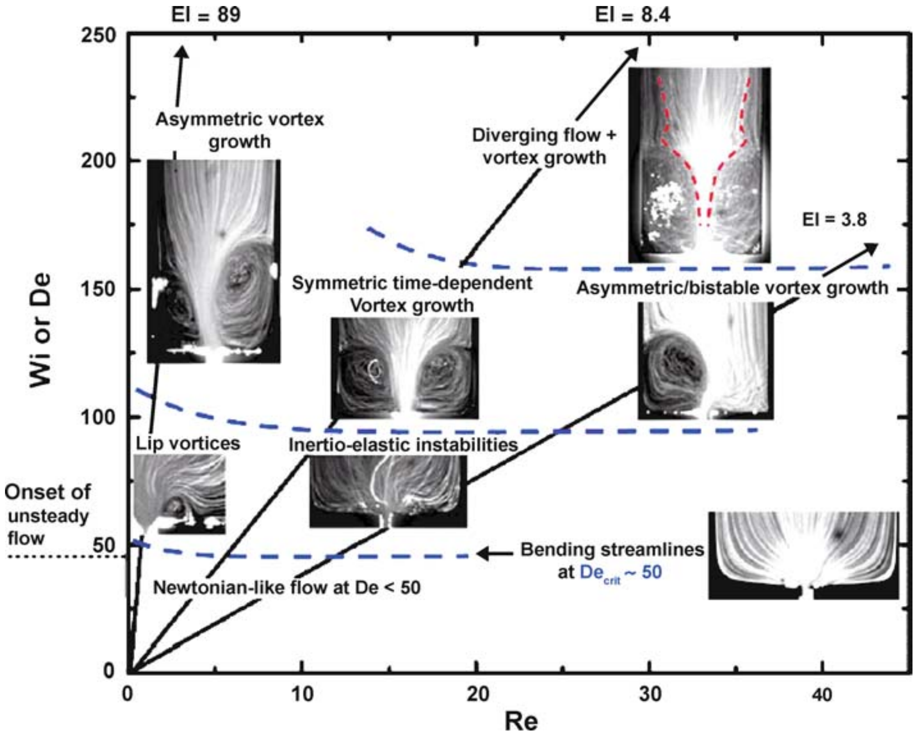
However, as $\dot{\gamma}$ is a function of flow rate, it implies that both λ and μ are functions of flow rate. Thus, in contrast to Eq. (4), Eq. (7) indicates that El is also a function of the flow rate.

Contraction–Expansion Flow Behavior

The flow phenomena of viscoelastic entry flow for macro channels have been explored more comprehensively for axisymmetric geometries as compared to planar geometries in the past few decades. Details of the complex interplay between the elasticity and inertia of viscoelastic fluids for macro channels with axisymmetric geometries can be found in Cable and Boger [10, 11], who employed a number of shear thinning viscoelastic fluids in axisymmetric contractions, spanning a wide range of the De–Re operating space.
However, planar geometrical configurations will be the main focus here, as they are commonly found in microfluidic devices due to their ease of fabrication. Rodd et al. [4] have summarized the nonlinear flow phenomena in microfluidic channels in the De–Re space (see Fig. 1). Care should be taken when relating various phenomena from axisymmetric to planar geometries at similar De–Re regimes. For example, the formation and changes of the vortical flow pattern can be qualitatively different as a result of the difference in total strains and strain-rate histories experienced by the fluid elements in the two geometries [4, 12].

Contraction Flow Behavior

Contraction flow is commonly known as converging entry flow. Interesting flow phenomena have been observed with increasing Deborah number in an entry flow. Flow structures observed in converging entry flows, for viscoelastic



Chaotic Mixing Based on Viscoelasticity, Figure 1 Flow regimes in De–Re space for dilute aqueous PEO solutions through microlength scale contraction geometries [4]

fluids, can be categorized into three distinct regimes: vortex growth, diverging flow and unstable flow.

Vortex Growth The formation and growth of the vortex upstream of the contraction is proportional to the De value, which increases with an increase in flow rate (see Eq. (3)). This implies that the elastic forces become more dominant as the flow rate increases. When the elastic effects are large enough to suppress the inertial effects, a viscoelastic fluid undergoes transitions from the Newtonian-like behavior (low flow rate structure) to regimes with vortex formation and enhanced vortex size. This competition between elastic and inertial forces within the flow becomes violent with further increments in the flow rate. At a high enough flow rate, the large vortex observed in many viscoelastic entry flows ultimately becomes unstable, resulting in large fluctuations in the flow field and gross distortion of the viscoelastic fluid downstream of the contraction.

According to the convention in macro scale entry flow study, the vortex length has been widely used to characterize the vortical flow pattern observed in viscoelastic converging entry flow (see Eq. (8)). The dimensionless vortex length is defined as the axial distance from the upstream contraction plane at which the primary flow first detaches from the wall to the upstream channel width. It can be expressed as

$$\chi_L = \frac{L_v}{W} \tag{8}$$

where L_v is the vortex length and W is the upstream channel width.

For similar geometrical dimensions and flow conditions, a difference in the observations between planar and axisymmetric entry flows is the size of the salient corner vortex. This difference is believed to be caused by the difference in the total Hencky strain imposed on the macromolecules during the converging entry flow, which is less for planar entry flows than for axisymmetric entry flows [4].

Diverging Flows Diverging streamlines upstream at the contraction are a feature of contraction flows, which are mainly controlled by both elasticity and inertia. When the flow system reaches a critical value of Re, inertial effects cause a reduction in the size of the vortex and are often accompanied by diverging flow patterns at the interface region between the main stream flow and the secondary stream flow (corner vortices), (see Fig. 1) as indicated by the dashed line at De ≈ 240. A comprehensive illustration

of this flow regime can be found in Cable and Boger [10]. These flow structures have also been predicted numerically in the presence of both elasticity and inertia, for shear-thinning fluids, by the PTT or FENE-P models [4]. However, the precise dynamical mechanisms that lead to the development of the diverging streamlines upstream of the contraction are yet to be fully elucidated.

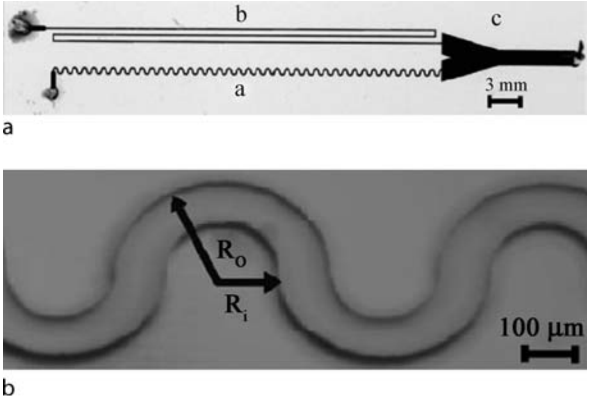
Unstable Flow Steady viscoelastic converging entry flows could become unstable at moderate Deborah and Reynolds numbers in both axisymmetric and planar geometries [4]. It has been found that viscoelastic fluids experience regimes consisting of diverging flow with unstable salient vortices, and regimes with Goertler-like and lip vortices [13].

Expansion Flow Behavior

Less research has been performed on the exit behavior of fluids from the contraction. Generally, the elasticity of a viscoelastic fluid has the opposite effects to fluid inertia. As a result, the large viscoelastic forces that generate vortex behavior upstream work in an opposite fashion downstream of the contraction, and thus suppress downstream vortex growth. These flow behaviors were reported by Townsend and Walters [14]. They investigated the expansion of viscoelastic and Newtonian fluids in an identical channel. They found that at a high Reynolds number, Newtonian fluids generated large circulation zones or corner vortices downstream of the contraction, which are a feature of the expansion flow behavior for Newtonian flow [15]. However, for a viscoelastic fluid with the same Reynolds number and a low Deborah number, the exit vortex behavior was completely suppressed.

Key Research Findings

Lately, the work of Groisman and Steinberg had been extended to micrometer-length scales [16]. By utilizing high molecular weight polyacrylamide, with a mean molecular weight (M_{wt}) = 1.8×10^7 g/mol, dissolved in two different Newtonian solvents with different viscosities, Burghelea et al. [16] demonstrated a chaotic flow through a flat curvilinear microchannel with a uniform square cross-section of 100 μm, as shown in Fig. 2. The characteristic mixing distance was estimated to be 7.3 segments of the curvilinear channel (two half-rings form one segment) or a nominal flow length of 6.88 mm. Characteristic mixing times were approximately 40 s. They showed that the stirring behavior induced in the flow by these viscoelastic dilute polymeric solutions results in efficient mixing in the microchannel with the characteristic mixing length significantly shorter than that of the herringbone

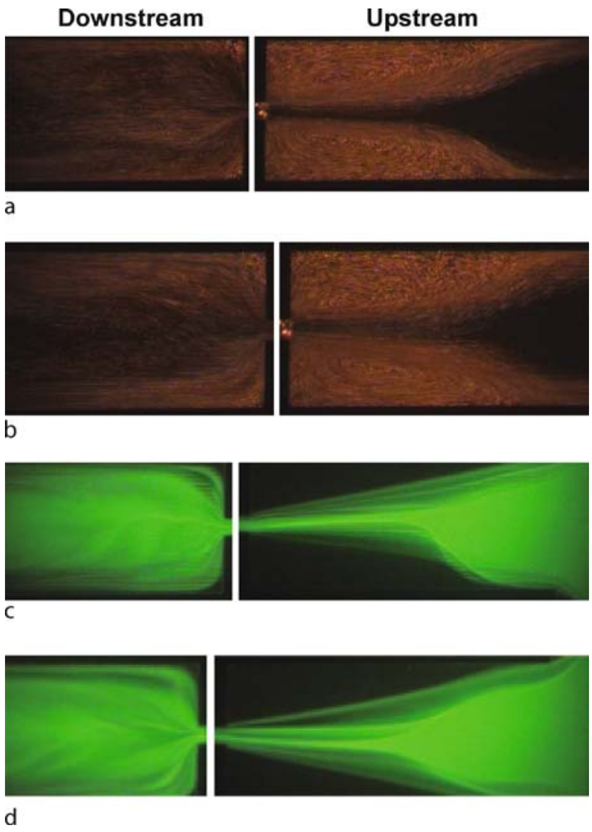


Chaotic Mixing Based on Viscoelasticity, Figure 2 (a) Curvilinear microfluidic device. (b) Zoom-in image of a section of the functional curvilinear channel [16]

patterning method for laminar flow of aqueous solutions. The characteristic mixing times for these viscoelastic fluids were reduced by approximately three to four orders of magnitude compared to the mixing mechanism based on molecular diffusion.

The promotion of viscoelastic instability by utilizing microchannels with abrupt contraction/expansion geometry for mixing has been exploited by Gan et al. [17, 18]. They employed a microchannel with a depth of 150 μm and an abrupt contraction/expansion of 1000 μm : 125 μm : 1000 μm to introduce the convergent/divergent flow. The viscoelastic fluids utilized consisted of 1 wt% poly(ethylene-oxide) (PEO) in 55 wt% glycerol water and green fluorescent dye for the main stream, and 0.1 wt% PEO in water and 3-μm red fluorescent microspheres for the side streams. The mean molecular weight (M_{wt}) of PEO is approximately 2×10^6 g/mol. These different viscoelastic fluids were mixed experimentally at very low Reynolds number ($Re < O(0.1)$), but large Péclet number ($Pe \sim O(10^6)$) and Elasticity number ($El > O(10^2)$). Rapid mixing with negligible diffusion was achieved with a characteristic mixing length of less than 5 mm and characteristic mixing time of the order of milliseconds. However, this microfluidic device requires high pressure to achieve a fast flow rate for mixing liquids of comparatively high viscosity and elasticity.

At such a large Elasticity number, the inertial effects were negligible. Thus, the Reynolds number is no longer relevant in describing the flow behaviors. The flow dynamics of these dissimilar viscoelastic fluids were mainly governed by the competition of the dominant viscous and elastic forces in the flow field. As such, the Deborah number would be the dominant governing parameter. They observed experimentally that with increasing



Chaotic Mixing Based on Viscoelasticity, Figure 3 Consecutive snapshots of viscoelastic fluids flow at $\dot{Q} = 12\,\text{ml/h}$. Each fluorescenttracer' snapshots, (a) and (b) or (c) and (d), were collected at 50 ms interval. Viscoelastic instability (whipping) upstream and downstream is highlighted. Significant and extensive mixing is illustrated clearly by extensive overlapping of the main stream (fluorescent dye) and side streams (microspheres) [18]

Deborah number, which increases with flow rate, the flow fields became increasingly unstable. At high enough Deborah number, unstable converging entry flows (unstable salient corner vortices) with large fluctuations of the central mainstream at upstream of the contraction were observed [18], which facilitated the subsequent mixing of the flow streams, as shown in Fig. 3. It is believed that the upstream viscoelastic whipping resulted in flow instability downstream of the contraction. This flow instability, together with the expansion-flow effects of the mainstream promoted effective mixing downstream. The mixing efficiency was found to be 22 % when upstream of the contraction and improved significantly to 68 % when downstream of the contraction. Gan et al. [18] further examined the flow of viscous fluid streams with no measurable elastic effects in an identical channel, but with the same viscosity ratio as the viscoelastic fluid streams. No mixing of the streams was observed. Thus, the necessity of fluid elasticity for flow instability and mixing was demonstrated.

Future Directions for Research

Chaotic mixing based on viscoelastic flow instability in rather simple microfluidic channel geometries was successfully demonstrated. These viscoelastic micromixers bypass the limitation of low Reynolds number in microfluidic flows and could potentially be implemented in a Lab-on-a-Chip platform with minimum requirements for design and fabrication. However, this type of micromixer is yet to be optimized.

In addition, there is a lack of a clear in-depth understanding of the nonlinear interaction between the shear and extensional rheology of the fluids with the generation of viscoelastic instability and mixing for a multiple streams flow in microfluidic channels. At a microlength scale, flow regimes not previously achievable at a macrolength scale could be explored. For example, with proper design of the channel and flow conditions, viscoelastic flows with devoid of inertial effects could be achieved. This type of flow can be characterized by the Deborah number alone. This provides an opportunity to investigate the critical Deborah number for the onset of flow instability, and thus for mixing. It could also facilitate the investigation of viscoelastic effects on the evolution of the various flow structures for single-stream and multiple streams flows.

Charge Coupled Device (CCD) Camera

Synonyms

CCD-Camera

Definition

A charge-coupled device (CCD) is an image sensor, consisting of an integrated circuit containing an array of linked, or coupled, light-sensitive capacitors. CCD's are used in digital photography and astronomy (particularly in photometry, sensors, optical and UV spectroscopy and high speed video capture techniques).

Chemical Bond

Definition

A *chemical bond* is the physical phenomenon responsible for the attractive interactions between atoms that confers stability to di- and polyatomic chemical compounds. There are mainly three kinds of chemical bonds: covalent bonds, ionic bonds and hydrogen bonds. Generally covalent and ionic bonds are often described as strong, whereas hydrogen bonds and van der Waals are generally considered to be weaker.

Definition

Chemical vapor deposition (CVD) is a method of forming dense and stable structural parts or coatings using the decomposition of relatively high vapor pressure gases. Gaseous compounds of the materials to be deposited are transported to a substrate surface where a thermal reaction/deposition occurs. Reaction byproducts are then exhausted out of the system.

Overview

Chemical vapor deposition or CVD is a generic name for a group of processes that involve depositing a solid material from a gaseous phase and is similar in some respects to physical vapor deposition (PVD). PVD is different in that the precursors are solid, with the material to be deposited being vaporized from a solid target and deposited onto the substrate.

CVD is relatively a mature and well-defined process and its application in industries has gained widespread usage over the last 40 years. CVD process has evolved from simple extraction into more complex techniques that involve coating technology for thin-film production and for surface treatment or improvement. In the early years, CVD was mainly used in semiconductor manufacturing and protective coatings of electronic components. The CVD technology now has rapidly and extensively been applied in more advanced processes such as in ceramic processing for high-temperature cutting tool bits and turbine blades, among others. More recently, the CVD technology has been explored in the field of microfluidics and nanofluidics.

Advantages of the Chemical Vapor Deposition Technique

Although CVD is a complex process, it has many distinct advantages [1]:

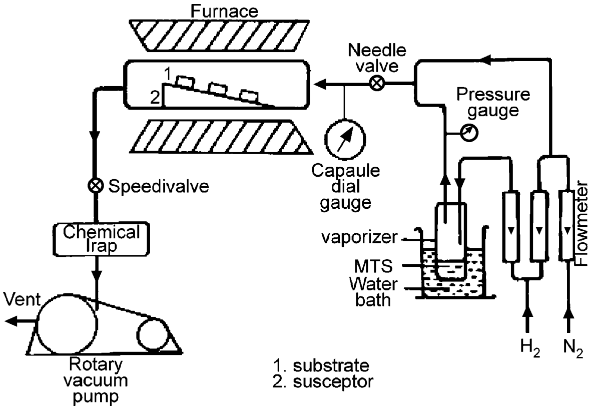
- Highly dense and pure substances can be produced.
- Uniform thin films with high adhesion and good reproducibility can be formed.
- Films with good conformal thickness can be deposited on the surface of complex shapes.
- The crystalline structure, surface morphology and orientation can be controlled by controlling CVD process parameters.
- The rate of deposition can be easily controlled.
- The cost of operation is lower for a typical conventional CVD.
- A variety of ►precursor materials including halides, hydrides and organometallics can be used, which enables deposition of metals, carbides, nitrides and oxides.
- It can operate at relatively low deposition temperatures enabling the deposition of refractory materials at a small fraction of their melting temperatures.

Disadvantages of the Chemical Vapor Deposition Technique

- The extremely hazardous precursor gases cause chemical and safety hazards.
- Difficulty in depositing different types of materials using multi-source precursors because different precursors have different vaporization rates.
- The cost of fabrication increases for the variant CVD processes such as PACVD and PCVD.

Basic Methodology

CVD process can be performed either in a closed or open system. The differences between the two methods are that, in the former, the reactants and products are reused or recycled. The application of closed systems is losing popularity nowadays due to the inherently expensive method



Chemical Vapor Deposition for Film Deposition, Figure 1 Schematic of a typical laboratory CVD equipment for the deposition of SiC coatings [1]

of recovering the reactants being not justifiable. Therefore, the usage of open system CVD processes is preferred, where, after the deposition process, the chemicals are removed from the system.

CVD Apparatus

There is no standard CVD system. Each system is individually tailored for a specific material and component. In general, a CVD apparatus consists of several basic components, for example as shown in Fig. 1.

Gas Delivery System

This component generates and supplies the vapor precursors that will be delivered to the reactor chamber. The delivery of precursors depends on the source temperature, carrier gas flow rate and pressure of the reaction chamber.

Reactor Chamber

The deposition takes place within this chamber. The design of this reactor depends on whether the starting material is solid, liquid or gas. The main function of the CVD reactor is to heat the substrate to deposition temperature. The reaction chamber wall can be either a hot wall or a cold wall.

Substrate Loading Mechanism

A system for introducing and removing substrates, mandrels, etc.

Energy Source

The energy source provides energy or heat required for precursors to react. For a hot-walled reactor system, heated furnaces are used for indirect heating of the substrate. The drawback of this mechanism is that the wall of the reactor chamber is also coated which lowers deposition efficiency and increases maintenance costs. For a cold-wall reactor system, only the substrate is heated, either inductively or resistively, and the wall of the chamber remains cold. Since most CVD processes are ►endothermic, the deposition process will occur on the heated substrate only and minimal deposition occurs on the cold chamber wall.

Vacuum System

This system is used to reduce the pressure in the reaction chamber for the CVD process that needs low pressure or high vacuum during deposition. A low-pressure CVD system requires a simpler vacuum system than that required in a PVD system.

Exhaust System

The main function of the exhaust system is to remove volatile byproducts from the reaction chamber.

Exhaust Treatment Systems

In some instances, exhaust gases may not be suitable for release into the atmosphere and may require treatment or conversion to safe/harmless compounds. Un-reacted precursors can be collected at the outlet and recycled.

Process Control Equipment

They include gauges and controlling units to monitor process parameters such as pressure, temperature and time. Alarms and safety devices would also be included in this category.

Chemical Precursors and Reaction Chemistry

Materials are deposited from gaseous state during CVD. Thus precursors for CVD processes must be volatile, but at the same time stable enough to be delivered to the reactor. Generally precursor compounds will only provide a single element to the deposited material, with others being volatilized during the CVD process. However, precursors may sometimes provide more than one element. Such materials simplify the delivery system, as they reduce the number of reactants required to produce a given compound.

When selecting a suitable precursor for coating applications, some characteristics should be considered as regards the precursor. It is necessary that the precursor [2]:

- is stable at room temperature;
- has suitable deposition rate;
- is safe to handle, has low toxicity, and is inflammable and not explosive;

- is cost effective for relatively low-cost deposition process;
- can generate vapor that is stable at low temperature;
- has low vaporization temperature and high saturation of vapor pressure.

Typical *Precursor Materials*

CVD *precursor materials* fall into a number of categories such as:

- Halides – $TiCl_4$, $TaCl_5$, WF_6
- Hydrides – SiH_4, GeH_4, $AlH_3(NMe_3)_2$, NH_3
- Metal organic compounds
- Metal alkyls – $AlMe_3$, $Ti(CH_2tBu)_4$
- Metal alkoxides – $Ti(OiPr)_4$, etc.
- Metal dialylamides – $Ti(NMe_2)_4$
- Metal diketonates – $Cu(acac)_2$
- Metal carbonyls – $Ni(CO)_4$
- Others which include a range of metal organic compounds, complexes and ligands.

Applications

CVD has applications across a wide range of industries such as [3, 4]:

- Coatings – for a variety of applications requiring specific properties including wear resistance, corrosion resistance, high-temperature protection, erosion protection and combinations thereof.
- Semiconductors and related devices – integrated circuits, sensors and optoelectronic devices.
- Dense structural parts – CVD can be used to produce components that are difficult or uneconomical to produce using conventional fabrication techniques. Dense parts produced via CVD are generally thin walled and maybe deposited onto a mandrel or former.
- Optical fibers – for telecommunications.
- Composites – preforms can be infiltrated using CVD techniques to produce ceramic matrix composites such as carbon–carbon, carbon–silicon carbide and silicon carbide–silicon carbide composites. This process is sometimes called chemical vapor infiltration or CVI.
- Surface modification for microchannels in microfluidic and nanofluidic devices.
- Powder production – production of novel powders and fibers.
- Catalysts.
- Micromachines and nanomachines.

Different CVD Methods

The conventional CVD method uses thermal energy to activate chemical reactions, which is commonly known as thermally activated CVD (TACVD). CVD reactions can be initiated by using different energy sources. Plasma and light energy are currently being used to activate the chemical reactions. Other types of CVD include atomic layer epitaxy, metalorganic CVD, flame-assisted CVD, and electrochemical vapor deposition. They are briefly discussed herewith [1, 5].

Thermally Activated CVD (TACVD)

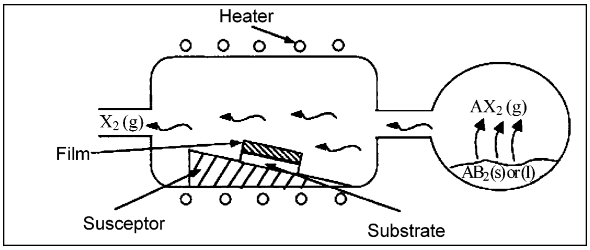
TACVD is a conventional CVD technique which uses thermal energy to activate chemical reactions in a hot-wall or a cold-wall reactor using chemical precursors. The heating energy is derived usually from RF heating, infrared radiation or resistive heating. The TACVD technique can be further classified according to the pressure range in which it operates, that is, atmospheric pressure CVD (APCVD), low-pressure CVD (LPCVD) and ultrahigh-vacuum CVD (UHVCVD). Basically the operation of different pressure CVDs is the same except that the different pressure ratings alter the rate-limiting steps during the deposition. Thermally activated CVD is used both for thin-film applications and also for coating applications.

Metalorganic CVD (MOCVD)

MOCVD is a method of ►epitaxial growth of materials, especially semiconductors from the surface reaction of organic compounds and metal hydrides containing the required chemical elements. For example, indium phosphide could be grown in a reactor on a substrate by introducing trimethylindium ($(CH_3)_3In$) and phosphine (PH_3). Alternative names for this process are organometallic vapor phase epitaxy (OMVPE), metalorganic chemical vapor deposition (MOCVD) and metalorganic vapor phase epitaxy (MOVPE). Formation of the *epitaxial* layer occurs by final pyrolysis of the constituent chemicals on the substrate surface. The MOCVD technique has been widely employed in the semiconductor industry for various thin-film growth processes, which is one of the most critical steps in high technical microfabrications.

Plasma-assisted CVD (PACVD)

PACVD is employed to deposit hard and colorful coatings at low temperatures. Active species are created when the vapors of organic and organometallic compounds are introduced in the plasma. These active species interact with the surface of the substrate, which results in the deposition of a coating. The properties of the coating can be tailored by varying process parameters like substrate temperature, power density, pressure, and diluting gas. Different colors are achieved by changing the composition



Chemical Vapor Deposition for Film Deposition, Figure 2 An illustration of a simple CVD process [1]

of metals and non-metals in the coating. Work has been initiated to develop hard coatings like Ti(O, C, N), TiO_2, Si(C, N), ZrO_2, etc. These coatings are being developed for various substrates like tools, optical components, artificial jewelry, high-temperature electronics, and automotive components.

Plasma-enhanced CVD (PECVD)

PECVD is a technique commonly used in microfabrication to deposit layers of insulating materials and amorphous or polycrystalline silicon. The plasma is used to help stimulate a reaction on the substrate surface of two or more species from the gas phase. The plasma helps break down the parent molecules and allows the reaction to occur at a lower temperature than conventional CVD. The major advantage of PECVD, in fact, is its capability of working at a lower temperature with respect to other conventional CVD systems. For example, while deposition temperatures of 700 – 900 °C are required for silicon deposition in CVD, a temperature range of 250 – 350 °C is sufficient in the PECVD systems.

Laser CVD (LCVD)

Laser-induced decomposition of a reactive gas is a well-known approach for depositing a material onto a surface. In this technique, a laser beam is directed through a vapor which contains a chemically reactive species. The energy of the laser beam activates the chemical reaction or decomposition of the reactive species, causing the formation of a reaction product. If the conditions are appropriate, the reaction product deposits upon the surface of interest. The deposition of coatings or layers by this approach is typically accomplished within a deposition chamber. The target surface is placed into the deposition chamber, which is partially evacuated prior to commencing the deposition. Partial evacuation is usually required because the reaction product is likely to recombine prior to deposition if the ambient pressure is too high.

Photochemical CVD (PCVD)

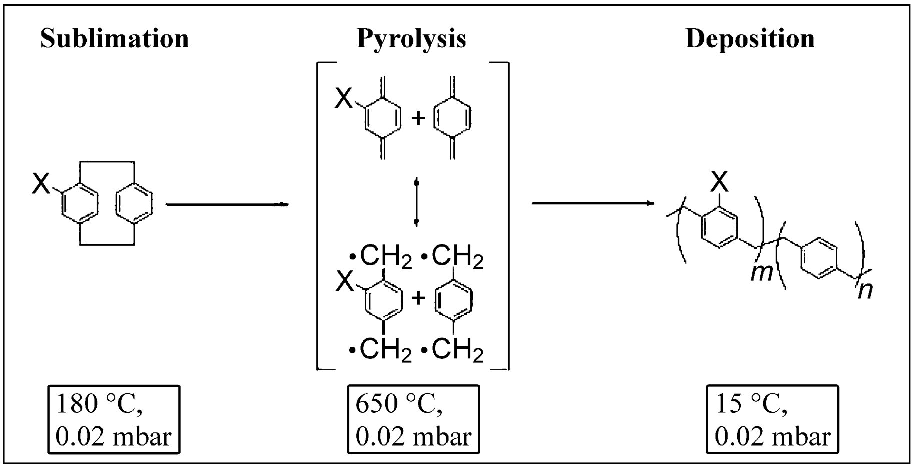
PCVD is a process wherein a source gas is in the vicinity of a substrate and is subjected to photolysis. Subsequently, the resulting active chemical species are deposited onto the substrate. It is an important low-temperature process as it does not cause damage to the substrate and does not induce unnecessary interdiffusion at the surface. The light source for the PCVD process can generally be either continuous light or discontinuous light (pulse beam). The former includes a low-pressure mercury lamp, a high-pressure mercury lamp, a deuterium lamp, a xenon lamp, an Ar ion laser and the like. These continuous light sources have a drawback that the deposition rate is very slow because a light of absorption range which induces excitation causing photolytic process inherent to the source gas is not emitted, or if the light of a wavelength existing in this absorption range is emitted, the power thereof is weak. The PCVD process is capable of forming films in a low-temperature process, which is never achieved in the other film forming processes, but there are problems to be solved, such as small deposition rate and poor film quality in the PCVD process using continuous light.

Chemical Beam Epitaxy (CBE)

CBE is a powerful growth technique which has come to prominence over the last ten years. Together with the longer established molecular beam epitaxy (MBE) and metalorganic vapor phase epitaxy (MOVPE), CBE provides a capability for the *epitaxial* growth of semiconductors and other advanced materials with control at the atomic limit. CBE is a hybrid form of molecular beam epitaxy where, instead of a solid source, a gas source is used. It is also called gas source molecular beam epitaxy. CBE uses room temperature gases as the source materials, thus avoiding significant contamination problems and the necessary higher substrate temperatures that can cause segregation of dopant atoms. The material is carried into a high-vacuum reaction chamber as a gaseous compound, typically as a hydride or a metalorganic.

Key Research Findings

Driven by major advances in microfluidic biosystems, such as the development of micro total analysis systems, microfabricated cell sorters, microseparators for DNA and proteins, and cell-based assays, the microfabrication of biologically meaningful microenvironments is within the scope of recent activities. Bioassays that exploit miniaturized formats are intrinsically advantageous (in part because of their small sample volumes and massively parallel processing), but they heavily rely on defined sur-



Chemical Vapor Deposition for Film Deposition, Figure 3 Chemical vapor deposition polymerization of reactive coatings, such as PPX-PPF [10]

face characteristics, such as wettability, surface topology, and interfacial charge distribution. Therefore, well-defined and stable surface properties along with the capability of immobilizing active biomolecules in the luminal surfaces of microfluidic devices are keys to their use as analytical tools. Often in the past, microfluidic devices have been made of silicon or glass, but these materials may not be the first choice for many special microfluidic applications, especially in biology or medicine. Several properties of silicon and glass could limit their use in microfluidic devices, including limited biocompatibility, intrinsic stiffness, unfavorable geometry, and incompatibility with soft materials needed, for example, for the incorporation of valves. The high surface-to-volume ratio in microfluidic devices implies that slight inhomogeneities in the surface can cause device malfunction. Polydimethylsiloxane (PDMS), a type of polymer, is often seen as an alternative because of its favorable mechanical properties and its straightforward manufacturing by rapid prototyping. However, PDMS is hydrophobic and allows nonspecific protein adhesion. The absence of functional groups at the PDMS surface prevents covalent immobilization of proteins, enzymes, or antibodies. PDMS also suffers from the lack of defined and constant surface properties under ambient conditions. Although surface modification of glass substrates via silane chemistry has been well established, simple but well-defined surface modification protocols for polymers, such as PDMS, are still being developed. The deposition of thin polymer films to establish chemically defined interfaces offers a unique way to overcome these limitations. Functionalized poly(*p*-xylylene)s are currently under investigation for protein attachment or for patterning of polymer brushes [6]. Thin film deposition is usually conducted by CVD polymerization, a room temperature process that requires no catalyst, solvent, or initiator. Recently, this approach was extended to the deposition of reactive coatings (Fig. 3) [7], that is, poly(*p*-xylylene carboxylic acid pentafluorophenolester-*co*-*p*-xylylene) (PPX-PPF) [8] and poly(*p*−xylylene-2,3-dicarboxylic acid anhydride) [9]. Without the need for further activation, the high chemical reactivity of their functional groups supported conversion with biological ligands or proteins and was used for surface patterning using microcontact printing.

Future Directions for Research

The CVD method is an important method for the deposition of highly pure thin-layer films for microfluidic and nanofluidic devices. The most common use of CVD techniques in microfluidic and nanofluidic devices is for surface modification. With the rapid development in microfluidic and nanofluidic research, the application of CVD will gain more momentum, especially in the process of surface modification.

Synonyms

Micro gas and liquid chromatography; μGC; Micro-LC

Definition

Chromatography is one of the most widely used molecular separation techniques. The separation occurs because the compounds within a complex mixture distribute between two phases differently: liquid and stationary phases in the case of liquid chromatography (LC) and gas and stationary phases in the case of gas chromatography (GC). Chromatographic chip devices aim to miniaturize chromatographic systems with the goal not only of size reduction, but also of improved function.

Overview

During a chromatographic separation process, different components of a mixture go through the system at different rates. Repeated sorption/desorption processes that take place during the movement of the sample over the stationary bed determine the rates at which the components are transported. The smaller the affinity a molecule has for the stationary phase, the shorter the time spent in a column. In principle, chromatography can purify basically any soluble or volatile substance if the right adsorbent material, carrier fluid and operating conditions are employed. Chromatography can accomplish separation, purification, detection and quantification of most molecules and is, thus, important for pharmaceutics, forensics and diagnostics.

The most common types of chromatography are:

- ►Gas chromatography
- ►High performance liquid chromatography (HPLC)
- Ion exchange chromatography
- Affinity chromatography

The initial theoretical work on open-tubular gas chromatography (Golay) and on packed-column liquid chromatography (van Deemter) was published as early as the 1950s. These papers led to the development of commercial gas chromatographs using capillaries with micrometer diameters, and liquid chromatographs with micrometer-scale particles for the stationary phase.

The development of chip-based GC systems has been motivated by the performance gains facilitated by miniaturization and integration and by the potential of creating portable and robust instruments for *in-the-field* and *on-site* chemical measurements.

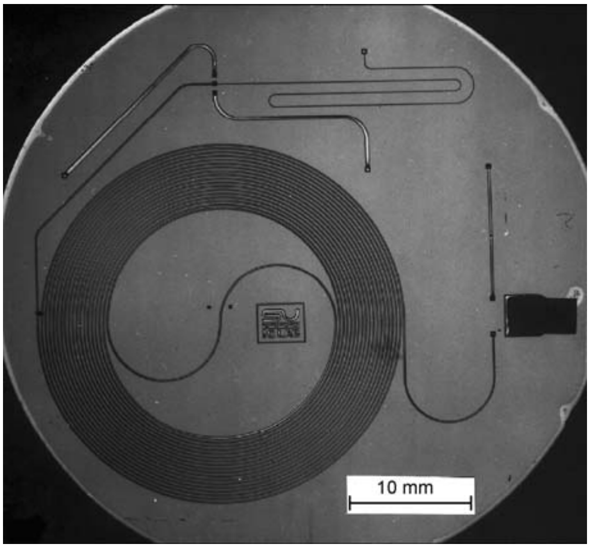
Basic Methodology

A typical high-performance liquid chromatography (HPLC) system consists of two pumps, a mixer, an injector, a guard column, a separation column, a detector, an electrospray nozzle and a mass spectrometer. The two pumps and the mixer allow establishment of desired solvent gradients. The injector is used to inject a small amount of sample into the column. In all separation techniques, definition of a small volume of injected sample is crucial in preventing adverse broadening of peaks and a consequent loss in component resolution. The injected compounds are separated in the separation column and then detected via a simple detector or a mass spectrometer. All of the parts of the HPLC system have been miniaturized and several research groups have been able to demonstrate on-chip HPLC separations.

Key Research Findings

Over the past several decades many macroscale separation techniques have been transferred to planar chip formats. The first microfabricated chromatography system was reported by Terry et al. [1] in 1979. Their micro-GC system consisted of a sample injection system, a 1.5 m column and a thermal conductivity detector.

The development of micro-chromatography systems has been motivated by the fact that as the system size is reduced, its performance is improved. The improvements that include reduction in analysis time and increase in separation efficiencies are a direct consequence of miniaturization as described in Janasek et al. (see Further Reading) and summarized here. The benefits of miniaturization can be demonstrated considering proportionalities within the system. We assume that miniaturization is a three-dimensional downscaling process characterized by a typical length parameter d. The separation system is a diffusion-related system in which hydrodynamic, heat and molecular diffusion behave exactly



Chromatographic Chip Devices, Figure 1 The first microchromatographic device developed by Terry et al. [1].

the same in the miniaturized as in the original system, while the time variables decrease by a factor of d^2. This means that as the tube diameter gets reduced by a factor of 10, the analysis time and the detector response time get reduced by a factor of 100. The pressure drop requirements increase by a factor of 100, while the voltage requirements (for electrophoresis or electro-osmosis) remain the same. Therefore a miniaturized system can achieve faster separations while maintaining comparable separation efficiency.

Examples of recent micro-chromatography systems are shown in Figs. 1–4.

Micro Gas Chromatography

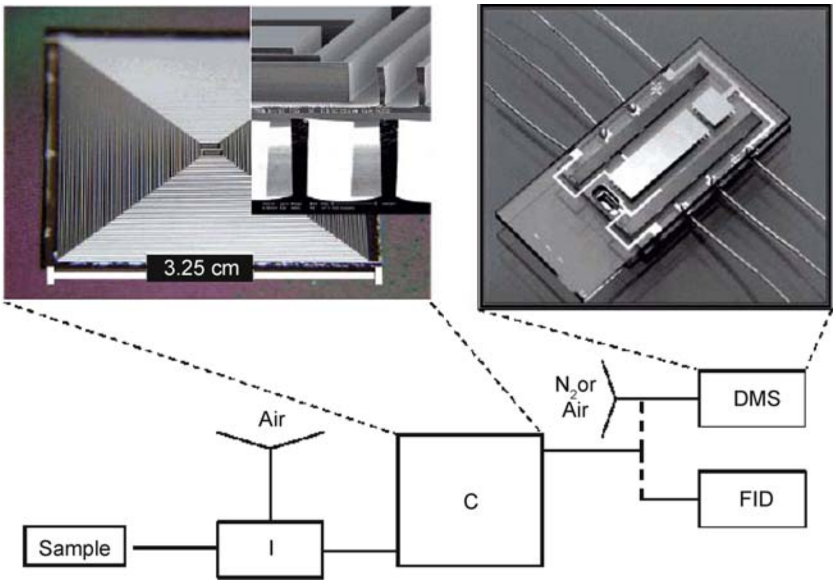
Sandia National Laboratories was one of the institutions that led the development by establishing the *Microanalytical Systems* program in 1997. The goal of the program was to develop highly portable micro total analysis systems for detection of chemical warfare agents and explosives. The *μChemlab* gas analysis system developed at Sandia consists of a microfabricated sample pre-concentrator, a chromatographic column and polymer-coated, surface acoustic wave (SAW) detectors. The sample pre-concentrator incorporates a thermally isolated (and sol–gel coated) membrane and resistive heater to effect rapid sample heating. Since, the membrane has a small thermal mass it can be heated to 200 °C within 10 ms, resulting in concentration enhancements of over two orders of magnitude and the creation of well-defined injection volumes. The entire, integrated system has been shown to successfully separate and detect a wide range of chemical species at parts-per-billion concentrations. Despite the problems associated with packing microfabricated chromatography columns, the Sandia group has also demonstrated the successful operation of packed, microfabricated GC columns.

Although successful operation of microfabricated GC systems has clearly been demonstrated, performance variability has been poor when compared to conventional GC technology. This is often associated with the ability to deposit or pack stationary phase materials in a homogeneous fashion, especially in the rectangular cross-sectional geometries of typical microfabricated channels.

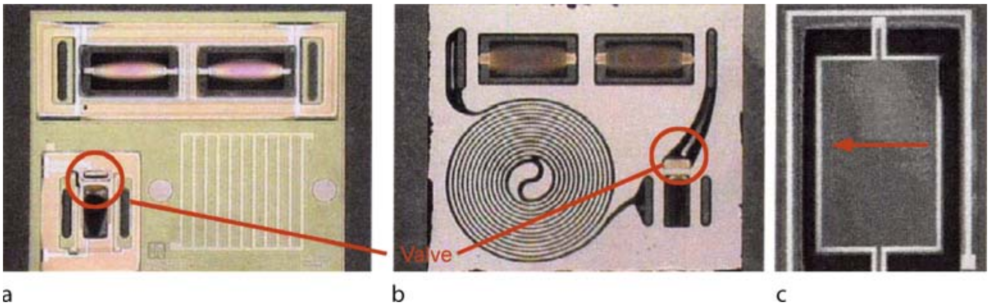
Injection of extremely small volumes of gaseous samples into microfabricated GC columns is also crucial for microscale separations. Usually this is accomplished by integration of valves on chips. Although successful, these methods increase the complexity of the fabrication process. Injection of samples by rapid thermal desorption or by introducing the sample through a plasma are some of the alternatives. Manz et al. proposed a novel method to inject gaseous samples onto microfabricated columns in which a sample is continuously introduced into a chromatographic column and passed through a plasma generator. If the plasma is then interrupted for a brief period, a short unmodified sample plug is introduced into the separation column and subsequently separated.

Micro Liquid-Phase Chromatography

One of the first chip-based LC structures was developed by A. Manz and colleagues as early as in 1990. The device incorporated a micromachined open-tubular separation column and an integrated platinum electrode detector. Although not all realized in that initial study, the potential advantages that miniaturization could achieve included superior efficiency per unit time when compared to conventional LC, facile positioning of detection cells and low unit cost. The more common approach to LC is through the use of columns packed with particles. The particles (which are normally porous) support the stationary phase, provide a large interfacial area for analyte partitioning and form a homogeneous medium for the transport of mobile phase. In conventional systems, this approach is generally more effective since in open-tubular methods ultra-small column widths are required to counteract the limited rates of mobile phase transfer. These small dimensions lead to reduced loading capacities and a propensity to blockages. Several microsystems that use microfabricated channels filled with conventional packed beads phase have been developed. Although packed columns may be desirable, the introduction of stationary-phase material into microfabricated channels is a non-trivial process. Frits must be fabricated within the channel structure to retain the packing, and a high-pressure interface between the chip and an external pump must be made. In addition, due to the reduced channel dimensions and the complexities of the manifold pattern, the packing process is difficult and can often lead to non-uniform particle densities at channel walls and thus reduced separation efficiencies. Consequently, several chromatographic methods within microfabricated columns also employ an open-tubular approach. The primary difficulties associated with packing microfabricated channels can be eliminated if the packed bed is replaced by a continuous, porous bed, sometimes also referred to as the *monolithic* phases. The advantages of this approach are that the polymerization of the porous bed is easy and that the continuous polymer bed is attached to the channels walls, making a retaining frit redundant. In recent years there has also been considerable development of stationary phases with controlled porosity and the ability to attach desired chemistry to the phase [5].



Chromatographic Chip Devices, Figure 2 Apparatus showing details of the microfabricated column (*upper left inset*) and the microfabricated DMS cell (*upper right inset*). A Varian 3400 GC is used as a platform. I, split inlet; FID, flame ionization detector; C, microfabricated column. The two detectors can be used alternately [2]



Chromatographic Chip Devices, Figure 3 Photographs of Sandia's Micro-Chem Lab system for gas chromatography integrated using surface micromachining with integrated fluidic technology (SwIFT) [3]

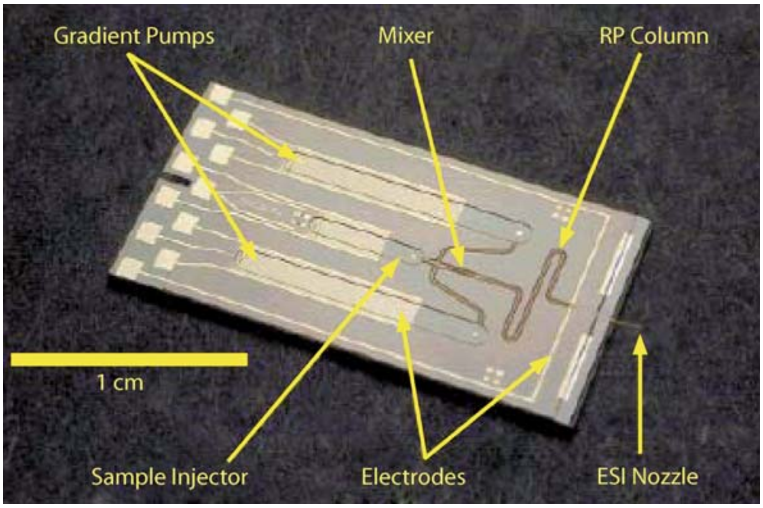
It is also worth noting that the use of electro-osmotic flow to pump the mobile phase during separation has been a major breakthrough, since it allows generation of high pressure in microfabricated channels.

Future Directions for Research

The transfer of macroscale chromatographic methods to chip-based formats, although advantageous, is not trivial and imaginative solutions to the problems of stationary phase introduction are required. It seems likely that future chromatographic chip systems will incorporate monolithic stationary phases due to the ease of their fabrication and localization within microchannels. Other nanoporous materials may also be of use.

Although several systems have been demonstrated, the big challenge in the development of micro-chromatography systems is still integration. The dead volume between different individual parts introduces a large amount of band broadening, which worsens the device performance.

As far as applications of on-chip chromatography go, we will most likely see developments geared towards two areas: miniature portable analysis systems and highly multiplexed systems. The benefits of miniaturization will enable the creation of detection and diagnostic instruments that are small and easy to use for point of care and military applications. Micro-chromatography devices will also enable development of systems of unprecedented complexity that will allow analysis of highly complex samples with compounds of interest in trace amounts. With



Chromatographic Chip Devices, Figure 4 Photograph of a microfluidic chip that integrates all the fluidic components of a gradient liquid chromatograph developed by Xie et al. [4]

such systems presymptomatic diagnosis of various diseases may become a reality.

Chromatography

Definition

General term defining a diverse group of techniques used to separate a sample mixture. The separation is based on differences in the relative affinities of the sample components for two different media, the mobile phase (a moving fluid) and the stationary phase (a porous solid or gel or a liquid coated on a solid support). The velocity at which each component is carried along with the mobile phase depends on its solubility and on its affinity for the stationary phase.

Closed-Loop

► Control of Micro-Fluidics

Closing Pressure

Definition

Closing pressure is the maximum pressure against which a valve or actuator can close completely.

Cold Light Sources

Definition

Cold light sources are used when strong illumination is needed, but drastic heat input into the object must be avoided, e. g. during microscopic observations. Usually a halogen lamp is installed with a concave mirror in the back and a system of lenses in the front. Unwanted IR and UV radiation are removed through glass filters. The lamp, all filters and lenses are fan cooled. The white light released from heat radiation is leaded through fiber optic cables to the object to be observed.

Colloidal Forces

► Disjoining Pressure

Color Cameras

Definition

In the main there are two kinds of technologies for digital color cameras, the CCD (Charged Coupled Devices) and the CMOS (Complementary Metal Oxide Semiconductor). While CCD cameras deliver images with a better quality and are more sensitive for low emittance, CMOS cameras are often used as high speed cameras. Today, common CMOS high speed cameras are able to record up to 32,000 images in a second.

Color Temperature

Definition

The color temperature is used to characterize the color of a light source. Its unit is Kelvin which is referred to the temperature a black body must have to emit light with the according color. It is directly related to the Planck's law of the black body radiation. Sun light for example has a color temperature of 5500 K. Light with a lower color temperature appears more red while light with a higher color temperature gets into blue.

Combinatorial Library

Definition

A collection of results of combinatorial chemistry tests.
The library is built by performing a number of parallel chemical reactions under nominally identical conditions, each of them differing in only one or a small number of variable parameters. The library may consist of the reaction products themselves, which makes them available for additional testing, or the library is virtual, consisting of only sets of numerical data. The data is needed in either case, because the are used as inputs into sometimes very sophisticated optimum seeking mathematical algorithms yielding as its result the optimum value of the variable parameter.

Combined Pressure-Driven Flow and Electroosmotic Flow

CHUN YANG, DEGUANG YAN
Nanyang Technological University, Singapore, Singapore
mcyang@ntu.edu.sg

Synonyms

Microchannel flow

Definition

Pressure-driven flow is bulk fluid motion resulting from either a globally applied difference (gradient) or an internally induced hydraulic pressure difference (gradient). Electroosmotic flow is the bulk liquid motion due to the interaction between an external electric field applied tangentially along a charged surface and the excess net charges in the electric double layer of such a charged surface. Specifically, the focus of this entry will be on the electroosmotic flow generated by an applied DC electric field only. In addition, the analysis of this entry is based on an assumption that the order of magnitude of the electroosmotic flow velocity is the same as that of the pressure-driven flow velocity. In the field of micro- and nanofluidics, the term *combined pressure-driven flow and electroosmotic flow* is referred to as the bulk liquid flow that is generated as a result of both pressure gradient and applied electric field.

Overview

The rapid development of microfluidics is mainly due to its promising applications as a well-controllable tool for studying fundamental physical and biochemical processes and a platform for performing chemical and biological assays. Advanced microfluidic devices can perform complete biochemical analyses in a single fabricated chip. The generic microfluidic systems involve buffer fluid and sample manipulations such as pumping, valving, mixing, injection, dispensing, etc. Fundamental understanding of the liquid flow characteristics in microchannels is thus essential for optimum design and precise control of microfluidic devices.

In general, liquid motion can be generated by either applying a pressure gradient or imposing an electric field, leading to, respectively, pressure-driven flow or electrokinetically driven flow. Traditionally, in large-sized channels flow is often driven by pressure that is usually generated by mechanical pumps. In microchannels however it becomes increasingly difficult to utilize the pressure-driven flow mode as the channel size shrinks, especially down to submicrometer range. Moreover, some systems like microvalves and micropumps with moving components are difficult to fabricate, and they are prone to mechanical failure due to fatigue and fabrication defects. Alternatively, electroosmotic flow enjoys numerous advantages (over pressure-driven flow), including ease of fabrication and control, no need for moving parts, high reliability, no noise, etc. Specifically, a plug-like velocity profile in electroosmotic flow can result in reduced dispersion of sample species, making capillary electrophoresis one of the most successful technologies for chemical and biomedical analyses.

The necessary condition for development of electroosmotic flow is the presence of electrostatic charges at the solid channel–liquid interface. The charging mechanisms of the solid–liquid interface are complex, possibly including the asymmetric dipoles of water molecules residing at the solid–liquid interface, adsorption of ions, disassociation of ionic groups, charge separation, etc. Such surface charges influence the distribution of nearby ions in the solution. Counter-ions (i. e. ions of opposite charge) are attracted towards the surface, while co-ions (i. e. ions of like charge) are repelled from the surface. This electrostatic interaction together with the random thermal motion of the ions leads to the formation of the so-called *electric double layer* (*EDL*). The model of the EDL was developed by Gouy and Chapman in 1906, and then improved by Stern in 1924 [1]. According to Stern's model, the EDL consists of a compact layer and a diffuse layer. The compact layer, usually less than 1 nm, exists immediately next to the solid surface, where counter-ions are strongly attracted to the solid surface thus immobile. The diffuse layer of the EDL is the layer from the compact layer to the bulk liquid, and its thickness ranges from several nanometers to micrometers, depending on liquid properties. Compared to the ions in the Stern layer, the ions in the diffuse layer are less influenced by the charged surface and hence are mobile. A review of modern EDL theory including recent descriptions and formulations of the basic structure (and component regions) of the EDL is given by Dukhin and Deryaguin [2].

Within the diffuse layer of the EDL, there is an excess of counter-ions over co-ions, and thus the net charge density is not zero so as to neutralize the surface charge. If an electric field is applied tangentially along a charged surface, the electric field will exert a Columbic force on the ions in the diffuse layer, resulting in a net migration of the liquid in the EDL region. This is called *electroosmosis* (*EO*). In a charged microcapillary, due to viscous forces the flow can be developed beyond the EDL region

to the rest of the liquid in the microcapillary, leading to a bulk *electroosmotic flow* (*EOF*). EOF is widely utilized in microfluidic devices to transport buffer solutions and to manipulate sample solutes. Examples include microfluidic pumping, flow control, mixing and reacting reagents, injecting or dispensing samples, capillary electrophoresis-based chemical separations, chromatography, etc. A recent review by Chang [3] demonstrates the viability of using electrokinetic flow in microfluidic platforms for miniature diagnostic kits.

Basic Methodology

Liquid Flow Field

Consider combined pressure-driven liquid flow and electroosmotic flow in a microfluidic channel. The liquid in the microchannel is assumed to be an incompressible, Newtonian, symmetric electrolyte with valence of $z_+ = -z_- = z$. Furthermore, if the Joule heating effect is negligible, the electrolyte is also assumed to have constant thermophysical and electrical properties including density, ρ, dynamic viscosity, μ, electrical conductivity, σ, and dielectric constant, ε_r. The channel wall is uniformly charged with a zeta potential, ζ. When an external DC electric field E is applied along the channel axial direction, the liquid starts to move due to electroosmosis that results from the interaction between the net charge density in the EDL of the channel and the applied electric field. The order of magnitude of the EOF velocity is assumed to be of the same order as that of the pressure-driven flow velocity. The governing equations for the combined pressure-driven flow and electroosmotic flow can be non-dimensionalized by using

$$\bar{\boldsymbol{r}} = \boldsymbol{r}/D_\mathrm{h} \qquad \bar{\boldsymbol{t}} = \boldsymbol{t}/\tau \qquad \bar{\boldsymbol{V}} = \boldsymbol{V}/U \tag{1a}$$

$$\bar{\boldsymbol{p}} = \boldsymbol{p}D_\mathrm{h}/(\mu U) \qquad \bar{\nabla} = D_\mathrm{h}\nabla \qquad \bar{\nabla}^2 = D_\mathrm{h}^2\nabla^2 \tag{1b}$$

where $\boldsymbol{r}$, $\boldsymbol{t}$, $\boldsymbol{V}$ and $\boldsymbol{p}$ are the position vector, time, local velocity vector and pressure, respectively. These quantities are normalized using D_h, τ, U and $\Pi = \mu U/D_\mathrm{h}$, which are the microchannel hydraulic diameter, characteristic time scale, characteristic flow velocity and characteristic pressure, respectively. Then we can write down the continuity equation

$$\bar{\nabla}\cdot\bar{\boldsymbol{V}} = 0 \tag{2}$$

and the Navier–Stokes equation

$$\mathrm{Re}\left(\frac{1}{\mathrm{St}}\frac{\partial\bar{\boldsymbol{V}}}{\partial\bar{\boldsymbol{t}}} + \bar{\boldsymbol{V}}\cdot\bar{\nabla}\bar{\boldsymbol{V}}\right) = -\bar{\nabla}\bar{\boldsymbol{p}} + \bar{F}_\mathrm{e} + \bar{\nabla}^2\bar{\boldsymbol{V}} \tag{3}$$

where $\mathrm{Re} = \rho U D_\mathrm{h}/\mu$ is the Reynolds number that characterizes the ratio of inertial force to viscous force, $\mathrm{St} = \tau U/D_\mathrm{h}$ is the Strouhal number that represents the ratio of characteristic process time, τ, to convective time, $\tau_\mathrm{c} = D_\mathrm{h}/U$ [4], and $\bar{F}_\mathrm{e} = D_\mathrm{h}^2\rho_\mathrm{e}E/\mu U$ is the dimensionless electrostatic body force due to the interaction between the net charge density in the EDL of the channel ρ_e and the applied electric field, E. Considering that usually the microchannel hydraulic diameter and the characteristic flow velocity respectively are of the order $D_\mathrm{h} = 10^2$ μm and $U = 1$ mm/s, we can estimate Re of the order of 10^{-1}, showing a low Reynolds number flow and thus a negligible inertial term, $\mathrm{Re}\bar{\boldsymbol{V}}\cdot\bar{\nabla}\bar{\boldsymbol{V}}$ in Eq. (3). Furthermore, for most microfluidic applications, the pumping time is of the order of $10^0 - 10^1$ s, the characteristic convective time scale is $\tau_\mathrm{c} = D_\mathrm{h}/U = 10^{-1}$ s, leading to the Strouhal number of the order of $\mathrm{St} = 10^1 - 10^2$. As a result, we can assume a pseudosteady flow by ignoring the transient term $(\mathrm{Re}/\mathrm{St})(\partial\bar{\boldsymbol{V}}/\partial\bar{t})$ [4]. Hence, Eq. (3) reduces to the Stokes equation expressed as

$$-\bar{\nabla}\bar{\boldsymbol{p}} + \bar{F}_\mathrm{e} + \bar{\nabla}^2\bar{\boldsymbol{V}} = 0 \tag{4}$$

Since the Stokes equation and its corresponding no-slip velocity boundary conditions are linear, we can treat the flow field as a linear superposition of two parts including the electroosmotic flow due to $\bar{F}_\mathrm{e}$ and the pressure-driven flow generated by $\bar{\nabla}\bar{p}$ resulting from either globally applied pressure or internally induced pressure (for instance due to geometry change of the microfluidic channel). Clearly, it is through the electrostatic body force $\bar{F}_\mathrm{e}$ that the Stokes equation is coupled with the governing equations for the net charge density in the EDL of channel, ρ_e, and for the externally applied electrical field, $E = -\nabla\phi$ (where ϕ is the local applied electrical potential).

Electric Double Layer Potential and Net Charge Density

According to the theory of electrostatics, the net charge density in the EDL of channel, ρ_e, is related to the EDL potential that is described by the Poisson equation, which in dimensionless form is expressed as [1]

$$\bar{\nabla}^2\bar{\psi} = -(D_\mathrm{h}\kappa)^2\bar{\rho}_\mathrm{e} \tag{5}$$

where the non-dimensional electric double layer potential is defined as $\bar{\psi} = ze\psi/(k_\mathrm{B}T)$. κ is the Debye–Hückel parameter defined as

$$\kappa = (2z^2e^2n_0/\varepsilon_r\varepsilon_0 k_\mathrm{B}T)^{1/2} \tag{6}$$

where k_b is the Boltzmann constant, T is the absolute temperature, ε_r is the dielectric constant of the fluid and ε_0 is the permittivity of vacuum. Physically, κ^{-1} represents the characteristic thickness of the EDL [1].

Therefore, the dimensionless net charge density is associated with the number concentration of N ions through

$$\bar{\rho}_e = \sum_{i=1}^{N} \frac{z_i}{z} \bar{n}_i \tag{7}$$

where the ionic concentration, n_i, and the net charge density, ρ_e, are normalized using the ionic number concentration in the bulk phase, n_0, and the quantity ezn_0, respectively.

Ionic Concentration Distributions

The Nernst–Planck Equation

Obviously, a full formulation of governing equations should also include the mass transfer equation for each type of ions in the system. The ionic concentration distribution, $n_i(r)$, is generally described by the Nernst–Planck equation. According to Dukhin and Deryaguin [2], the time scale related to electromigration within the EDL is characterized by $(\kappa^{-1})^2 / D_i$, which is of the order of $O(10^{-7} - 10^{-5})$ s, by assuming the reciprocal Debye–Hückel parameter, $\kappa^{-1} \approx 10 - 10^2$ nm (corresponding to an electrolyte of typical concentration $10^{-3} - 10^{-5}$ M) and the ion mass diffusion coefficient, $D_i = 10^{-9}$ m^2/s. This suggests a negligible transient effect of the EDL *relaxation*, i. e. $\partial n_i / \partial t = 0$, and thus the Nernst–Planck equation that governs the concentration of two most concentrated cations and anions in the buffer solution takes the convective-diffusion form as

$$\mathrm{Pe}_+ \bar{\nabla} \cdot (\bar{\boldsymbol{V}} \bar{n}_+) = \bar{\nabla}^2 \bar{n}_+ + \bar{\nabla} \cdot (\bar{n}_+ \bar{\nabla} \bar{\psi}) \tag{8a}$$

$$\mathrm{Pe}_- \bar{\nabla} \cdot (\bar{\boldsymbol{V}} \bar{n}_-) = \bar{\nabla}^2 \bar{n}_- - \bar{\nabla} \cdot (\bar{n}_- \bar{\nabla} \bar{\psi}) \tag{8b}$$

where $\mathrm{Pe}_i = U\kappa^{-1}/D_i$ is the Peclet number of type i ions. The gradient, ∇, and Laplacian operator, ∇^2, are scaled with respect to the reciprocal Debye–Hückel parameter, κ^{-1}.

The Boltzmann Distribution

Substituting typical values of $U = 1$ mm/s, $D_i = 10^{-9}$ m^2/s and $\kappa^{-1} = 10 - 10^2$ nm, we can estimate the Peclet number of order $\mathrm{Pe}_i = 10^{-2} - 10^{-1}$, indicating a negligible convection effect in Eq. (8b). Therefore, Eq. (8b) can be written as

$$\bar{\nabla}^2 \bar{n}_i = \bar{\nabla} \cdot \left(-\frac{z_i}{z} \bar{n}_i \bar{\nabla} \bar{\psi} \right) \tag{9}$$

We can readily solve Eq. (9), and obtain its solution, which is

$$\bar{n}_i = \exp\left(-\frac{z_i}{z} \bar{\psi} \right) \quad \text{or} \quad n_i = n_0 \exp\left(-\frac{z_i e \psi}{k_B T} \right) \tag{10}$$

This is the well-known Boltzmann distribution. In fact, Tang et al. [5] have performed a full numerical simulation, and their findings show that when the EDL is thin compared to the characteristic channel dimension, both the Nernst–Planck equation and the Boltzmann distribution predict identical ionic concentration distributions in the microchannel flow. Therefore, it can be concluded that from a microfluidic applications viewpoint, the Boltzmann distribution is adequate to describe the ionic concentration distributions in electrokinetic flow.

Externally Applied Electrical Potential

Since the electroosmotic flow is driven by an externally applied electric field, the applied electrical potential distribution needs to be formulated, and is governed by the conservation of charges equation, which is written as

$$\frac{\partial \rho_e}{\partial t} = -\nabla \cdot i \tag{11}$$

The electric current, i, is a result of the motion of all the ions in the electrolyte solution, and consists of three contributions, the convection current, i_{conv}, the diffusion current, i_{diff}, and the electromigration current, i_{cond} : $i = i_{conv} + i_{diff} + i_{cond}$. The expressions for each current are given by

$$\begin{aligned} i_{conv} &= \rho_e \boldsymbol{V} \\ i_{diff} &= -e \sum_{i}^{N} D_i z_i \nabla n_i \\ i_{cond} &= -\frac{e^2}{k_B T} \sum_{i}^{N} z_i^2 D_i n_i \nabla \phi = -\sigma \nabla \phi \end{aligned} \tag{12}$$

where $\boldsymbol{V}$ is the liquid velocity vector, $\sigma = -e^2 \sum_i^N z_i^2 D_i n_i / k_B T$ is the temperature-dependent electrical conductivity of the electrolyte solution and ϕ is the externally applied electrical potential.

In microfluidic systems where the EDL is thin compared to the characteristic microfluidic channel dimension, it can be approximated that the net charge density is zero and the ionic concentration is uniform throughout the channel domain. Furthermore, if the Joule heating effect is not concerned, we have $i_{conv} \approx 0$, $i_{diff} \approx 0$ and $\sigma \approx$ const. In addition, as discussed earlier the ion relaxation effect is

neglected, namely $\partial \rho_e / \partial t = 0$. Therefore, the conservation of charges equation reduces to

$$\nabla^2 \phi = 0 \tag{13}$$

which shows that the distribution of the externally applied electrical potential, ϕ, is governed by the Laplace equation. Thus, the local applied electrical field strength, E, can be calculated using

$$E = -\nabla \phi \tag{14}$$

Key Research Findings

General Model for Combined Pressure-Driven and Electroosmotic Flow

So far, all governing equations are presented. It can be seen that a closed mathematical model of the combined pressure-driven flow and electroosmotic flow in microfluidic channels should include the continuity equation, the Stokes equation, the Poisson equation, the Boltzmann distribution and the Laplace equation. A set of the governing equations for such combined pressure-driven flow and electroosmotic flow can be rewritten in dimensional form as

$$\nabla \cdot \boldsymbol{V} = 0 \tag{15}$$

$$-\nabla p - \rho_e \nabla \phi + \mu \nabla^2 \boldsymbol{V} = 0 \tag{16}$$

$$\nabla^2 \psi = -\kappa^2 \rho_e \tag{17}$$

$$\rho_e = \sum_{i=1}^{N} z_i n_i \tag{18}$$

$$n_i = n_0 \exp\left(-\frac{z_i e \psi}{k_B T}\right) \tag{19}$$

$$\nabla^2 \phi = 0 \tag{20}$$

The appropriate boundary conditions for solving these governing equations are specified as follows. The liquid velocity tangential and normal to all the channel walls must obey the no-slip and impermeable conditions. The EDL potential at the solid–liquid interface is specified as the zeta potential, which depends on channel material and electrolyte solution chemistry such as ionic strength, pH, etc. The externally applied electrical potential is generally specified by prescribed potentials imposed on inlet and outlet boundaries, and the electrical insulation condition is usually implemented to the channel walls. The prescribed global pressure values (if any) are provided on both inlet and outlet boundaries.

Obviously, in general no analytical solutions are available because of the complex governing equations, geometric domains and boundary conditions. A computational fluid dynamics (CFD) technique usually has to be applied in order to solve the governing equations together with the aforementioned boundary conditions. However, due to low Reynolds number flow, the Stokes equation is linear, and thus there is almost no challenge encountered when using numerical techniques to solve such kinds of single-phase flow problems. A more detailed discussion of numerical simulation of electroosmotic flow in microchannel geometries can be found elsewhere [6].

Simplified Model for Combined Pressure-Driven and Electroosmotic Flow

In microfluidic systems, due to the very thin EDL compared to the microchannel dimension, the electroosmotic velocity distribution and EDL potential profile inside the EDL region become insignificant. Thus we do not need to solve the Poisson equation together with the Boltzmann distribution. Instead the electroosmotic flow velocity at the edge of the EDL (i. e. from the diffuse layer to the bulk phase) is given by the Smoluchowski equation [1], expressed as

$$\boldsymbol{V}_{eo} = -\frac{\varepsilon_0 \varepsilon_r \zeta E}{\mu} \tag{21}$$

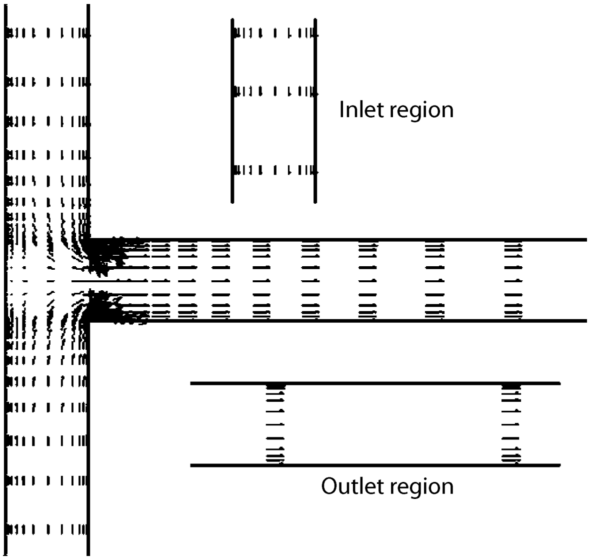
where ζ is the zeta potential of channel wall. As a result, when modeling two and three dimensional flow in microfluidic systems, it is usual practice to apply the Smoluchowski velocity to the tangential direction of the channel wall such that the EOF field can be considered as flow induced by a moving wall with such velocity. Since electrically neutral condition is assured outside the EDL region, namely the net charge density $\rho_e = 0$, the Columbic body force term in equation (16) becomes zero, and thus we can obtain a simplified model for the combined pressure-driven flow and electroosmotic flow. Such a model only involves the continuity equation and the simplified Stokes equation (i. e. without the presence of the Columbic body force):

$$\nabla \cdot \boldsymbol{V} = 0 \tag{22}$$

$$-\nabla p + \mu \nabla^2 \boldsymbol{V} = 0 \tag{23}$$

All the boundary conditions are the same as those described earlier except the no-slip condition is replaced by assigning the Smoluchowski velocity as a velocity tangential to the channel walls.

In the literature, this approximation, referred to as the slip velocity approach, in fact can provide a good estimation of the flow field in microfluidic geometries. Using the simplified model with the slip velocity boundary conditions, two case studies are considered. Case I considers electroosmotic flow in a T-shaped microgeometry of uniform zeta potential. The simulation results of the velocity field in vector form are shown in Fig. 1. It can be seen from Fig. 1 that the presence of the T-junction causes the flow to become two dimensional while inducing a local pressure gradient. As a result, the velocity field in the neighborhood of the T-junction exhibits a combined pressure-driven and electroosmosis-driven flow. However, the flow in the inlet and outlet regions still exhibits the usual *plug-like* EOF velocity pattern. In case II, EOF in a suddenly changed microchannel with height $2H_1$ and $2H_2$, and length L_1 and L_2 as shown in Fig. 2 is considered. Due to symmetry, only a half channel domain is computed. Specifically, the two channel walls are assumed to have different zeta potential values. Figure 3a presents the velocity vector of electroosmotic flow and Fig. 3b the streamtrace of electroosmotic flow in the microchannel shown in Fig. 2. It can be noted that the profiles of the EOF velocity deviate from the normal *plug-like* EOF shape due to internal pressure gradient induced by a sudden change in cross-section and zeta potential. Moreover, Fig. 3 also shows that the complex secondary flow near the step region is generated.

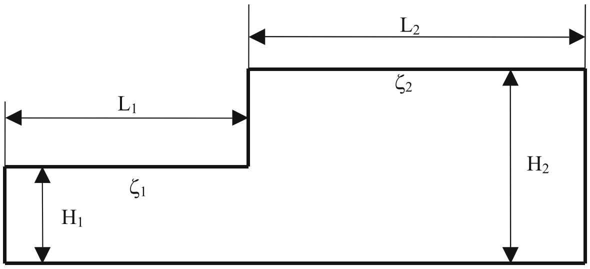


Combined Pressure-Driven Flow and Electroosmotic Flow, Figure 1 Simulation results of the velocity vector of EOF in a T-shaped microgeometry of uniform zeta potential. The parameters used in computation are: cross-section dimensions of the microchannels 100 μm × 100 μm; concentration of $NaHCO_3$ electrolyte 1 mM; zeta potential 70 mV; applied electric field strength 120 V/cm

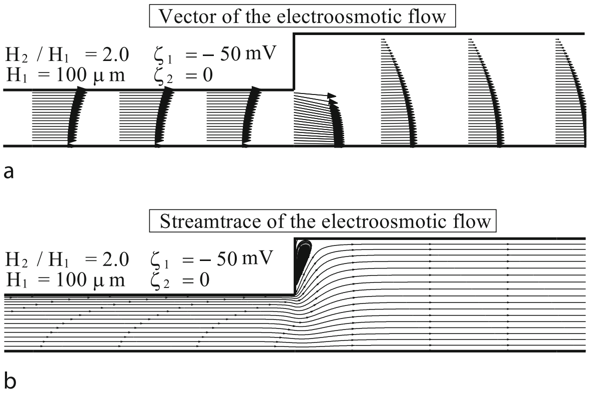
Further Simplification for Combined Pressure-Driven and Electroosmotic Flow in Straight Microchannels

As a straight microchannel constitutes the basic segment in microfluidic structures, several examples of the combined pressure-driven and electroosmosis-driven flow in straight microchannels are demonstrated in this entry. Usually a microchannel length dimension is much larger than its lateral dimensions, and the flow in such a channel can be considered as unidirectional; this implies that the flow can be modeled as a fully developed flow, namely $\partial u/\partial x = 0$, $v = 0$ and $w = 0$ in terms of Cartesian coordinates. Furthermore, the following analyses are restricted to microchannels of a rectangular cross-section, $2w \times 2h$ (width by height), which is close to the real shape of microchannels made using the microfabrication technologies. With these considerations, the model, based on the slip velocity approach, describing the velocity field of such flow can be further simplified to

$$\frac{\partial^2 u}{\partial x^2} + \frac{\partial^2 u}{\partial y^2} = \frac{1}{\mu}\frac{\mathrm{d}p}{\mathrm{d}z} \tag{24}$$



Combined Pressure-Driven Flow and Electroosmotic Flow, Figure 2 Schematic of a microchannel with sudden change in cross-section and zeta potential



Combined Pressure-Driven Flow and Electroosmotic Flow, Figure 3 Simulation results of the velocity vector and streamline of EOF in the microchannel shown in Fig. 2

Because of linearity, the resultant velocity field is a linear superposition of the EOF velocity and the pressure-driven flow velocity, and is given by

$$u(x, y) = u_{\mathrm{eo}} \pm u_{\mathrm{p}}(x, y) \tag{25}$$

Here the choice of sign depends on the relative direction of the EOF and the pressure-driven flow. The EOF velocity is specified by the Smoluchowski velocity as

$$u_{\mathrm{eo}} = \frac{\varepsilon_0 \varepsilon_{\mathrm{r}} \zeta E_z}{\mu} \tag{26}$$

The pressure-driven flow velocity profile is described by the well-known Poiseuille flow which in a rectangular channel is expressed as

$$u_{\mathrm{p}}(x, y) = -\frac{h^2}{2\mu}\frac{\mathrm{d}p}{\mathrm{d}z} \times \left[1 - \left(\frac{y}{h}\right)^2 + 4\sum_{k=1}^{\infty}\frac{(-1)^k}{\alpha_k^3}\frac{\cosh\left(\frac{\alpha_k x}{h}\right)}{\cosh\left(\frac{\alpha_k w}{h}\right)}\cos\left(\frac{\alpha_k y}{h}\right)\right] \tag{27}$$

where $\alpha_k = (2k-1)\frac{\pi}{2}$ (here $k = 1, 2, \ldots$).
Recently, Xuan and Li [7] formulated a comprehensive model to describe AC or DC field-driven EOF in a straight channel with arbitrary cross-sectional shape.

Liquid Flow in a Straight Microchannel under Applied Pressure and Electrical Potential Difference

In this case, the global pressure values are specified, and we have $\mathrm{d}p/\mathrm{d}z = -\Delta p/l$ (where Δp is the pressure difference between inlet and outlet of the channel and l is the channel length along the flow direction). Therefore, if both the electric field and the pressure difference are imposed along the same direction, the velocity distribution can be obtained as

$$u(x, y) = \frac{\varepsilon_0 \varepsilon_{\mathrm{r}} \zeta E}{\mu} + \frac{h^2}{2\mu}\frac{\Delta p}{l} \times \left[1 - \left(\frac{y}{h}\right)^2 + 4\sum_{k=1}^{\infty}\frac{(-1)^k}{\alpha_k^3}\frac{\cosh\left(\frac{\alpha_k x}{h}\right)}{\cosh\left(\frac{\alpha_k w}{h}\right)}\cos\left(\frac{\alpha_k y}{h}\right)\right] \tag{28}$$

Electroosmotic Flow in a Straight Microchannel with two Closed Ends

Due to the closed-end structure, an inner backpressure gradient $\mathrm{d}p/\mathrm{d}z$ is induced to fulfill the condition of the zero net flow rates, which mathematically is expressed as

$$\int_0^{2w}\int_0^{2h} u(x, y)\mathrm{d}x\mathrm{d}y = 0 \tag{29}$$

Substituting Eqs. (25–27) into Eq. (29) yields

$$\frac{\mathrm{d}p}{\mathrm{d}z} = \frac{3\mu}{h^2}\frac{u_{\mathrm{eo}}}{\left[1 - \frac{6h}{w}\sum_{k=1}^{\infty}\frac{1}{\alpha_k^5}\tanh\left(\frac{\alpha_k w}{h}\right)\right]} \tag{30}$$

Therefore, we can obtain the electroosmotic velocity distribution in a closed-end rectangular microchannel:

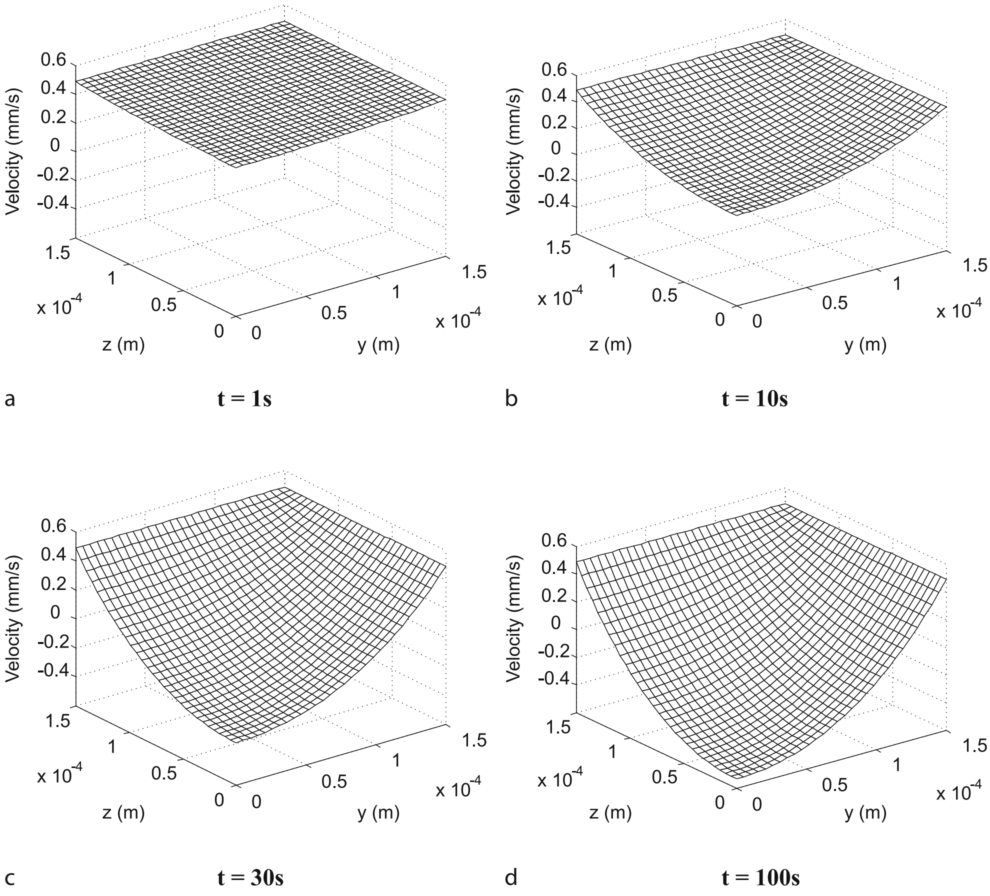
$$u(x, y) = \frac{\varepsilon_0 \varepsilon_{\mathrm{r}} \zeta E_z}{\mu}\left[1 - \frac{3/2}{\left[1 - \frac{6h}{w}\sum_{k=1}^{\infty}\frac{1}{\alpha_k^5}\tanh\left(\frac{\alpha_k w}{h}\right)\right]}\right] \times \left[1 - \left(\frac{y}{h}\right)^2 + 4\sum_{k=1}^{\infty}\frac{(-1)^k}{\alpha_k^3}\frac{\cosh\left(\frac{\alpha_k x}{h}\right)}{\cosh\left(\frac{\alpha_k w}{h}\right)}\cos\left(\frac{\alpha_k y}{h}\right)\right] \tag{31}$$

Such a velocity distribution given by Eq. (31) was verified experimentally by Yan et al. [8] in which a method is proposed to simultaneously determine the zeta potentials of the channel surface and the tracer particles in aqueous solutions. This is achieved by carrying out microscale particle image velocimetry (micro-PIV) measurements of the electrokinetic velocity distributions of tracer particles in both open- and closed-end microchannels under the same water chemistry condition.

Electroosmotic Flow in a Straight Microchannel with Finite Reservoir Size Effect

In electrokinetically driven microfluidic applications, reservoirs are indispensable and have finite sizes. During operating processes, as the liquid level in reservoirs keeps changing as time elapses, a backpressure is generated. Thus, the flow in microfluidic channels actually exhibits a combination of the steady EOF and the time-dependent induced backpressure-driven flow. Yan et al. [9] developed a model to describe the effect of the finite reservoir size on EOF in a rectangular microchannel in connect with two identical cylindrical reservoirs of radius R. It can be shown that the induced backpressure gradient along the channel can be expressed as (see [9] for details)

$$\frac{\Delta p(t)}{l} = -\frac{\varepsilon_0 \varepsilon_{\mathrm{r}} \zeta E_z}{\mu}\frac{8\rho g w h}{\pi R^2 l}\left[1 - \exp(-Ct)\right] \tag{32}$$



Combined Pressure-Driven Flow and Electroosmotic Flow, Figure 4 Simulation results of the time evolution of EOF velocity distributions due to finite reservoir size effects: (**a**) t = 1 s, (**b**) t = 10 s, (**c**) t = 30 s and (**d**) t = 100 s. The parameters used in computation are: cross-section dimensions of the microchannels 300 μm × 300 μm; channel length l = 4 cm; zeta potential 62 mV; applied electric field strength 100 V/cm; reservoir radii $R_1 = R_2$ = 1 mm

where

$$C = \frac{8wh^3\rho g}{3\pi\mu R^2 l}\left[1 - \frac{6h}{w}\sum_{k=1}^{\infty}\frac{1}{\alpha_k^5}\tanh\left(\frac{\alpha_k w}{h}\right)\right]$$

Therefore, the velocity distribution of EOF in a straight rectangular microchannel with finite reservoir size effect is expressed as

$$u(x, y, t) = \frac{\varepsilon_0\varepsilon_r\zeta E}{\mu}\left[1 - \frac{4\rho g w h^3}{\pi\mu C R^2 l}\left(1 - \exp(-Ct)\right)\right] \times \left[1 - \left(\frac{y}{h}\right)^2 + 4\sum_{k=1}^{\infty}\frac{(-1)^k}{\alpha_k^3}\frac{\cosh\left(\frac{\alpha_k x}{h}\right)}{\cosh\left(\frac{\alpha_k w}{h}\right)}\cos\left(\frac{\alpha_k y}{h}\right)\right] \tag{33}$$

It should be pointed out here that the velocity given by Eq. (33) now becomes time dependent because of the change of the liquid level in the two reservoirs. The evolution of the velocity distribution with time is simulated using Eq. (33), and the simulation results are shown in Fig. 4. It is noted in Fig. 4a that the velocity field keeps the *plug flow* during the period of EOF effective pumping. Afterwards the fluid velocity profile starts changing its shape due to the induced backpressure resulting from the difference of fluid level in the two reservoirs (see Fig. 4b). As time elapses, the induced backpressure-driven flow becomes stronger by showing a parabolic velocity distribution in Fig. 4c. In Fig. 4d, it is observed that the flow velocity field finally reaches a stage that the total volumetric flow rate is zero due to a counterbalance between the EOF velocity upward in the near wall region and the induced backpressure-driven flow downward in the central region of the channel.

In addition, a new concept termed *effective pumping period* is introduced to characterize the reservoir size

effect, and an analytical expression for such effective pumping time is given by

$$\Delta t_{\mathrm{eff}} \approx \frac{0.05}{C} \tag{34}$$

This time scale, Δt_{eff}, usually is of the order of about $O(10-10^2)$ s depending on channel and reservoir sizes, and is much larger than that of start-up EOF which is of the order of $O(D_{\mathrm{h}}^2\rho/\mu) \sim O(10^{-3})$ s. The proposed model was verified experimentally using the micro-PIV technique [9].

Electroosmotic Flow in a Straight Microchannel with a Step Change in Zeta Potential

Consider EOF in a straight microchannel consisting of two parts, segment I and segment II, with different lengths l_1 and l_2, respectively. Two segment are made from different material, and thus are uniformly charged with zeta potentials ζ_1 and ζ_2, respectively. As a result, the flow rates of pure EOF in the two segments are different. Since the liquid fluid is incompressible, the real flow rate going through segment I should be equal to that through segment II. Hence, the unbalance of the electroosmotic flow rate will induce a positive pressure gradient, $-(\mathrm{d}p/\mathrm{d}z)_1 > 0$, in segment I and a negative pressure gradient, $-(\mathrm{d}p/\mathrm{d}z)_2 < 0$, in segment II if $\zeta_1 < \zeta_2$, and vise versa. Mathematically, the equal flow rate condition reads

$$\int_0^{2w}\int_0^{2h} u_1\,(x,y)\mathrm{d}x\mathrm{d}y = \int_0^{2w}\int_0^{2h} u_2\,(x,y)\mathrm{d}x\mathrm{d}y \tag{35}$$

where the velocity profile in each segment is expressed as

$$u_i\,(x,y) = \frac{\varepsilon_0\varepsilon_{\mathrm{r}}\zeta_i E_z}{\mu} - \frac{h^2}{2\mu}\left(\frac{\mathrm{d}p}{\mathrm{d}z}\right)_i \times \left[1-\left(\frac{y}{h}\right)^2 + 4\sum_{k=1}^{\infty}\frac{(-1)^k}{\alpha_k^3}\frac{\cosh\left(\frac{\alpha_k x}{h}\right)}{\cosh\left(\frac{\alpha_k w}{h}\right)}\cos\left(\frac{\alpha_k y}{h}\right)\right] \quad (i = 1 \text{ or } 2) \tag{36}$$

Furthermore, since there is no applied pressure gradient across the entire length of the channel, the induced pressure should also fulfill the following relationship:

$$\left(\frac{\mathrm{d}p}{\mathrm{d}z}\right)_1 l_1 + \left(\frac{\mathrm{d}p}{\mathrm{d}z}\right)_2 l_2 = 0 \tag{37}$$

Therefore, the two induced pressure gradients in each segment can be determined by simultaneously solving Eqs. (35) and (37). The final velocity profile in each segment can be obtained by substituting the induced pressure gradient into Eq. (36). Using the caged-fluorescence technique, Herr et al. [10] carried out experiments, and found that such a velocity pattern is in agreement with their measured results.

Future Directions for Research

Fundamental understanding of the liquid flow characteristics in microfluidic geometries is the key to achieving optimum design and precise control of microfluidic devices used for chemical analyses and biomedical diagnoses. Based on the continuity mechanics approach, the theoretical framework of pressure-driven flow and electroosmotic flow in microfluidic channels has been well established. It is the author's opinion that the challenges we are now facing are multi-physics and multi-scale modeling and characterization. For example, the theoretical model presented in this entry assumes negligible Joule heating effect. However, when the applied electrical field is large and the buffer concentration is high, the Joule heating becomes significant. The presence of such Joule heat will cause a temperature rise, leading to a change of the electrical and thermophysical properties such as electrical conductivity, dielectric constant, zeta potential, viscosity, etc. The interplay or coupling among electrical, hydrodynamic and thermal phenomena will alter the flow characteristics, which will affect the pumping of buffer solution and manipulation of sample species.

The fast development of nanotechnology will lead to the emergence of nanofluidic technology. It is expected that the transport of ions and macromolecules and the control of liquid in nanofluidic channels and structures will still likely involve the use of an electrical field. This will open a completely new territory for nanofluidics-based electrokinetic phenomena which will be the main focus of the next decade of research.

Compactness

► Viscosity

Compact Support

Definition

A function is said to have compact support if its value vanishes outside a certain distance. In other words, the function is non-zero only within a certain region. In the finite element method, compact support ensures that the solution inside an element depends only on its nodal points. In meshless methods, the notion of compact support ensures that the number of neighbouring nodes or particles affecting the solution at a certain point is finite.

Computational region

Definition

The computational domain refers to a simplified form of the physical domain both in terms of geometrical representation and boundary condition imposition. This simplified form should retain all physically important features of the problem but can ignore minor details. For example, when simulating fluid flow about a car, one can ignore gaps between doors while the actual boundary of the fluid flow domain may be replaced by a simple box-like boundary.

Diffusion-based mixing

Definition

The concentration gradient of a solute is the change of concentration per unit distance in a solution. A concentration gradient is generated by diffusion between two regions where the concentration of a substance differs; diffusion proceeds until the concentrations in the two regions become equal.

Overview

Concentration gradients of diffusible molecules play an important role in many biological and chemical processes, such as chemotaxis, nerve growth cone guidance, surface patterning, and microfabrication. Traditional approaches (e. g., the Boyden chamber [1], micropipettes [2], generation under agarose [3], and derivatives of these approaches [4, 5]) are mainly used to release factors and investigate cell behavior subject to a concentration gradient. Although instrumental in furthering many biological studies, none of these methods are effective for generating stable gradients of complex shape, owing to the unbalanced flux of soluble factor into and from the region of interest. An alternative approach to generating and maintaining predictable and stable concentration gradients with control over the shape of the profile is needed for a number of applications in biology and chemistry. Recently, microfluidic microchannel networks have been extensively utilized for concentration-related analysis since they allow accurate and reproducible manipulation of the locations and quantities of samples released into the system. A "Christmas tree"-like microfluidic network for generating concentration gradients of complex shape (e. g., linear, parabolic, and periodic) along the width of a channel has been proposed by Jeon et al. [6] and Dertinger et al. [7]. Sample solutions with different concentrations were supplied at multiple inlets, and then mixed, split, and recombined in branch channels, which eventually converged to the main channel to yield a complex transverse profile (i. e., across the channel width). This device was later improved by integration of a simple *mixer module* with the gradient-generating network to enable on-chip dilution of initial samples and obtain dynamically controlled temporal and spatial gradients [8]. In spite of the many advantages of this "Christmas tree"-like gradient generator, the device has several drawbacks.

- The device can only generate gradients under fluid flow, which induces shear and drag forces that may alter intracellular signaling or cause changes in cell shape and attachment that may lead to migrational bias.
- The gradient evolves as the fluid flows downstream, such that the cells in the microchannel do not all experience the same concentration gradient.
- Under typical experimental flow rates, any autocrine/paracrine factors that are secreted by the cells will be washed away.

To compensate for these weakness, free-diffusion-based gradient generators have been developed. These devices have improved on conventional assays such as those done with a Boyden chamber or micropipette. This free-diffusion-based approach is less amenable to flexible manipulation of the gradients compared with the continuous-flow mixing approach, but generates gradients with no external control, allowing easier design of high-throughput experimental apparatus. The ladder chamber, as the name implies, consists of two main channels connected by several bridge microchannels. The purpose behind this design is to establish gradients in the bridge channels by allowing diffusion of molecules between the two main streams. The molecules diffuse across the microchannels and this results in the establishment of a linear gradient in the steady state [9]. If on-chip valves are incorporated into the device, the temporal delivery of the gradient can be flexibly regulated, allowing 2D or 3D gradients to be generated [10]. Flow-free gradients do not induce shear stress, and thus minimize mechanical disturbance to cells. Because of these advantages, these devices form a unique class of microfluidic gradient generator, and have been applied to studies of cell migration, drug delivery, and intracellular responses. When valves and micro/nanofabricated apertures are used to control the release of chemicals on-chip, a local chemical gradient near the source can be generated and controlled. This approach allows precise manipulation of local stimulation.

Two methods to generate concentration gradients in microfluidic devices, one based on laminar flow, and the other on free diffusion, will be summarized below.

Basic Methodology

Flow-Based Concentration Gradient Generation

A simple method for generating gradients is to continuously infuse two or more streams of different species into a simple microfluidic channel. Diffusion between the streams generates a gradient across the channel, perpendicular to the flow direction, having a diffusive profile that is stable at any fixed position in the channel but evolves along the channel. The upstream gradient has a step-like profile with a clear concentration interface, while the downstream gradient has a more continuous profile, resulting from diffusion. The process of mixing of laminar streams in microfluidic channels is governed by a diffusion model and has been well characterized by theory and experiments. On the basis of the well-characterized mixing process of continuous-flow streams in simple microfluidic channels, concentration gradients can be manipulated more flexibly by use of microfluidic networks.

Figure 1a shows the schematic design of a representative gradient-generating microfluidic network. This network consists of three inlets and one outlet. Each inlet is connected to syringes which contain solutions of chemicals of different concentration. When they are simultaneously infused into the microfluidic device, the three solutions are split, mixed, and recombined, resulting in different proportions of the solutions in each branch. Finally, the solutions in each branch are brought together into a single channel, establishing a gradient perpendicular to the flow direction.

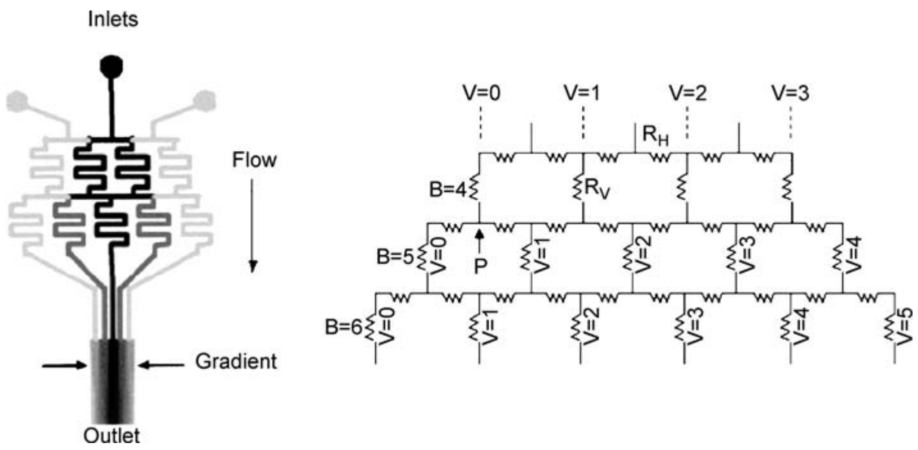
The concentration gradient profile depends on the splitting ratio of the flow at each branch point. An electronic-circuit model was introduced to understand the splitting ratio in a pyramidal microfluidic network. As shown in Fig. 1b, the part of the network containing n vertical channels is defined as an nth-order branched system ($B = n$), and each vertical channel (V) is labeled from left to right by $V = i$, where i is an integer between 0 and $B - 1$. As the horizontal channels are shorter (by ~ 20 times) than the vertical ones, the resistance of the horizontal channels (R_H) is negligible compared with the resistance of the vertical ones (R_V). The flow rates are $[B - V]/[B + 1]$ and $[V + 1]/[B + 1]$ to the left and right, respectively. For instance, at the point P in Fig. 1b ($B = 4, V = 0$), the relative volumetric flows to the left and right are $4/5$ and $1/5$, respectively. This splitting characteristic determines the shape of the concentration gradient in the single channel where all branches join together.

To guarantee a spatially equilibrated concentration in each channel as a result of diffusive mixing between laminar streams, the two flows must spend a sufficiently long time in the serpentine channel that equilibrium is reached. An analytical solution for the concentration at any time in one dimension can give the approximate time required to reach the equilibrium state:

$$C(t,x) = \frac{1}{2}C_0 \sum_{n=-\infty}^{\infty} \left\{ \operatorname{erf}\frac{h + 2nl - x}{2\sqrt{Dt}} + \operatorname{erf}\frac{h - 2nl + x}{2\sqrt{Dt}} \right\} \tag{1}$$

where $C(t,x)$ is the concentration at point x and time t, C_0 is the initial concentration in the channel, h is the width of the initial distribution, l is the width of the channel, and D is the diffusion coefficient. The percentage mixing across a channel of width l at time t is defined as

$$\%\,\text{mixing}\,(t) = \left(1 - \frac{\int_0^l |C(t) - C(\infty)|\,\mathrm{d}x}{\int_0^l |C(0) - C(\infty)|\,\mathrm{d}x}\right) \times 100\% \tag{2}$$



Concentration Gradient Generation and Control, Figure 1 (**a**) Schematic design of a representative gradient-generating microfluidic network. (**b**) Equivalent electronic-circuit model of a pyramidal microfluidic network

where $C(t)$, $C(\infty)$, and $C(0)$ are the concentrations across the width of the channel at times t, ∞, and 0, respectively.

Shape of Concentration Gradient

The shape of the concentration gradient created at the junction in the broad channel is governed by the splitting ratios of the streams at the individual nodes in the pyramidal network and depends on the number of inlets in the network and the relative concentrations of the solutions that are fed into the network. In general, the larger the number of inlets, the broader the range of accessible shapes. The number of outputs determines the number of steps that compose a profile. The width of the broad channel defines the overall width of the profile. Changing the number of outputs does not affect the overall shape of the profile.

Owing to the varying splitting ratios at the branching points in the network, streams injected from different inlets are mixed in different ways with neighboring streams while flowing through the network. As a result, different concentration gradients are generated. In general, all accessible concentration profiles that can be generated using an n-input network can be expressed as a linear combination of the profiles generated by using the individual inputs. All calculated concentration profiles generated by a microfluidic device with n inlets lie on a curve described by a polynomial of order $n-1$.

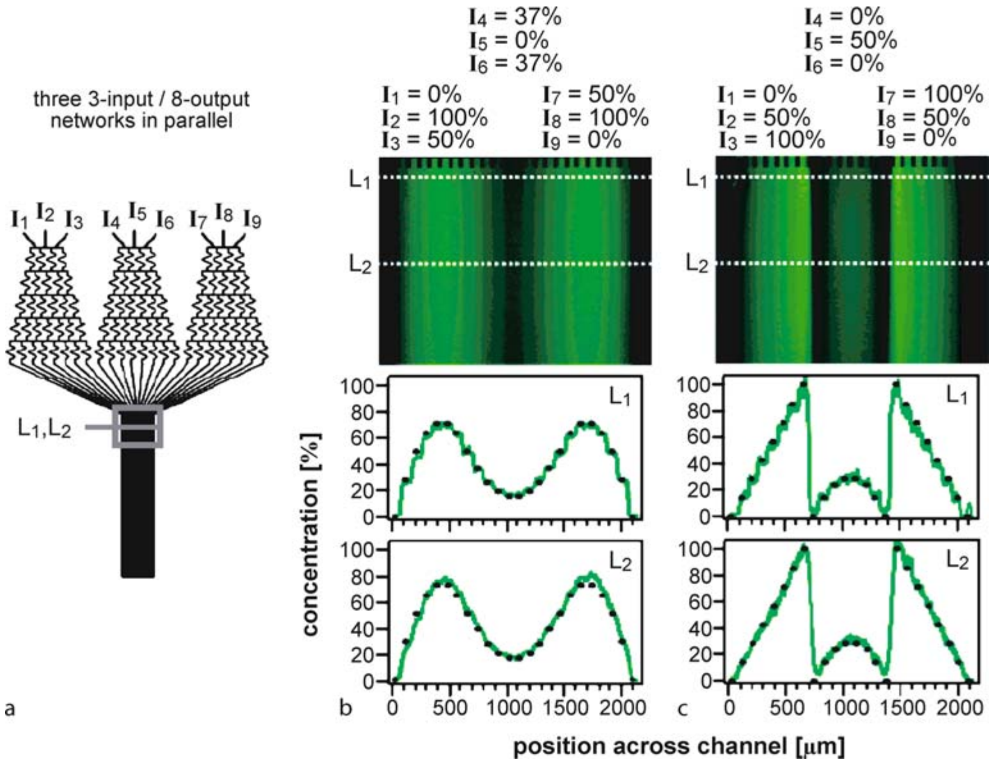
Generation of Periodic Gradients

There are two ways to generate periodic gradients. One way is to use a microfluidic network with an appropriately large number of inlets. It is more convenient, however, to generate the concentration profile by combining multiple pyramidal networks in a parallel way. By following this latter approach, a broad range of concentration profiles can be generated using a small number of inlets. A variety of sawtooth gradients can be established when the individual linear concentration gradients which are independently generated are brought together in the broad channel [7]. Increasing the number of inlets from two to three in the individual networks extends the accessible range of profiles, since composite gradients with parabolic parts can be generated. Figure 2b shows a symmetric gradient consisting of three parabolic parts. Since linear gradients are accessible with networks that have three inlets, mixed gradients consisting of both linear and parabolic parts can be generated (Fig. 2).

Generation of Dynamic Concentration Gradients

Although useful for many applications, an important limitation of the methods described above is that the shape of the gradient is fixed for each device, limiting application to a single static experiment. Moreover, these methods cannot be applied in applications requiring temporal variations in concentration. The following section describes a method of generating dynamically controlled temporal and spatial gradients using a single microfluidic device, by integrating a simple *mixer module* with individually controlled fluidic inputs with a gradient-generating network.

Mixer Module A simple microfluidic mixer module (Fig. 3a) was designed to generate controlled mixtures of two fluidic inputs. Buffer and FITC–dextran solutions, individually controlled by separate syringe pumps, were introduced into the microfluidic device via two inputs. The mixing channel was 40 mm long, to allow complete mixing in the range of flow rates tested for this experimental configuration. The final concentration in the obser-



Concentration Gradient Generation and Control, Figure 2 (**a**) Schematic of the microfluidic network used (**b, c**) Fluorescence micrographs of two different periodic gradients, (**b**) consisting of parabolic parts and (**c**) a mixture of parabolic and linear parts

vation area, 40 mm downstream of the inputs, was spatially homogeneous. The final concentration is controlled by varying the ratio (k) of the flow rates of buffer (V_{buffer}) and FITC–dextran ($V_{\text{FITC–dextran}}$), where

$$k = \frac{V_{\text{buffer}}}{V_{\text{FITC–dextran}}} \tag{3}$$

If the portion of the mixing channel occupied by a fluidic input is proportional to its flow rate, the relationship between the normalized final concentration of FITC–dextran (c) in the observation channel and the flow rate ratio(k) is given by

$$c = \frac{1}{1+k} \tag{4}$$

If the total flow rate in the observation channel is kept constant (as in this experiment),

$$V_{\text{buffer}} + V_{\text{FITC–dextran}} = V_0 \tag{5}$$

The flow rates of buffer and FITC–dextran as a function of the normalized FITC–dextran concentration c and the total flow rate V_0 can then be readily determined:

$$V_{\text{FITC–dextran}} = cV_0$$
$$V_{\text{buffer}} = (1-c)V_0 \tag{6}$$

Since the FITC–dextran concentrations for $k = 0$ (FITC–dextran only) and $k = \infty$ (buffer only) are known, and their fluorescence intensities can be measured, these values were used as reference points to test the proposed mixing strategy by examining whether the relative fluorescence intensity was linearly proportional to the FITC–dextran concentration at other k values. Plotting the normalized fluorescence intensity versus the normalized FITC–dextran concentration gave a straight line, indicating that the strategy was valid (Fig. 3b).

Generation of Dynamic Linear Gradients To generate dynamically controlled spatial and temporal linear gradients with varying slope, baseline, and direction, the outlet of the mixer module described in the previous section was connected to the inlets of a gradient-generating device. By adjusting the relative flow rates of the buffer and the FITC–dextran inputs, while maintaining a constant total

flow rate, the concentration of FITC–dextran injected into each inlet can be dynamically varied to change the slope, baseline, and direction of the linear gradients. Keeping the left inlet constant, the slope can be changed by changing the concentration of FITC–dextran in the right inlet. The linear gradient is represented by the normalized change in the FITC–dextran concentration from the left edge to the right edge of a 350 μm wide microchannel.

Generation of Dynamic Nonlinear Gradients A three-inlet nonlinear spatial-gradient generator has been demonstrated in earlier work [6, 7]. In that device, the gradient was described by the equation $c = ax^b + O(x)$, where c is the concentration, x is the position in the channel, a and b are the proportionality coefficient and the power of the major term, respectively, and $O(x)$ represents the remaining terms. The nonlinearity (or power) of the gradient was modified by adjusting the relative chemical concentration at the middle inlet. To change the concentration at the middle inlet, the experiment had to be stopped and the solution being pumped into the inlet had to be manually replaced with another solution. This section describes the incorporation of a mixer module into the middle inlet to allow dynamic control of the nonlinearity of the gradient (Fig. 4a). A mixer module with a buffer input and an FITC–dextran input was used. The gradient profile was of the power-law form

$$c(x) = ax^b \tag{7}$$

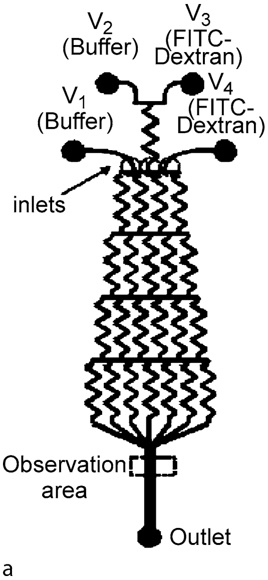
where c is the normalized FITC–dextran concentration as a function of the position (x) in the observation channel (the origin is at the left edge of the channel), and was directly proportional to the fluorescence intensity; a and b are fitting parameters. The power b varied from ~ 0.5 to ~ 2, depending on the FITC–dextran concentration at the middle inlet, and was in agreement with simulations (Fig. 4b). The gradient profiles were simulated by calculating the spatial distribution of the FITC–dextran concentration resulting from the repeated splitting and mixing of FITC–dextran and buffer flowing through the microchannel network from the inlets.

Free-Diffusion-Based Concentration Gradient Generation

Ladder Chamber

Design and Layout of Ladder Chamber A ladder chamber, as the name implies, consists of two main channels connected by several bridge channels. An inlet feeds into each of the main channels, which converge to a common outlet (Fig. 5).

The purpose behind this design is to establish gradients in the bridge channels by allowing diffusion of molecules between the two main streams. Diffusion across the bridge channels is theoretically equivalent to diffusion in a thin film, in which a linear gradient is established at steady state. The chamber can thus be seen as a source/sink diffusion system, with the key feature that the source and



Gradient \ Relative Input Flow Rate	V_1	V_2	V_3	V_4	b

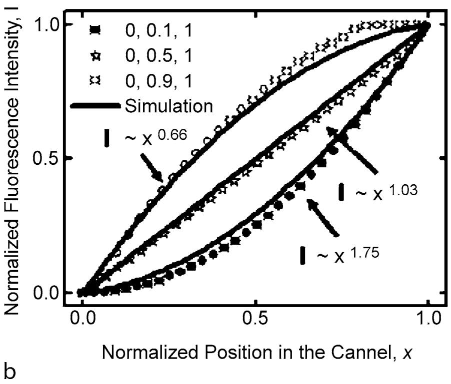
(0, 0.9, 1)	1/3	1/30	9/30	1/3	0.66



Concentration Gradient Generation and Control, Figure 4 Generation of dynamic nonlinear gradients. (**a**) Schematic of the microfluidic device. A mixer module was connected to the middle inlet of a three-inlet gradient device that generates nonlinear gradients. (**b**) Nonlinear gradients are represented by a combination of the three inlet concentrations and are in power-law form ($I = ax^b$). The graph shows gradient profiles for $(0, 0.1, 1)$, $(0, 0.5, 1)$ and $(0, 0.9, 1)$ obtained from experiments and simulations

sink are fluidic, rather than static; continuous flow provides constant replenishment of the solutions and ensures that the concentrations remain constant.

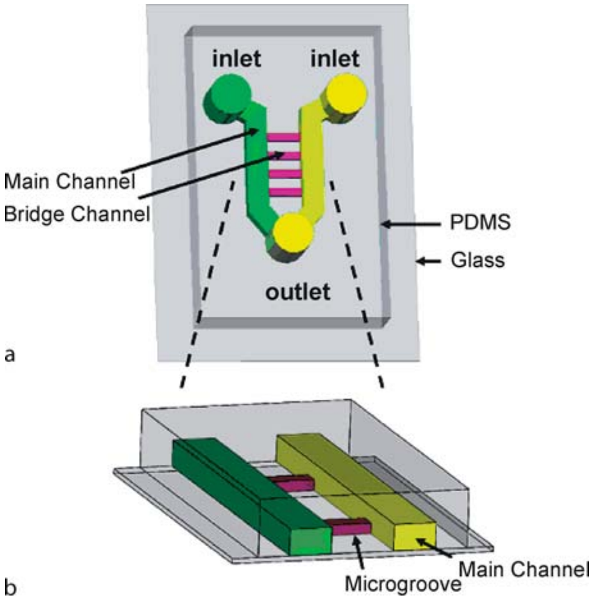
Flow Dynamics in Microgrooves In order to generate stable linear gradients, the fluid in the bridge channels must be static, such that only diffusion takes place, confining bulk fluid flow to the main channels. The bridge channels were thus designed in the form of microgrooves, having substantially smaller dimensions than the main channels, and consequently a higher fluidic resistance. To determine the optimum relative dimensions that satisfied these requirements, a finite element model was used to predict the flow dynamics in ladder chambers of various dimensions. To simplify the simulation, one main channel and one bridge channel were used, and the flow dynamics was examined when equal pressure differences existed across the bridge channel and along the main channel. When the height of the bridge channel was equal to that of the main channel (1 : 1 height ratio), part of the flow was diverted at a higher velocity into the bridge channel. When the ratio was 1 : 10, the flow was confined to the main channel, and no flow was able to enter the bridge channel. On the basis of these results, only ratios $\geqslant 1 : 10$ can successfully maintain a flow-free environment and ensure that diffusion is the only mode of transport in the microgrooves.

Gradient Generation in Microgrooves The ladder chamber was designed with two inlets and a common outlet to facilitate the loading of solutions and allow a constant flow to be easily maintained. Using the inlets as reservoirs, and withdrawing solution from the outlet using a syringe pump, flow was generated in both of the main channels simultaneously. By loading FITC–dextran and PBS into the reservoirs, a fluorescence gradient was generated across the microgrooves. Figure 6 shows the evolution of the gradient in a 400 μm long microgroove, going from its initial nonlinear profile to a linear steady state in 18 min. The gradient remained constant at 40 min, and was still stable at 90 min. It must be emphasized that the gradient stability is dependent on the flow, and remains stable as long as the flow is maintained.

Microfluidic Multiinjector (MMI)

MMI Design

The MMI was designed to integrate the functionality of pressure-actuated glass micropipettes on a single device using microfabrication and multilayer soft lithography. To generate a microscopic gradient, a device was fabricated with a network of fluidic channels that was controlled with a set of pressure control channels. Steady ejection of chemical solution from a microchannel-based orifice into a large reservoir resulted in gradients similar to



Concentration Gradient Generation and Control, Figure 5 Design and layout of the ladder chamber. (**a**) The chamber was fabricated from PDMS bonded to glass and consists of two main channels connected by bridge channels. (**b**) Constant flow in the main channels allows steady-state diffusion in the microgrooves

those produced by micropipettes. In the MMI, the macroscopic pressure tubing and valves were replaced with pressure control channels and on-chip barrier valves, while the glass micropipette was replaced with a fluidic channel with a 10 μm orifice. Figure 7a shows a schematic of a representative MMI device. The device consists of fluidic channels and valves made from PDMS that are separated by a 25 μm thick membrane. These valves were actuated by applying positive pressure (10 psi) to the control channel. The pressure caused the membrane between the channels to deform and close the fluidic channel. Venting the pressure channel opened the underlying fluidic channel to fluid flow. Repetitive actuation of the barrier valve allowed ejection of picoliter amounts of fluorescent solution into the reservoir. Similarly to a micropipette, steady pulsatile release of solution from an orifice resulted in stable gradients around the orifice.

Generation of Steady-State Concentration Gradient

The release volume must be accurately controlled with the valves to minimize macroscopic fluid flow and fluctuations in the gradient profile. Building on the results described in the previous section, the valve opening times and frequency were optimized to avoid rippling fluctuations in the gradients. Figure 7b shows the development of a stable gradient as a function of time for valve actuation at 0.67 Hz with 1 s opening. To quantitatively analyze the concentration gradient of the ejected substance, the fluorescence intensity was measured near the microfluidic orifice. Figure 7c shows 2D fluorescence intensity profiles at various times after the start of pulsatile release. The profile was governed by diffusion from a point source and reached steady state after 10 min. The measured fluorescence intensity profiles after 10 and 30 min fit well with the diffusion profile predicted by simulation. The concentration gradient produced by repetitive ejection of the solution was calculated by summing the concentration profiles from each pulse. The concentration profile after n injections was expressed as

$$C(r, t) = \sum_{i}^{n} \frac{r e^{\frac{-r^2}{4D(t-it_0)}}}{4[\pi D(t - it_0)]^{\frac{3}{2}}} \tag{8}$$

where $C(r, t)$ is the concentration at a position r relative to the injector and at time t after the onset of ejection, i is an integer from 0 to n, t_0 is the inverse of the ejection frequency, and D is the diffusion constant. From Fig. 7a, the volume of a single ejection is approximately 66.5 pl for $t_0 = 1.5$ s (valve-opening duration = 1 s). D for FITC–dextran was approximated as 1.7×10^{-6} cm^2/s for a dilute solution at room temperature. Because the injector is located at the bottom of the reservoir, the gradient formed around the injector tip is radial. The fluorescence profile is a sum of the fluorescence over the entire depth of the reservoir ($h = 2.5$ mm) and may differ slightly from the actual gradient that is present immediately above the substrate.

Generation of Overlapping Gradients using MMI

To demonstrate the potential of integrating multiple injectors to produce complex superimposed gradients, we fabricated a dual injector on a single chip. This device is capable of producing two identical gradients or two different competing gradients simultaneously. Figure 8a shows the schematic design of this MMI device that can produce overlapping gradients. Different, overlapping gradient profiles can be generated by fabricating multiple injectors on a single chip for high-throughput experiments. Figure 8b shows a 2D fluorescence intensity profile of overlapping gradients. Symmetric, overlapping gradients were formed simultaneously. The fluorescence intensity of the overlapping gradients was visualized by 3D fluorescence intensity plots, as shown in Fig. 8c.

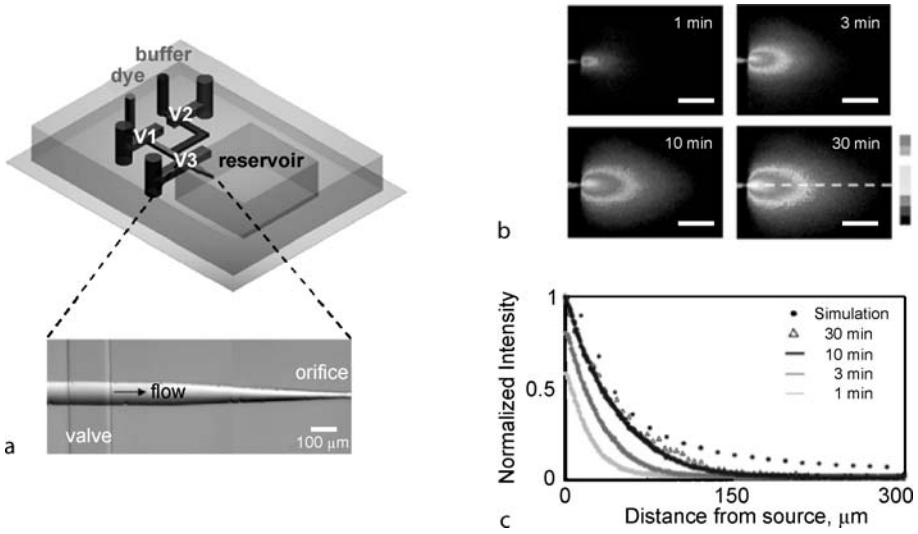
Key Research Findings

There are a number of advantages in using microfluidic networks to generate gradients. First, a variety of gradients can be generated by using appropriate fluids or solutions. These gradients, in principle, can be used to generate gradients in topology, medium, and surface, all in the same channel. Second, it is possible to generate gradients with a resolution from several microns to several hundreds of microns; the larger channels are the right size to be relevant to studying cell biology. Third, gradients of different shapes (symmetric and asymmetric), types (smooth, step, and with multiple peaks), and kinds (static and dynamic) can be obtained with modification of the design of the microfluidic network or modification of the implementation of the experiment (i. e. the relative flow rates).

Jeon et al. [6] reported a microchannel network method for generating defined concentration gradients in a microfluidic device. Solutions of different concentrations were introduced into the microfluidic device by syringe pumps at separate inlets and repeatedly mixed and split through the microchannel network, producing multiple diluted streams with predictable concentrations. These streams flowed side by side in a common channel and generated a soluble or surface gradient across the channel. Dertinger et al. [7] developed the network method further to create concentration gradients with complex profiles. By configuring the inlet concentrations, gradients with various shapes such as linear, periodic, and parabolic gradients were produced. If multiple microchannel networks are arranged side by side in a single chip and the output streams are connected to a common gradient channel, the individual gradients produced by each network can be aligned to configure complex gradients. Superimposed gradients of two or more species could be also formed using the same approach. Lin et al. [8] improved the network approach to generate dynamically controlled temporal and spatial gradients. A two-inlet *mixing module* was developed to control the resulting concentration by varying the relative input flow rates. When mixing modules were incorporated into the microchannel network device, linear gradients with different slopes, baselines, and directions, as well as nonlinear gradients with different nonlinearities, could be produced, and altered dynamically.

In contrast to the generation of microfluidic gradients by continuous-flow mixing, the other method for gradient generation is the free diffusion of molecules in miniaturized flow-free microenvironments. Two methods have introduced to generate a flow-free concentration gradient of molecules. One method is the ladder chamber, which consists of two main channels connected by several microchannels. Using the inlets as reservoirs, and withdrawing solution from the outlet using a syringe pump, flow is generated in both of the main channels simultaneously. The concentration gradient in microgrooves has been found to reach to a linear steady state in 18 min. The duration of the gradient was limited only by the size of the reservoirs [9].

Another method is based on a microfluidic multiinjector (MMI) that combines the functionality of glass micropipette-based assays with integrated microfluidic valves on a single chip. Pulsatile release of solution using



Concentration Gradient Generation and Control, Figure 7 (**a**) Schematic design of the microfluidic multiinjector (MMI). Crossings of control channels and fluidic channels make up the on-chip barrier valves ($V1, V2, V3$). These valves were actuated by pressurizing the control channel and deforming the membrane between the channels to close the fluidic channel. These valves controlled the pulsatile release of solution into the reservoir to generate a gradient. (**b**) 2D intensity profiles showing the gradient of FITC–dextran and its evolution with time. The barrier valve was actuated at 0.67 Hz and opened for 1 s. (**c**) 1D normalized fluorescence intensity profile along a horizontal line in Fig. 7b. Steady-state gradients were achieved within 10 min. The experimental measurements agreed closely with simulations. The scale bars represent 50 µm

integrated valves made from PDMS has produced microscopic chemical gradients near the orifice. Dynamic temporal and spatial gradients have been achieved reliably using this MMI [10]. Overlapping gradients have also been obtained. Miniaturized integration of multiple injectors on a single device will allow reproducible, high-throughput experiments with spatiotemporal gradients, with potential applications in basic and applied studies in chemotaxis and axon guidance.

Future Directions for Research

Gradient-generating microfluidic devices are an enabling experimental platform for fundamental research into a number of physiological and pathological processes that range from immune response through cancer cell migration to axon guidance. Compared with conventional macroscale devices, microfluidic devices allow precise control and manipulation of cellular microenvironments. Generation of stable and well-defined gradient profiles affords more accurate and reproducible quantitative analysis of cellular behavior. Although a microfluidic microchannel network can generate flexible shapes of concentration gradients using a single microfluidic device, this requires integration of computer-controlled syringe pumps that add complexity and limit the shapes obtainable, owing to the pulsatile nature of the stepper-motor-driven syringe pump. To overcome this limitation, pulse-free pumps or gravity-based pumps may be used. In spite of these limitations, the added flexibility in the gradient shape and the capacity to generate dynamic temporal and spatial gradients will be very useful in many areas of application where flexible gradient generation is needed.

The ladder chamber provides a powerful yet simple approach for generating and maintaining stable gradients on two-dimensional substrates. With its simple source-and-sink design, the chamber can generate steady-state gradients in a straightforward manner, without the need for specialized equipment. The chamber's microfluidic nature ensures precise and constant delivery of soluble factors, preventing depletion or accumulation of molecules in the streams, and thus maintaining gradient stability. This combination of characteristics has been lacking among previous chemotaxis assays. The simplicity of the ladder chamber is also complemented by its high throughput. The *ladder* design enables multiple experiments to be performed in parallel. Using a large number of parallel grooves of varying length, gradients of different steepness can be generated simultaneously in a single chamber. Consequently, the influence of gradient steepness on chemotaxis can be rapidly characterized in a single experiment, whereas most other assays, including those using a microfluidic chemotaxis chamber, would require multiple experimental runs. Moreover, it may be possible to generate gradients of several different concentrations in a single chamber by increasing the number of inputs. Since the inlet reservoirs

are open to access, the solutions can also be easily replaced and exchanged to allow dynamic control of the gradient during the course of the experiment.

One of the main advantages of the microfluidic multi-injector is that generation of dynamic temporal and spatial gradients can be achieved reliably using a simple experimental setup. Since each injector can be controlled independently, it is possible to generate dynamic spatiotemporal gradients, with potential applications in basic and applied studies of chemotaxis, axon guidance, and yeast polarization. For example, the direction and shape of the concentration gradient can be switched easily by controlling appropriate injectors in an array. When opposing microinjectors are alternately turned on and off, cells can be stimulated by competing gradients of chemoattractants and chemorepellents.

Phase-change heat transfer in microchannels

Definition

Condensation is a heat transfer process in which vapor is cooled below its saturation temperature while it undergoes a change of phase from vapor to liquid.

Overview

Recently, condensation in microchannels having cross-sectional areas of different shapes, such as circular, triangular, square, trapezoidal, and rectangular, has received a great deal of attention because of its important application to micro heat exchangers [1, 2]. It has been found that mist flow, annular flow, injection flow, plug/slug flow, and bubbly flow may occur in different locations in a microchannel, depending on the local vapor quality and mass flux. Injection flow occurs where the shearing force is overcome by the surface tension force. The occurrence frequency of injection flow depends on the condensation heat transfer rate, the mass flux of vapor, and the cross-sectional shape of microchannels. At the same mass flux, it has been found that the average condensation heat transfer coefficient in microchannels is higher than that in a minichannel due to the thinning of the liquid film [3].

Microchannel Classification

Based on the analytical results of Li and Wang [4] on gravitational effects on condensation in channels, Cheng and Wu [2] proposed the classification of condensation heat transfer in channels according to the Bond number which is defined as

$$\mathrm{Bo} = \left(\frac{D_\mathrm{h}}{\ell_\mathrm{c}}\right)^2 = \frac{g\,(\rho_\mathrm{l} - \rho_\mathrm{v})\,D_\mathrm{h}^2}{\sigma} \quad (1)$$

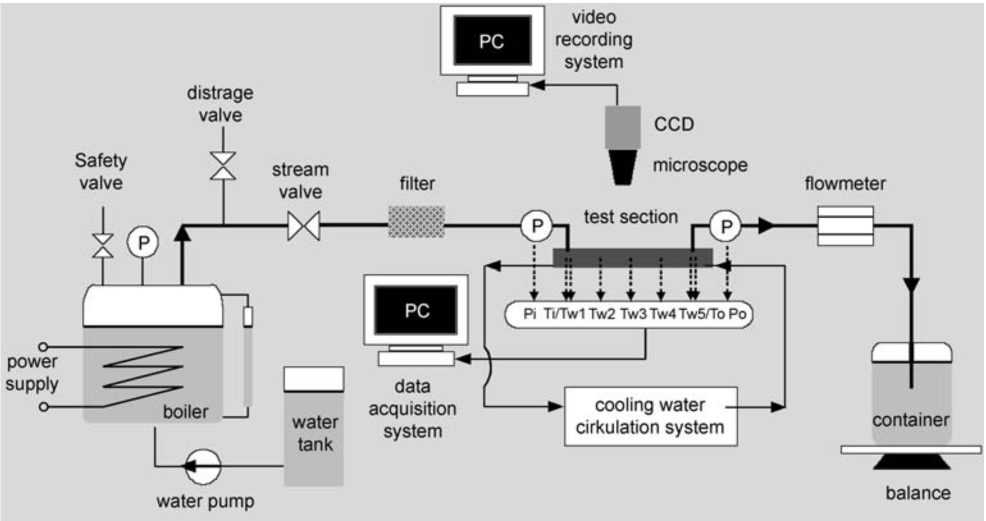
where $\ell_\mathrm{c} = \left[\sigma/(\rho_\mathrm{l} - \rho_\mathrm{v})\,g\right]^{1/2}$ is the capillary length; D_h is the hydraulic diameter of the channel; g is the gravitational acceleration; σ is the surface tension; and ρ_l and ρ_v are density of the saturated liquid and the saturation vapor at a particular temperature (or pressure), respectively. Equation (1) shows that the Bond number is a ratio of the hydraulic diameter to the capillary length, which is also a measure of the relative importance of the buoyancy force to surface tension force. Furthermore, Cheng and Wu proposed the classifications of microchannels, minichannels, and macrochannels as follows [2]:

- Microchannel: if $\mathrm{Bo} < 0.05$ where the gravity effect can be neglected.
- Minichannel: if $0.05 < \mathrm{Bo} < 3.0$ where the surface tension effect becomes dominant and the gravitational effect is small.
- Macrochannel: if $\mathrm{Bo} > 3.0$ where the surface tension is small in comparison with the gravitational force.

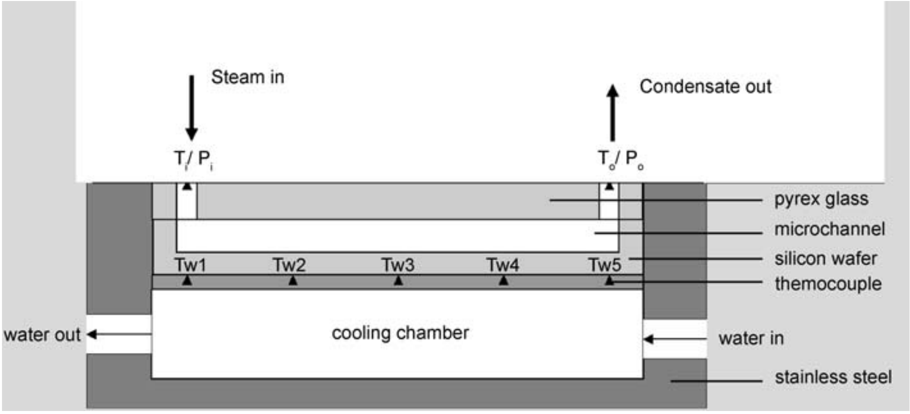
According to the above classification, a channel with its hydraulic diameter less than 490 μm (at 450 K) is considered to be a microchannel if water is used as a working medium.

Basic Methodology

Figure 1 shows the experimental setup for the study of condensation in a microchannel [5]. The deionized water in the water tank was pumped into the electric boiler where water was vaporized. Saturated steam from the boiler flowed successively through the valve, filter, and test section and was finally collected by a container at atmospheric pressure. Figure 2 shows the test section of the parallel microchannels etched in a silicon wafer, which was cooled by circulation of cooling water from the bottom of the wafer. Temperature and pressure of steam at the inlet and the condensate at the outlet were measured by thermocouples and pressure transducers, respectively. Wall temperature distribution along the bottom of the microchannels was measured by thermocouples embedded in the silicon wafer substrate. The microchannels were then covered with thin transparent Pyrex glass from the top. To visualize condensation flow patterns



Condensation in Microchannels, Figure 1 Experimental system [5]



Condensation in Microchannels, Figure 2 Test section [5]

in the microchannels, a high-speed video recording system connected with a microscope was located above the microchannels (see Fig. 1).

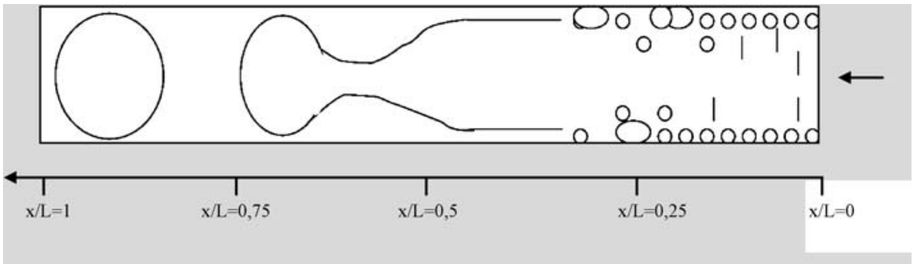
Key Research Findings

Experimental Investigations

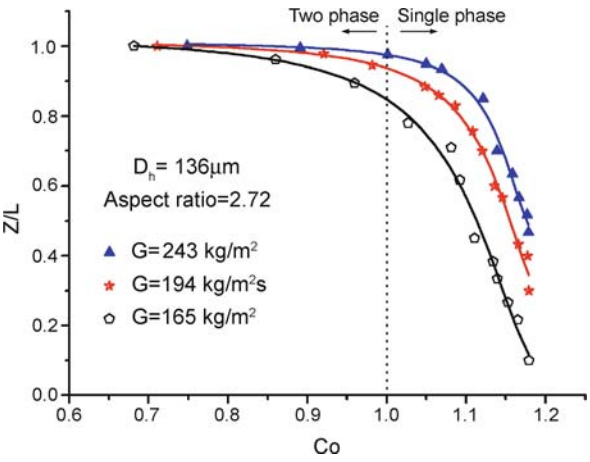
Flow Patterns and Transition Criteria

To study condensation flow patterns of refrigerant R134a in circular tubes and in *minichannels* having hydraulic diameters of 1 mm $< D_h <$ 5 mm, Garimella [6] used digitized frames of video and categorized four major flow regimes as annular, intermittent, wavy, and dispersed, which were further subdivided into 16 flow patterns. With decreasing hydraulic diameter ($D_h <$ 3 mm), it was found that (i) the overall range of the annular flow regime increases, (ii) the wavy regime decreases and thoroughly disappears at $D_h = 1$ mm, and (iii) the intermittent regime (plug/slug flow) increases. Wu and Cheng [5] carried out a series of simultaneous visualization and measurement experiments on saturated steam condensing in parallel silicon microchannels, having a trapezoidal cross-section with a hydraulic diameter of 83 μm and a length of 30 mm. Figure 3 shows that mist flow, annular flow, plug/slug flow, and bubbly flow occurred at different locations in the microchannel, depending on the local vapor quality. They observed for the first time the so-called "injection flow", which is a transition process from annular flow (where shearing force is predominant) to plug/slug flow (where the surface force is predominant).

C



Condensation in Microchannels, Figure 3 Schematic of condensation flow pattern [5]



Condensation in Microchannels, Figure 4 Effects of mass flux on the dimensionless distance Z/L at different Co in microchannels having a hydraulic diameter of 136 μm [7]

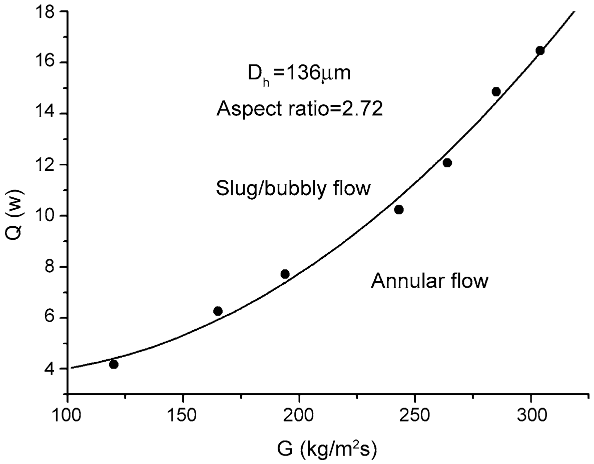
Quan et al. [7] carried out further studies on the transition from annular flow to plug/slug flow in condensation of saturated steam in microchannels with trapezoidal cross-sections, having two different aspect ratios of 2.72 and 8 (where the aspect ratio is defined as the microchannel top width to height ratio) and two different hydraulic diameters of 136 and 128 μm, both having a length of 60 mm. Figure 4 shows the location of the dimensionless distance Z/L (with L being the length of the microchannel) along the microchannel (with $D_h = 136$ μm and aspect ratio $A = 2.72$) where the transition takes place versus the condensation number Co at three different mass fluxes of steam $G = 165$, 194, and 243 kg/m^{2}s respectively. The condensation number, Co, is defined as

$$\mathrm{Co} = \frac{Q}{m_v h_{fg}} \tag{2}$$

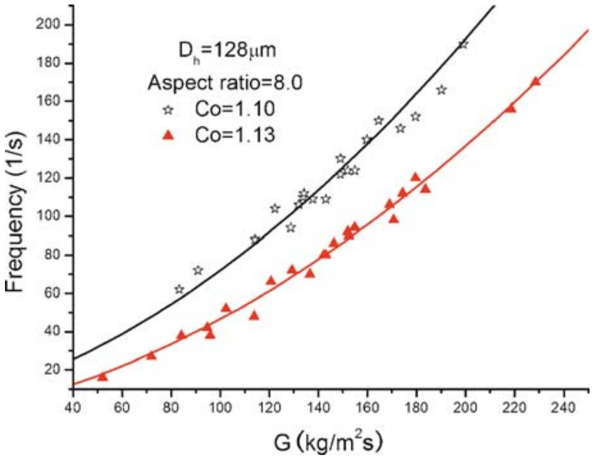
where Q is the amount of condensation heat transfer rate in the microchannel, m_v is the mass rate of steam, and h_{fg} is the latent heat of vapor. Note that $Z/L = 0$ means that the microchannel is fully occupied by plug/slug flow and single-phase liquid while $Z/L = 1$ means that the microchannel is fully occupied by annular flow in the microchannels. It can be seen from Fig. 4 that (i) at a constant Co, Z/L increases with the increase in mass flux (G), indicating that the location of the breakup point of injection flow will move toward the outlet, i.e. the annular flow regime in microchannels will be expanded and the slug/bubbly flow regime will shrink as the value of G increases; (ii) at a constant G, Z/L increases with the decrease in the condensation number, indicating that injection flow occurs further downstream, and the annular flow regime is expanded; (iii) at $Z/L = 1$, Co increases with increasing G; and (iv) Co = 1 is the criterion whether two-phase flow or liquid phase exists at the outlet: Co < 1 means that two-phase flow exists at the outlet while Co > 1 means that steam is completely condensed at the outlet. It is seen from Fig. 4 that the transition from annular flow to plug/slug flow takes place further upstream in the microchannels as dimensionless Co increases, or as the mass flux decreases. A flow pattern map in terms of heat transfer rate versus mass flux for condensation in microchannels having $D_h = 136$ μm and $A = 2.72$ is presented in Fig. 5, where the annular flow regime exists below the curve while the slug/bubbly flow regime exists above the curve. Figure 6 shows that the occurrence frequency of the injection flow in a microchannel (having $D_h = 128$ μm and $A = 8$) increases as the steam mass flux increases because of higher interface instability. At the same mass flux, it is shown that higher cooling rate leads to lower occurrence frequency because interfacial condensation tends to reduce instability.

Heat Transfer

Shin and Kim [3] carried out an experiment on condensation of R134a in single circular tubes ($D_h = 493$, 691, 1067 μm) and in mini-/microchannels having rectangular cross-sections ($D_h = 494$, 658, 972 μm) with mass flux in the range of $100 < G < 600$ kg/m^{2}s. It was



Condensation in Microchannels, Figure 5 Flow patterns of annular flow and slug/bubbly flow in a microchannel [7]



Condensation in Microchannels, Figure 6 The effects of mass flux on occurrence frequency of injection flow at different cooling rates [7]

reported that the heat transfer coefficient was independent of the heat flux and the values of the Nusselt number increased with the vapor quality. Also, it was found that Nusslet numbers at low mass fluxes ($G \leq 200\,\text{kg/m}^2\text{s}$) were higher than existing correlations for condensation in macrochannels (Fig. 7a) whereas those at high mass fluxes ($G = 400\,\text{kg/m}^2\text{s}$, for example) agreed well with some existing correlations (Fig. 7b). The average condensation heat transfer coefficient of a microchannel was found to be higher than that of a minichannel at the same mass flux. Also, it was found that the condensation heat transfer coefficients for channels with rectangular cross-sections at low mass fluxes were slightly higher than those for circular shape, and the whole situation would reverse at high mass fluxes of the refrigerant.

Pressure Drop

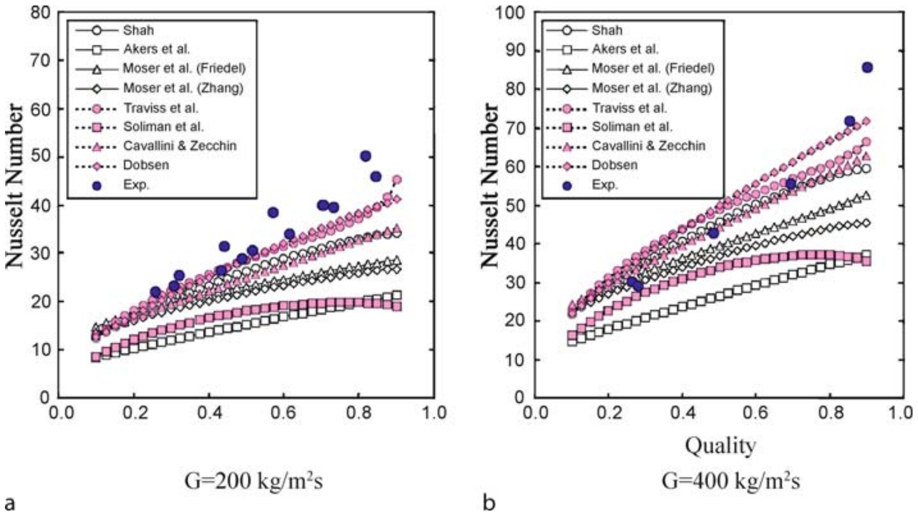
Shin and Kim [8] obtained pressure drop measurements for condensation flow of R134a in a microtube having a hydraulic diameter of 691 µm. Figure 8 shows a comparison of their pressure drop measurements with available correlation equations for macrochannels. Figure 8a shows that the pressure drop in condensation flow at low mass flux ($G \leq 200\,\text{kg/m}^2\text{s}$) in a microchannel is lower than that predicted by Friedel's correlation for macrotubes [9]. At higher mass fluxes ($G = 400\,\text{kg/m}^2\text{s}$, for example), however, their pressure drop measurements for condensation flow in a microchannel can be predicted well by Friedel's correlation, as shown in Fig. 8b.

Theoretical Studies

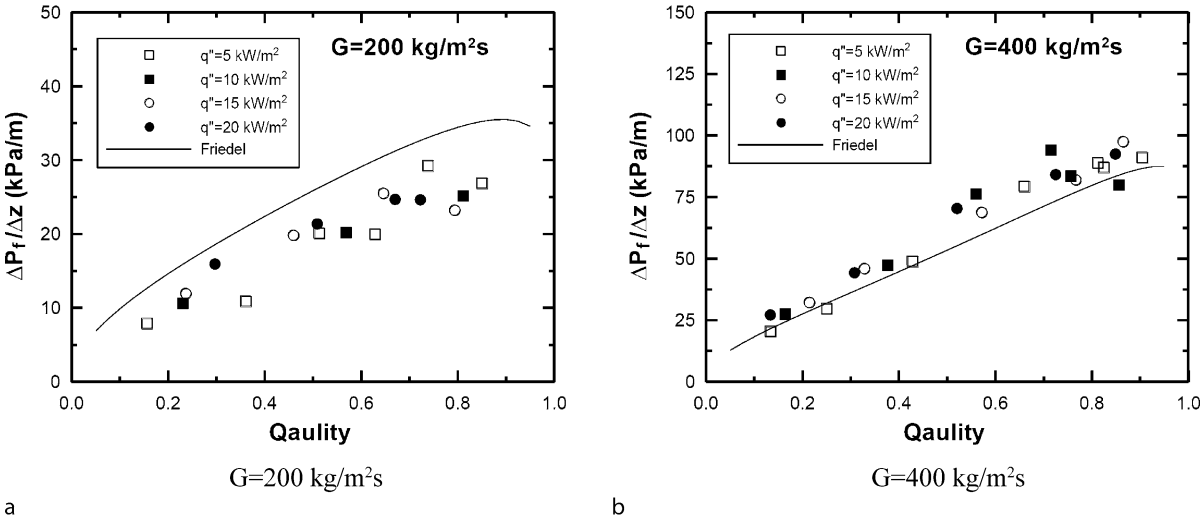
Teng et al. [10] investigated the effects of surface tension and shear force on interface instability of condensate film that resulted in a capillary bubbly flow. They pointed out that the surface tension effect on film instability depended on the wavenumber: surface tension stabilizes the interface if the dimensionless wavenumber is greater than 1; otherwise, it has a destabilizing effect. In contrast, the shear force always has a destabilizing effect on film instability.

Tabatabai and Faghri [11] put forward a new flow map to emphasize the importance of surface tension in condensation flow including annular, slug, plug, and bubble flow patterns in horizontal mini-/microtubes ($D_h < 4\,\text{mm}$). They noticed that the interface instability could result in ripple formation on the liquid surface, leading to the formation of collars that grow to form a bridge to establish slug, plug, and bubble flow regimes. However, in a macrotube, due to high gravitational pull on the liquid film, the bridge was not formed.

An analysis of droplet condensation heat transfer in a microchannel was carried out by Chen and Cheng [12], who found that droplet condensation heat flux increased as the hydraulic diameter decreased. Taking into account effects of surface tension (σ), interfacial shear stress (τ), and gravity (g) and assuming laminar condensate flow, Wang and Rose [13] presented a theoretical model to predict film condensation heat transfer for vapor flowing in horizontal noncircular micro-/minichannels. When the model is applied to channel sizes (side of square or triangle) in the range 0.5 – 5 mm and for refrigerants R134a, R22, and R410A, the results show that the initial enhancement is higher in smaller channels but falls off after a shorter distance along the channel; higher mass velocities result in increased length of enhanced heat transfer. Heat transfer coefficients of R22 and R134a are almost the same whereas those of R410A are somewhat smaller.



Condensation in Microchannels, Figure 7 Nusselt number versus quality at different mass fluxes for a microchannel having a hydraulic diameter of 493 μm [3]



Condensation in Microchannels, Figure 8 Comparison of pressure drop for condensation in microchannels with existing correlations for condensation in macrochannels [8]

Figure 9 shows the profile of film thickness along the circumference of the triangular cross-section of the channel, where b is the side length of the channel, T_S is the vapor saturation temperature, ΔT is the temperature difference between vapor and channel wall, and G is the mass flux. It is shown that the film is substantially thicker at the corners of the triangular channel (at $x = 0$ mm, 1 mm). At the inlet, the thinnest film occurs near the corners. This location moves towards the center of the wall (at $x = 0.5$ mm) downstream. Figure 10 shows the local heat transfer coefficient along the circumference of the triangular cross-section of the channel. It is shown that low values of the heat transfer coefficient occur where the film is thick and high values occur where the film is thin. The maximum heat transfer coefficient becomes smaller, and its location moves towards the center of the sides, downstream along the channel. At the same time, the average heat transfer coefficient decreases because of the increase of liquid film thickness, as shown in Fig. 11. In the entry region of the channel, the heat transfer coefficient is higher for smaller channels because of the surface tension enhancement effect. However, the heat transfer coefficient becomes lower for smaller channels further along the channel because the meniscus zone increases more rapidly.

Condensation in Microchannels, Figure 10 Heat transfer coefficient along sides of a triangular microchannel [13]

Future Directions for Research

Although some experimental work has recently been carried out to study condensation flow patterns, and transition from annular to plug/slug flow in microchannels, the basic mechanisms of two-phase instability in condensing flow in microchannels are still not well understood. More experimental work is needed to investigate pressure drop and heat transfer characteristics in condensation in microchannels. Furthermore, the effects of hydrophilic and hydrophobic surface properties on condensation heat transfer in microchannels remain to be investigated experimentally. Improved experimental techniques, using integrated temperatures and pressure transducers for temperature and pressure drop measurements in condensing flow in microchannels are needed. Numerical simulations have yet to be carried out to study condensation flow patterns from mist flow, annular flow, injection flow, plug/slug flow to bubbly flow along microchannels.

Confocal Microscope

Definition

A confocal microscope is a special kind of a microscope where the optical elements are arranged in such a way that the out-of-focus light is obstructed and only the light coming from the focal plane is used for the image. As a result, it is possible to obtain thin optical sections without physically damaging the specimen. These thin optical slices can be digitally processed to construct a 3D image of the specimen. Confocal microscopes are widely used in biological applications to observe processes inside living cells.

Definition

Confocal microscopy is a form of light microscopy that allows for high contrast imaging, and three-dimensional reconstruction. A confocal microscope employs laser excitation sources focused through pinhole(s) to excite fluorophores in a thin plane of a sample while rejecting out-of-focus light. The result is increased contrast and selective imaging at relatively high resolution across a wide range of wavelengths. Major advantages of confocal microscopy over conventional light microscopy include the availability of laser light sources in a broad range of wavelengths, the shallow depth of field, elimination of out-of-focus flare generated by fluorescence, noninvasive (optical) sectioning ability from relatively thick sections, and marginal improvement in axial and lateral resolution. With regards to micro- and nanofluidics, many of the current detection schemes utilized in fluidic devices would not be possible without confocal microscopy techniques.

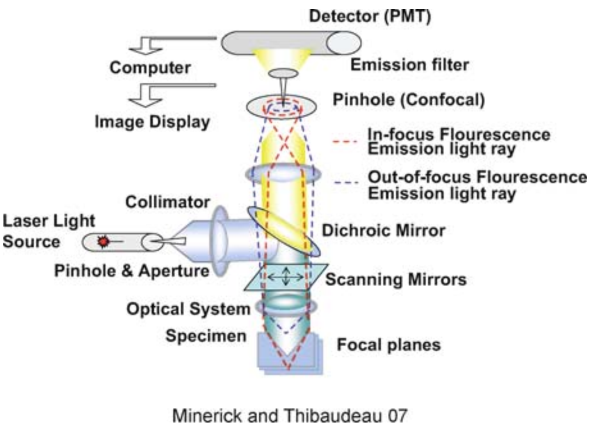
Overview

The principle of confocal imaging was patented by Marvin Minsky in 1957 and is employed, at least in part, in modern confocal microscopes. The confocal microscope uses a laser light source, combined with sensitive photomultiplier tubes (PMTs) and scanning mirrors, all computer controlled to facilitate image acquisition, display, digital storage, and analysis. A confocal microscope uses point-by-point illumination within one fine focal plane and eliminates out-of-focus information, resulting in image quality that is significantly better than that of conventional (wide-field) microscopes. It is important to note that while confocal microscopy affords improved resolution of samples, it is still a form of light microscopy and is therefore limited by the wavelength of light. The resolution achieved by confocal microscopy is collectively determined by the individual specimen properties, the wavelength of light, and the objective lens being used. The fundamental optics of light microscopes, including the confocal microscope, have remained unchanged since the 1950s. What have improved significantly are other technologies associated with microscopy and the molecular labels (dyes) used to tag molecules, structures, and/or cells of interest.

The most useful molecular labels for confocal applications are fluorescent dyes. These molecules absorb light at a higher energy (shorter wavelengths) and emit light at a lower energy (longer wavelengths). The energy lost between absorption and emission is due to thermal, vibrational energy internal to the molecule. This phenomenon is particularly useful in confocal microscopy because one can attach one color fluorophore to a specific portion of the sample, a second color fluorophore to another portion of

the sample, and so forth, to gain spatial and higher quality resolution of sample characteristics.

Confocal microscopy can be a valuable tool for studies involving microfluidics, but poses significant limitations for nanofluidics. Because the resolution obtained with any sample is limited, fluorescent emission amplifiers will be required to improve the resolution to the degree needed for confocal microscopy at the nanoscale. The best horizontal resolution typically attained via confocal microscopy is approximately 0.2 μm, while the best vertically resolution is 0.5 μm [1]. This entry of the encyclopedia focuses on fluorescence detection using confocal microscopy as adapted for micro-/nanofluidics research.



Confocal Microscopy, Detection, Figure 1 Schematic representing the optical pathway and image information flow of the laser scanning confocal microscopy (LSCM) technique. All principle components of generic LSCM are labeled. (Redrawn in part from Carl Zeiss *The Confocal Laser Scanning Microscope*)

Basic Methodology

This section is broken into two main parts. The first outlines the basic methodologies and techniques available with confocal microscopes (laser scanning confocal microscopy or LSCM). The second describes the adaptation of these technologies to a variety of microscale imaging devices involving everything from single cells to single molecules.

When the light source is transmitted through the sample and light is collected via an objective on the other side of the sample, this is known as trans-fluorescence. At times, it is advantageous to use the objective to not only deliver the excitation light, but to also collect emission light from a fluorophore. This is known as epi-fluorescence, and due to the expense of equipment, this technique is more common. A dichroic (dichromatic) mirror is used to separate the excitation light from the emission light, in order to reflect the excitation light and to pass light of wavelength longer than the excitation wavelength (emitted light) to a detector.

The basic optical pathway for the confocal microscope is shown in Fig. 1. This schematic diagram represents the optical pathway and image information flow of LSCM. All principle components of a generic LSCM system are labeled.

Light is focused through a pinhole in order to create a point source of light (or more appropriately, an Airy disk of light), which is then refocused down onto the sample with a lens. Recall that information does not have to be exactly at the focal point of an optical lens for the lens to transmit the light information. Therefore, it is necessary to utilize a second pinhole just before the detector in order to exclude light information that is not exactly at the focal point. Hence the name confocal has been used to describe this microscopy technique.

This exclusion of out-of-focus information gives confocal microscopy a distinct advantage over regular fluorescence microscopy. The surrounding sample is not uniformly illuminated, so widely scattered background fluorescence is minimized. Further, fluorescent light emitted from sample regions just outside of the point of focus are filtered through use of the pinhole in front of the detector.

One of the limitations created by focusing through a pinhole and rejecting out-of-focus light however is that there are fewer emitted photons to collect at any given time, resulting in the need for long collection times. One solution, the one used for confocal microscopes, is to use a laser light source, which adds the benefit of delivering a large number of photons in a dense stream of light and is available in a wide range of wavelengths (Table 1).

In order to reconstruct an image of a large area from information at single points, two main methods are used to scan the region of interest:

- fixed beam with sample stage moving to enable scanning in the *xy* plane; and
- fixed sample stage with the illuminated beam moved to scan in the *xy* plane.

Biological confocal microscopes have moved away from scanning the sample stage. However, with micro-/nanofluidic devices, scanning the stage has once again become a popular methodology because precise *xy* coordinates can be used to track to sample chambers or channel locations.

Within the class of techniques involving scanning the illumination beam, single or multiple beam scanning can be used. Single beam scanning involves controlling a single beam with computer-controlled mirrors or utilizing oscillating mirrors (also known as acousto-optical deflectors). Either way, a single beam is precisely directed in an *xy*

plane of the sample. This is relatively slow and in order to speed up the process to near real time, multiple beam scanning can be used. The most common method utilized is to direct a spread laser beam over a microlens array in the shape of a Nipkow disk (also termed spinning disk) to create multiple focused beams of light. A corresponding Nipkow disk perfectly aligned with the first can be used to create focal points of the multiple beams of light, which are all simultaneously focused onto the sample. Epi-fluorescent detection can occur by using the same objective and a dichroic mirror leading to a detector (i. e. a photomultiplier tube). This detector feeds information to a computer, which reconstructs the image, one pixel at a time [1].

The focused laser beam not only enhances the clarity of light information in the *xy* plane, but also can section through a sample in the *z*-direction. By scanning sections at increasing heights in a sample, it is possible to stack the two-dimensional images into a three-dimensional reconstruction of the sample. Therefore, confocal microscopy has gained popularity because three-dimensional renditions of cells or even microchannels can be created. Further, particle tracking in three dimensions has led to interesting particle velocity measurements. The main concepts involved in confocal microscopy have been adapted and permutated for a variety of microscope applications. A number of common types of specialized confocal microscopy are outlined here.

Two-Photon Excited Fluorescence or Two-Photon Confocal Microscopy

This method has the advantage that it increases the signal-to-noise ratio and the resulting image quality is much improved. This technique is similar to LSCM minus the need for pinholes. A mode-locked titanium:sapphire laser generates light in the near infrared. The laser is pulsed at a frequency about twice that of the absorption wavelength of the sample. This is done so that only a couple of photons hit at a single point of the sample to produce an emission signal. This is possible because the precise optics ensure that the energy from the photons occurs only in the plane of focus [3]. Sample penetration is increased with the greater laser power and out-of-focus photobleaching is avoided with this technique.

Near-Field Scanning Optical Microscopy

Near-field scanning optical microscopy (NSOM) is a type of microscopy where a sub-wavelength light source is used as a scanning probe. This fiber optic probe is coated with metal except for a small region at the tapered fiber tip and is used to deliver light to precise locations of the sample. Fluorescent photons emitted by the sample are collected by the same fiber optic. This is possible because fluorophores always emit light at a longer wavelength and the two wavelengths of light are able to propagate independently within the fiber optic. The tip is then rastered across the sample surface via the same mechanism as in atomic force microscopy (AFM) and a fluorescent image of the surface is digitally compiled. NSOM fiber optics require high-power lasers due to the loss of energy at all stages of the process. However, this tool can obtain resolutions well beyond the usual “diffraction limit” down to about 50 nm. Some examples of the uses of NSOM in the literature include its use in the field of magneto-optics and to investigate polymer blends and composites.

Pseudo-Confocal Technology (Deconvolution)

The Zeiss ApoTome is a less expensive alternative to confocal microscopy and can be added as an attachment to

motorized fluorescent microscopes. This technique uses a rapidly sliding grid (which cannot be seen in observed images) and a computer algorithm to subtract light that is bouncing off of structures outside of the focal plane. Image quality is greater than traditional light microscopy, but not as clear or rapid as confocal laser scanning microscopy.

Fluorescence Correlation Spectroscopy (FCS)

FCS is a type of spectroscopy that is based on the measurement of fluorescence intensity and the analysis of its fluctuations, which result from diffusion of the observed fluorophore in the excitation volume or changes in the fluorescence quantum yield arising from chemical reactions. Measurements are usually made on only a few molecules at a time, of the order of 10 ms. This is achieved by illuminating tiny volumes (~1 femtoliter) by employing two-photon excitation microscopy or confocal microscopy. FCS is used to measure translational diffusion coefficients of macromolecules, the number of fluorescent molecules under observation, and the relative fluorescence yield of different molecules in a (inhomogeneous) solution, which gives the amount of each species.

Fluorescence Recovery After Photobleaching (FRAP)

FRAP is an optical technique capable of quantifying the two-dimensional lateral diffusion of a molecularly thin film containing fluorescently labeled probes. The sample is first exposed to a very high energy laser beam which destroys fluorophores in that region. New, undamaged fluorophores then begin diffusing into that region and are imaged. This technique provides great utility in biological studies of cell membrane diffusion and protein binding. In addition, surface deposition of a fluorescing phospholipid bilayer (or monolayer) allows the characterization of hydrophilic or surfaces in terms of surface structure and free energy.

Total Internal Reflection Fluorescence (TIRF) Microscopy

TIRF microscopy is one of the more complicated techniques for more advanced users of fluorescence microscopy. In order to obtain fluorescent information about a very small feature, this technique uses decaying evanescent waves to probe a focal volume below the diffraction limit of light.

Programmable Array Microscopy

One step of sophistication above the multibeam scanning in confocal microscopy is the programmable array microscopy (PAM) technique, which uses a spatial light modulator (SLM) to generate a pattern of conjugated illumination and detection elements. The advantages of PAM include the ability to generate full-scale images rapidly. In addition, it can be combined with fluorescent quantification techniques such as fluorescence lifetime imaging, Forster resonance energy transfer (FRET), and other photoreactions.

Confocal Infrared (IR) Laser Microscopy

Confocal IR laser microscopy is very useful for the microelectronics industry because IR light is at ~1300 nm, which passes through silicon wafers (and other inorganic substrates). Further, the confocal technique reduces light flare and other image-enhancing behaviors. Given that many micro- and nanofluidic devices utilize silicon-derived fabrication techniques, confocal IR laser microscopy will likely gain popularity [4].

Adaptation of Confocal Techniques for Microdevice Applications

The largest challenge in adapting micro- or nanofluidic devices for confocal detection is in designing the device for thin sample cross-sections. Many fabrication techniques utilize thick sheets of poly(methyl methacrylate) (PMMA) or polydimethylsiloxane (PDMS) annealed to microscope slides or additional sheets of optically amenable polymers. However, the working distance of many confocal objectives is quite short and requires a maximum thickness of a 0.01 coverslip between the objective and the sample of interest. Laser light sources improve this, but the challenge still exists. A large number of novel and exciting fluidic schemes exist to enable mixing and the in situ tagging of specific molecules for fluorescent applications.

Key Research Findings

Even though the concept of confocal microscopy was invented and patented by M. Minsky in the 1950s, it took until the 1980s for technology to progress to the point where confocal microscopy was a widely used tool. A comprehensive summary of the historical progression of confocal video microscopy is available elsewhere [5]. Further, the 1990s saw an explosion in microfluidics built upon the technology developed for computer microchips. The integration of these areas is a natural extension from their foundations. The following discussion is a brief highlight of the current state of confocal microscopy in micro- and nanofluidics.

By nature, fluidics at small length scales transports a small number of cells or analytes of interest. Therefore, it is necessary for optical detection technology to be sensitive enough to detect these small numbers of cells or analytes. The current phase of research is seeing exciting results in accomplishing this very goal. LSCM coupled with poly-

merization techniques and microchannel device fabrication has been used to detect and analyze electrophoretic migration of DNA in three dimensions [6]. Such studies will enable the more efficient design of polymerization and detection systems for both biological and non-biological materials.

Just as LSCM became very useful for biologists requiring real-time monitoring of cell processes in three spatial dimensions, laser confocal microscopy has become a very popular solution for many micro- and nanofluidics researchers working to detect single cells and single molecules flowing past a fixed location (i. e. at the end of a separation channel). On the single cell detection front, recent work with single-cell time-correlated single-photon counting (scTCSPC) has enabled the recognition for cell sorting purposes of single-cell populations of green, cyano, and yellow fluorescent protein-tagged E. coli cells. This ultrahigh-sensitivity detection is accomplished via confocal focusing of light across a microchannel [7].

Moving to smaller scales, fluorescent confocal microscopy has been used to detect and count individual protein molecules in a cell within the construct of a PDMS microfluidic chip. The confocal laser beam was modified and focused to span the width of the microfluidic channel. The setup detects approximately 60% of the molecules flowing down the microchannel [8].

The challenge then becomes having a photomultiplier tube that can detect and amplify fewer and fewer photons of light for separate events. Technological advances in the area of nanolenses may be the answer to this challenge. For example, nanofabricated structures of 10 – 100 nm are now being utilized to allow for single-molecule experiments [9].

Future Directions for Research

Technological advances continue to equip life and materials scientists with the capability to probe the detailed nature of materials (biological and non-biological) at an ever-decreasing scale and have led to a great deal of excitement in new areas of research (e. g. nanoscience and nanotechnology). Given the well-known limitations of light microscopy, one might be hesitant to consider confocal microscopy a technology of the future. However, advances in optical collection techniques and fluorescent probe technologies have allowed significant progress in detection using confocal microscopy. Progress has been twofold: amplification (magnification) of the light emitted (captured) and/or amplification of the fluorescence signal to be detected.

Plasmon-based superlens [10] and/or hyperlens refract light in unconventional ways to allow the optics of a light microscope to see beyond the normal limit, i. e. magnify light and prevent the loss of so much information in the sub-wavelength features.

The ability to detect smaller and smaller amounts of analytes (small and large molecules alike) is needed in order to increase the sensitivity of Lab-on-a-Chip devices. One of the challenges with low concentration fluorescence is delivering enough light energy to a sample to then have enough light emitted that it is possible to collect a measurable amount with a given uni-directional detector. Therefore, at very low concentrations, amplification of single photons of light will need to be accomplished. Advances in the speed of spatial scanning will enable more applications. However, imaging at a single point along the time dimension will enable continuous screening in micro- and nanochannels as process streams flow past the detectors.

Key advances in this area will continue to be in the development of specialized microscopes utilizing combinations of the optical techniques discussed here. Increasing the reliability and reproducibility of such systems is important. Once developed, engineering systems for widespread use as (a) laboratory-scale commercial units and (b) microscale for portable Lab-on-a-Chip units will need to occur.

To fully integrate the confocal concept with portable, stand-alone micro-/nanodevices, inexpensive, yet functionally equivalent miniature microscopes are required. Diode lasers, microlenses, pinhole structures, and PMT detectors must be reliably fabricated, then aligned with precise focal lengths and pinhole apertures to focus directly into micro-/nanochannels or chambers. The task seems daunting, but the idea of seamlessly integrating all of these technological leaps in fluorescent microscopy is exciting!

Contact Temperature Sensors

Synonyms

Temperature probes; Temperature sensors; Thermistors

Definition

Contact temperature sensors represent a class of temperature probes that are used to determine the temperature of a medium through the thermal equilibrium attained between the sensor and the medium when in contact. The change in the medium temperature is inferred from a corresponding variation in the sensor resistance or output voltage that can be used to obtain the temperature difference via an *a priori* calibration of the sensor output with temperature. The commonly implemented contact temperature sensors include thermocouples, resistance temperature detectors (RTDs) and thermistors.

Definition

►Control, or more fully ►feedback control, refers to using measurements from system sensors to decide what actions should be taken by system actuators to perform a system task. So sensing, algorithm decisions, and actuation are performed in feedback, in a closed-loop, in real time. Feedback is ubiquitous in biology and in complex engineering systems: sensing and correcting for errors enables systems to carry out high performance tasks in the presence of uncertainty and noise. The theory and practice of feedback control is a research area in its own right.

This entry discusses applications and extensions of feedback control as applied to micro-fluidic systems. Broadly speaking, feedback control has been developed for electronic systems and mechanical, fluid, and chemical systems on the macro-scale, but not for micro-fluidic systems.

Chemical and Physical Principles

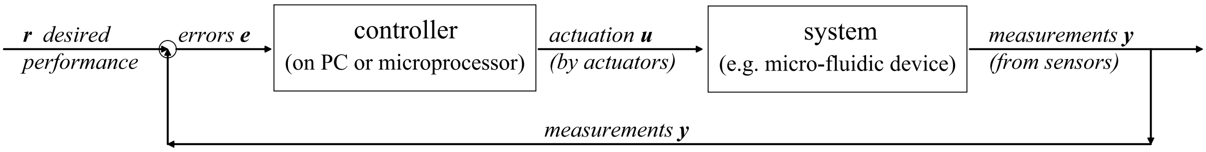
The basic principle of feedback control is shown schematically below. A system is observed by sensors that produce measurements (y) at each time; these measurements are compared to the desired performance of the system (r); and the difference between the desired (r) and actual state (y) is used to create an error ($e = r - y$); a controller, usually implemented on a computer or via analog circuitry, operates on this error to decide which actuation actions (u) should be applied to the system to change its state from where it is to where it should be.

This feedback (y to e to u to y to ...) repeats at each time and, if the controller is successfully designed, drives the system dynamics to their desired performance. Sensing and correcting for errors fundamentally enables high performance and complex robust behavior in the face of uncertainty. This is familiar to those who study engineering and biological systems. Feedback regulatory mechanisms enable cells to correct for and carry out their functions even when their environmental conditions change dramatically [1]. In complex engineering systems, closed-loop behavior can track desired performance even if system dynamics are incompletely known, there are system uncertainties, and there is noise in the measurements and the actuation actions [2, 3].

An introduction to ►control theory; with sample applications in biological, electronic, quantum, information, mechanical and aerospace systems, and robotics; and a discussion of the modeling that is necessary for control algorithm design can be found in Astrom and Murray [2]. A more limited discussion of implementing control for systems well described by linear dynamics can be found in [4]. Modern and future high-impact applications for control theory are discussed in the report [5]. Directions for and challenges in control of micro- and nano-scale systems are reviewed in the March 2004 NSF report [6, 7], organized and directed by the author of this entry.

Control theory is well-developed for systems well-described by linear models (see, for example, Zhou [8]). (A linear model is, essentially, one in which doubling the inputs, the actuator actions, will double the outputs, the measurements.) All systems are nonlinear, but for small excursions about equilibria or prescribed trajectories, many systems can be linearized and effectively controlled using linear control techniques. For systems that cannot be approximated as linear, nonlinear control techniques [9] are available to varying degrees of success for sub-classes of systems: for Hamiltonian systems (e. g., [10]), for nonlinear systems that can be made linear by a clever choice of variable transformation (e. g., [11], chapter 10 in [12]), or other system sub-classes. Nonlinear control design has been motivated by systems that commonly appear in applications: these have traditionally been in electronic circuits and mechanical, fluid, and chemical systems on the macro-scale.

Fundamental principles for effective control of MEMS, including micro-fluidic systems, have not yet been established. In micro-fluidics, there is a need to control the



Control of Micro-Fluidics, Figure 1 A simple and classic feedback loop example. The system and controller are connected in a closed-loop by measurements $y(t)$, errors $e(t)$, and resulting actuator actions $u(t)$. At each time t, errors are continually corrected by the actuation actions to drive the system to its desired performance $r(t)$

motion of bulk flows usually actuated through physical effects at fluid boundaries. For example, electroosmotic and electrowetting bulk flows are actuated by an electric field acting on a thin electrical double layer and modulating the surface tension forces at the edges of the bulk liquid respectively. Such scenarios are best modeled by ►partial differential equations (PDEs) for the fluid bulk flow, with system specific models for the actuation effects on the fluid boundaries. Hence the control design question is control of PDEs through their boundary conditions – a mathematically technical and difficult problem. Further, there is a need to control the behavior, distributions, and interactions of objects (cells, DNA fragments) and chemicals inside micro-fluidic systems, both in the bulk and at surfaces. Chemical species are described by diffusion, convection, and reaction PDEs, but chemical species and discrete objects may be described by other means: by random walk equations superposed on the flow (for particles in a flow), by thermo/mechanical equations appropriate for DNA chains, or by adsorption/ desorption equations at surfaces. So the control question is control of PDEs, coupled to PDE or other equations that describe objects and chemicals inside the liquid, all actuated through the PDE boundary conditions.

There is a community of researchers that focus on control of PDEs, see for example [13], but they have been motivated by applications in macro-scale fluid dynamics and chemical processes, and although their research contains valuable insights and technical results, their methods cannot be directly applied to micro-fluidic systems.

Key Research Findings

The broad key finding can be simply summarized: there is no general micro-fluidic controls tool yet, instead it is necessary to phrase each application task as a tractable control-design mathematical question, to find an implement an answer, and then to validate this answer experimentally.

For example, splitting of droplets accurately in an electrowetting system or steering of cells by flow control, both systems tasks described in words, must be phrased as a mathematics control-design questions in-line with the feedback diagram of Fig. 1. This requires quantifying the actuation (electrowetting or elecroosmotic), choosing and describing the sensing (e. g., vision based sensing), modeling the physics of the system, and then phrasing and solving the control design question.

Specific research findings are described within the context of two sample applications next.

Examples of Application

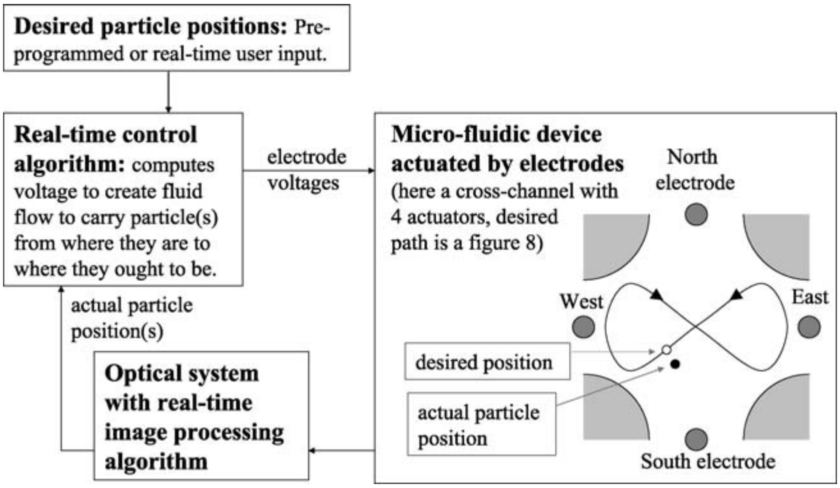
Independently Steering Multiple Cells by Routine Electroosmotic Actuation and Feedback Control

Exploiting feedback control we can use electroosmotic actuation, which is routine and easy to implement in micro-fluidic devices, to steer cells – a task usually reserved for expensive, delicate, and large laser-tweezer systems. Our results in this area are described in [14–18] and the text below is adapted from these sources.

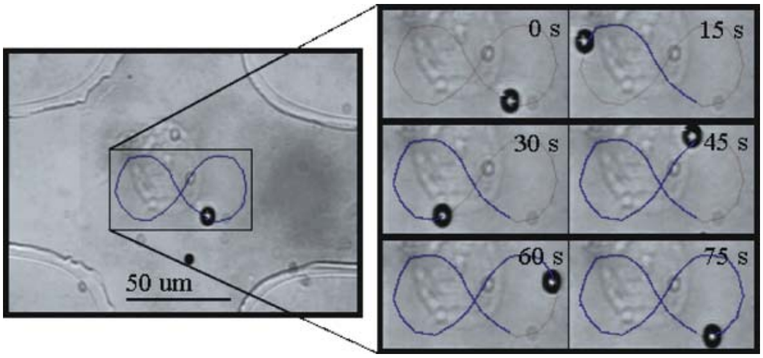
Our approach uses vision-based micro-flow control to steer particles by correcting for particle deviations – at each time we create a fluid flow to move the particles from where they are to where they should be. Figure 2 shows the basic control idea for a single particle: a micro-fluidic device, an optical observation system, and a computer with a control algorithm, are connected in a feedback loop. The vision system locates the position of the particle in real time, the computer then compares the current position of the particle with the desired (user input) particle position, the control algorithm computes the necessary actuator voltages that will create the electric field, or the fluid flow, that will carry the particle from where it is to where it should be, and these voltages are applied at electrodes in the micro-fluidic device. For example, if the particle is currently North/West of its desired location, then a South/East flow must be created. The process repeats at each time instant and forces the particle to follow the desired path.

Experimental steering of a bead along a figure ‘8’ path in a simple 4-channel PDMS device is shown in Fig. 3 (from [18]).

C



Control of Micro-Fluidics, Figure 2 Feedback control particle steering approach for a single particle. A micro-fluidic device with standard electroosmotic actuation is observed by a vision system that informs the control algorithm of the current particle position. The control algorithm compares the actual position against the desired position and finds the actuator voltages that will create a fluid flow, at the particle location, to steer the particles from where it is to where it should be. The process repeats continuously to steer the particle along its desired path



Control of Micro-Fluidics, Figure 3 Control of a bead with significant surface charge along a figure '8'. The bead has an approximate electrophoretic mobility of $c = (-57.3 \pm 5.6) \times 10^{-9} \mathrm{m}^2\mathrm{V}^{-1}\mathrm{s}^{-1}$. (By comparison, the electroosmotic mobility of our PDMS devices is $u = (36.5 \pm 3.6) \times 10^{-9} \mathrm{m}^2\mathrm{V}^{-1}\mathrm{s}^{-1}$.) Left: Photograph of the micro-fluidic devices with the figure '8' path super-imposed on the image. Right: The actual path of the chosen 5 μm polystyrene bead (Polysciences Inc.) (black circle) in the feedback control experiment. Snapshots are shown at 6 equally spaced times. The bead follows the required trajectory to within 3 μm

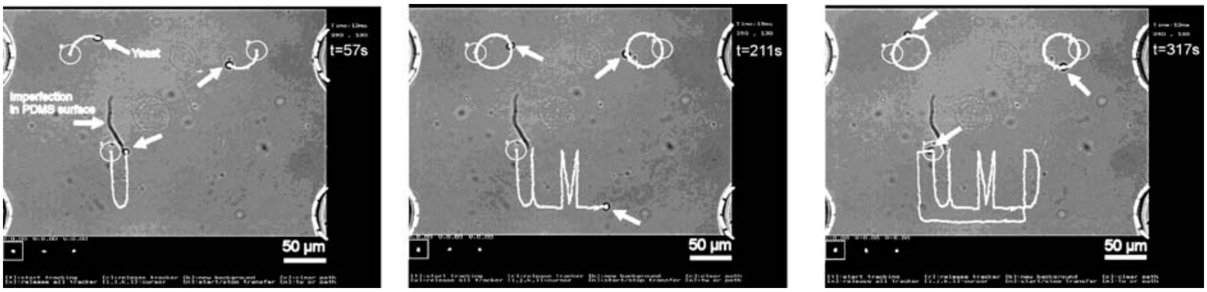
It is also possible to independently steer multiple particles at once. This requires a model of the electroosmotic actuation and fluid dynamics, and a more sophisticated control algorithm that essentially inverts the model at each moment: given desired velocities at each particle locations, it find the set of actuator voltages that will create a fluid flow that most nearly achieves those velocities. For an 8-channel device, where there are 7 fluid modes available for actuation (one of the electrodes acts as ground so only 7 degrees of freedom remain), different modes force particles at different locations in different directions. By intelligently actuating a combination of modes, we can force all the particles towards the right locations at each instant in time. Figure 4 shows steering of 3 yeast cells independently using such an 8-electrode PDMS device. It is also possible to trap all 3 cells, or to steer 1 or 2 while holding 2 or 1 cells stationary.

Modeling, control design, and experimental details are provided in [16, 18].

Control of Flows Driven by Electrically Actuated Surface Tension

In electrowetting-on-dielectric (EWOD) systems, the overall goal is precise and robust control of liquid motion. The following results are taken from [17, 19, 20].

In simulation, we have demonstrated the possibility of using the available electrodes in an EWOD system to actu-



Control of Micro-Fluidics, Figure 4 Steering of 3 yeast cells (5 µm diameter, Red Star, Giant Food) with small surface charge (electrophoretic mobility $c = (-23.3 \pm 6.9)10^{-9}\ \mathrm{m^2V^{-1}s^{-1}}$) around two circles and a 'UMD' path (for 'University of Maryland'). The yeast cells are visible as small black dots with a white center (the three target cells are marked with a white arrow in each image), and the white curves are the trajectories that the target cells have traced out. The three beads are being steered to within an accuracy of one pixel (corresponding to less than 1 µm)

ate a single droplet in such a way that the resulting fluid flow inside the drop will carry a particle around a figure 8 path or carry two particles along separating trajectories. Steering particles inside droplets introduces another level of functionality into electro-wetting systems. For example, cells can be precisely placed over local sensors or moved from one location to another at rates much faster than those created by diffusion. In addition, particles can be sorted inside a droplet and then separated by controlled splitting of the droplet.

Our steering results are demonstrated using an experimentally validated numerical model [20] of droplet motion inside the UCLA electrowetting system [21, 22]. This model of EWOD fluid dynamics includes surface tension and electrowetting interface forces, viscous low Reynolds 2-phase fluid flow, and the essential loss mechanisms due to contact angle saturation, triple point line pinning, and the related mechanism of contact angle hysteresis.

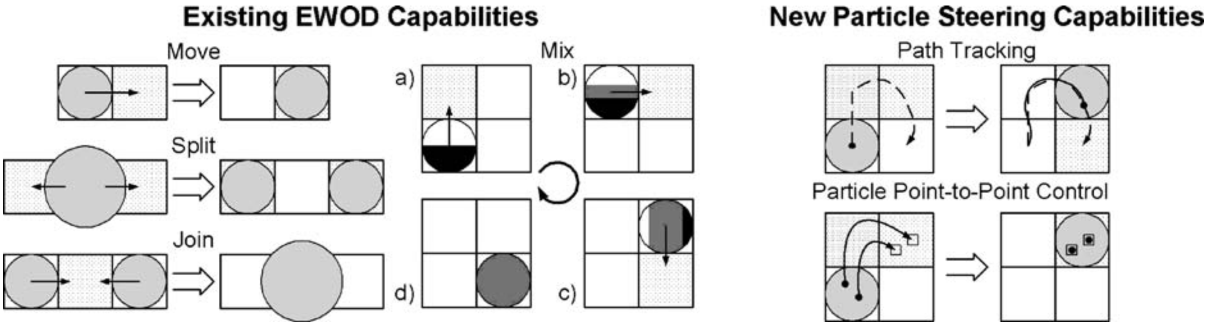
The electrode voltages in an EWOD device directly influence the pressure gradient field inside a droplet which, in turn, controls the velocity field [20, 23, 24]. This allows us to steer multiple particles inside droplets by manipulating the fluid flow field through the voltages. Therefore, the control problem is to find an electrode voltage sequence that creates a temporally and spatially varying flow field that will carry all the particles along their desired trajectories.

However, the particle motion depends on the droplet shape and the number of electrodes that the droplet overlays at any given moment. Since this is not known a priori, we use local estimation and control at each time step of our simulation to compute the pressure boundary conditions needed to realize the desired flow field. At each instant in time, the control algorithm is provided with the droplet shape and particle locations, as would be available through a vision sensing system. Any deviation of the particles from their desired trajectories that may arise from thermal fluctuations, external disturbances, and actuation errors is corrected using feedback of the particle positions. We now give an overview of our algorithm.

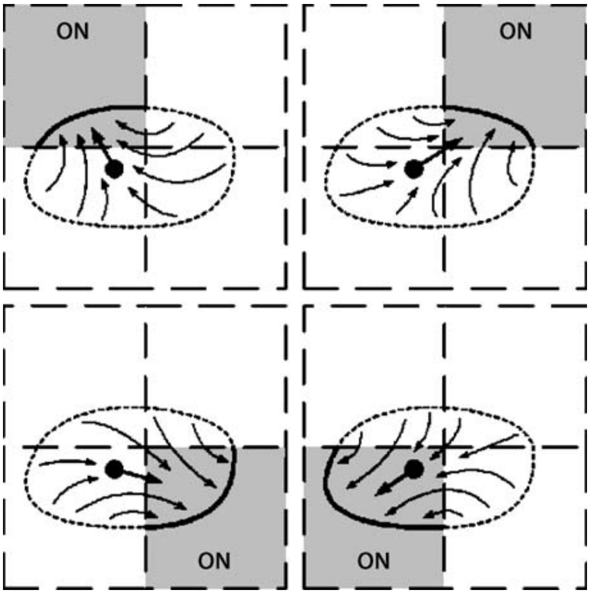
1. *Initialization*: Represent the desired trajectory of each particle as a set of points connected by straight line segments.
2. *Sensing*: Feed back the particle position data and the location of the droplet boundary to the control algorithm (as would be provided by the vision sensing system).
3. *Control algorithm part A*: Choose the desired velocity directions of each particle so that the particles will move towards and then along the desired trajectories.
4. *Control algorithm part B*: Solve a least squares problem for the necessary voltage actuations to induce a pressure gradient field that will create a flow field that will carry the particles along the desired directions obtained in step 3.
5. *Actuate*: Apply the computed control voltages at the current time step of our simulation and advance the simulation to the next time step. This updates the droplet shape and particle positions. Then go back to step 2 and repeat the feedback control loop.

Step 4 of the algorithm requires more elaboration. Since the pressure field obeys Laplace's equation, which is linear, we can consider linear combinations of pressure boundary conditions due to voltage actuation at the electrodes (see Fig. 6). The problem of computing the necessary boundary conditions to create a pressure gradient field to move the particles in the directions we want, leads to a least squares problem.

This least squares problem is defined next. First, knowing the current droplet configuration, we solve Laplace's equation for the pressure field inside the droplet due to a single active electrode. The pressure boundary conditions are defined to be one on the droplet boundary that lies over the active electrode and zero everywhere else (see Fig. 6).



Control of Micro-Fluidics, Figure 5 The EWOD system manipulates fluids by charging a dielectric layer underneath the liquid that effectively changes the local surface tension properties of the liquid/gas interface creating liquid motion. Existing (move, split, join, and mix) capabilities of electrowetting devices are shown schematically above alongside the new particle steering capability discussed in this entry. The view is from the top of the EWOD device. Shaded circles represent droplets of liquid. Squares are electrodes where the dotted hatching indicates the electrode is on. Directed lines specify the direction of motion. The multi-shaded droplet shows the diffusion and mixing of two chemicals, here mixing is enhanced by the fluid dynamics created inside the droplet due to its imposed motion



Control of Micro-Fluidics, Figure 6 Linear combination of pressure gradients for a single droplet overlaying four electrodes (small dashed squares). The diagram above shows a droplet in an EWOD system with four different instances of voltage actuation. In each instance, only one of the four electrodes is on. The particle floating inside the droplet (black dot) has a thick arrow indicating its direction of motion for each single electrode actuation. These arrows actually represent the opposite direction of the pressure gradient when a unit pressure boundary condition is set on the thick curve that overlays the shaded electrode, with zero pressure boundary conditions everywhere else. The thin curvy arrows show the fluid flow inside the droplet. Since the pressure field obeys Laplace's equation, it is linear and we can make the particle move in any desired direction by taking an appropriate linear combination of the four possible boundary conditions given above

From the pressure solution, the pressure gradient at each particle's position is computed. After repeating this for each electrode, we obtain a matrix of pressure gradients

$$G = -\begin{bmatrix} \nabla P_1(x_1, y_1) & \cdots & \nabla P_{\mathrm{N}}(x_1, y_1) \\ \vdots & \ddots & \vdots \\ \nabla P_1(x_{\mathrm{m}}, y_{\mathrm{m}}) & \cdots & \nabla P_{\mathrm{N}}(x_{\mathrm{m}}, y_{\mathrm{m}}) \end{bmatrix}, \qquad (1)$$

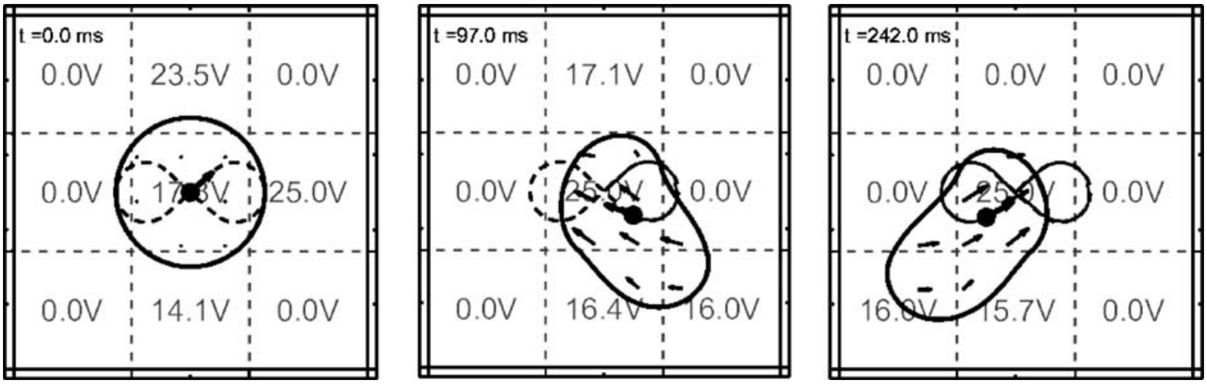
where $(x_{\mathrm{j}}, y_{\mathrm{j}})$ are the coordinates for the jth particle. Each column of pressure gradients $\nabla P_{\mathrm{k}}(x_{\mathrm{j}}, y_{\mathrm{j}})$ in the matrix corresponds to a single active electrode; each row to a single particle. The total number of particles is m and the number of available electrodes is N. The minus sign accounts for the direction of particle motion. (In the example of Fig. 6 the droplet overlays 4 electrodes and there is one particle, so $N = 4$ and $m = 1$.)

Next, we set the desired pressure gradient at particle j, $\nabla P_{\mathrm{D}}(x_j, y_j)$, equal to the desired velocity direction (denoted b) obtained in step 3 of our algorithm. This gives the following linear system

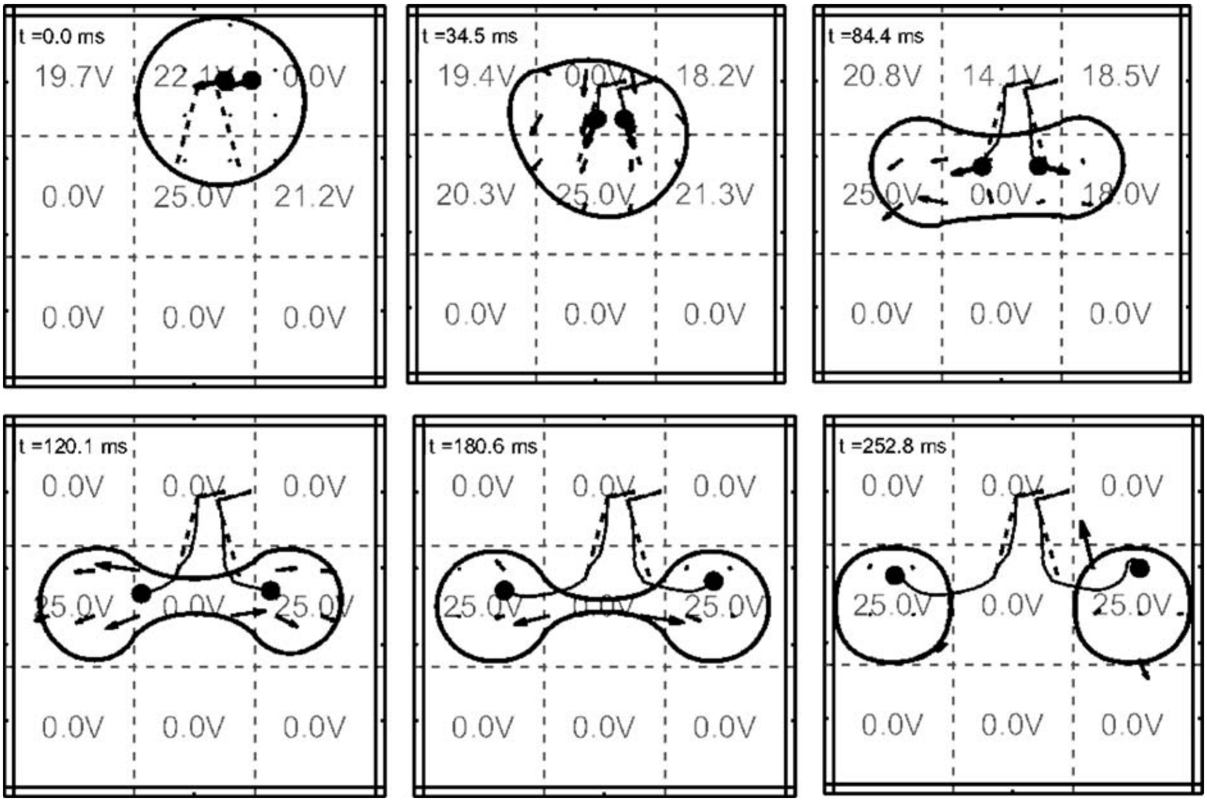
$$G\alpha = b\,, \quad \alpha = \begin{bmatrix} \alpha_1 \\ \vdots \\ \alpha_{\mathrm{N}} \end{bmatrix}, \quad b = \begin{bmatrix} \nabla P_{\mathrm{D}}(x_1, y_1) \\ \vdots \\ \nabla P_{\mathrm{D}}(x_{\mathrm{m}}, y_{\mathrm{m}}) \end{bmatrix}, \qquad (2)$$

where α is the vector of pressure boundary values that will achieve b. If $2m \geq N$, the number of particle degrees of freedom is greater than the available actuators and (in general) Eq. (2) cannot be solved exactly. A least squares solution is needed to obtain the best fit of actuations α. Otherwise, it is a pseudo-inverse problem, which has a solution as long as the matrix G has full row rank [25].

We solve Eq. (2) for α using the singular value decomposition (SVD) [25]. However, the range of boundary pressure actuations is limited by contact angle saturation. Using experimental data on the saturation characteristics for the



Control of Micro-Fluidics, Figure 7 Particle following a figure '8' path. In the simulation results above, we have a droplet (denoted by the thick black curve) lying on a 3×3 grid of electrodes (denoted by the dashed lines). The blue dashed curve is the desired figure '8' path and a black dot represents the particle with a thick red arrow pointing in the desired direction of travel. The red curve is the actual path of the particle. The black arrows inside the droplet denote the fluid velocity field inside the droplet. The voltages on the grid are time varying in such a way as to keep the particle moving along the desired path with less than 20 μm deviation



Control of Micro-Fluidics, Figure 8 Two-particle separation into two satellite drops (same format as in Fig. 7). Each particle first follows a trajectory that takes them away from each other. When there is sufficient distance between the two particles, our control algorithm turns off and the separation is completed by applying open loop voltages that split the droplet

UCLA EWOD device [22], we linearly map each component of the solution vector α so that these constraints are satisfied. As far as the steering algorithm is concerned, this mapping effectively changes the magnitude of b, which only affects the speed, and not the direction, of the particle motions. Hence, we choose the mapping so that the full dynamic range of boundary actuation is utilized, therefore maximizing the speed of the particles.

Finally, given that pressure on the boundary is directly related to the local contact angle [20], we again use experi-

mental data for the contact angle versus voltage characteristics of the EWOD device [22] to compute the electrode voltages needed to achieve the boundary pressures α. In general, there will be some uncertainty about the device parameters.

Simulations were run assuming the device characteristics described in [22]. A 3×3 electrode grid was used to actuate and control the droplet where each square electrode is 1.4 mm on a side. All voltage actuations in these simulations are within the limits of the UCLA EWOD device.

In Fig. 7, a droplet is shown moving in a way that makes a particle floating inside follow a figure '8' path. The droplet starts as a circle on the center electrode with a particle resting in its center. The voltages on the electrode grid are actuated using our algorithm and, throughout the motion, the droplet always overlaps enough electrodes to allow it to be controlled in a way that keeps the particle moving forward on the desired trajectory.

In Fig. 8, we demonstrate particle separation. A droplet starts in the first panel with two particles spaced 0.31 mm apart. Both particles follow separate diverging trajectories designed to stretch the droplet and separate the particles. Once the particles near the ends of their trajectories (see the third frame), our control algorithm turns off and we command an open loop voltage of 25 V on the middle left and right electrodes and zero volts everywhere else. This causes the droplet to split into two smaller drops, each of which contains a single particle. The reason for not using our control algorithm to complete the split is because of numerical instability. When both particles are in the lobes of the dumbbell shape of the pinching droplet, the available forcing at the particles' positions is fairly weak. This causes the condition number of the G matrix in Eq. (2) to degenerate and produce errors in the least squares solution. Therefore, we avoid this by commanding open loop voltages that will split the droplet [22].

Our simulations demonstrate the potential for performing particle placement and separation in the current UCLA EWOD devices with a reasonable number of electrodes. It is interesting to note that existing EWOD systems have enough control authority to steer a single particle along complex trajectories and to steer two particles along simple paths.

Convective Heat Transfer in Microchannels, Figure 1 Sketch of a straight microchannel with constant cross-section and Cartesian coordinate system

Definition

Convective heat transfer in microchannels is a process involving a forced mass movement of fluids through channels having hydraulic diameters less than 1 mm. The temperature difference between the microchannel walls and the fluid produces a net heat transfer that depends on the velocity and temperature gradient near the heated walls.

Overview

Single-phase forced convection through microchannels can be studied by determining the velocity distribution and the temperature field in the fluid region with the aid of the mass conservation principle (*continuity equation*), the fluid momentum balance equations and the energy balance equation [1]:

$$\begin{aligned} -\frac{1}{\rho}\frac{\mathrm{d}\rho}{\mathrm{d}t} &= \nabla\cdot\boldsymbol{v} \\ \rho\frac{\mathrm{d}\boldsymbol{v}}{\mathrm{d}t} &= -\nabla p + \rho\boldsymbol{g} - \nabla\cdot\tau - \boldsymbol{f}_{\mathrm{ext}} \\ \rho\frac{\mathrm{d}U}{\mathrm{d}t} &= -\nabla\cdot\boldsymbol{q} - p\ (\nabla\cdot\boldsymbol{v}) - \tau : \nabla\boldsymbol{v} + S_{\mathrm{g}} \end{aligned} \quad (1)$$

in which $\boldsymbol{v}$ is the velocity vector, ρ is the fluid density, t is the time, p is the pressure, $\mathrm{d}/\mathrm{d}t$ is the total derivative, τ is the viscous tensor, $\boldsymbol{f}_{\mathrm{ext}}$ denotes an external force per unit of volume, U is the specific internal energy of the fluid, S_{g} indicates a generic internal thermal source and $\boldsymbol{q}$ is the heat flux.
If we consider a steady-state, laminar, constant property (i. e. dynamic viscosity μ, specific heat c_{p}, thermal con-

ductivity k) flow in a straight microchannel of constant cross-sectional area (see Fig. 1), in the absence of free convection, mass diffusion and change of phase, the governing equations can be written as follows:

$$\mu\nabla^2 v_z = \frac{dp}{dz} + f_{ext,z} \tag{2}$$

$$\rho c_p v_z \frac{\partial T}{\partial z} = k\nabla^2 T + v_z \frac{\partial p}{\partial z} + \mu\Phi'_{inc} + S_g \text{ (ideal gases)} \tag{3}$$

$$\rho c_p v_z \frac{\partial T}{\partial z} = k\nabla^2 T + \beta T v_z \frac{\partial p}{\partial z} + \mu\Phi'_{inc} + S_g \text{ (liquids)} \tag{4}$$

Details about these balance equations can be found in the sections on ▶ viscous dissipation and ▶ pressure-driven single-phase liquid flow.

The expression of the viscous dissipation term for an incompressible fluid (Φ'_{inc}) with constant properties for different geometry coordinates can be found in the ▶ viscous dissipation entry.

Equations (3) and (4) differ only for the term related to the reversible work done by the fluid against the external pressure field (*flow work*). In general, Eq. (4) is written for liquids by neglecting the flow work term; this means considering $\beta = 0$ for liquids. This hypothesis is critically evaluated in the viscous dissipation entry; in fact, in microchannels, for liquids and gases, the flow work term can be important because the pressure gradient along the tube is in general very large, namely inversely proportional to the square of the hydraulic diameter of the channel.

In general $f_{ext,z}$ and S_g can be neglected in Eq. (2)–(4) if the external forces (i. e. electric forces), chemical and/or nuclear reactions are absent. On the contrary, for electro-osmotic flows these terms must be considered in the balance equations and they assume the following forms:

$$\begin{aligned} f_{ext,z} &= \rho_e E_z \\ S_g &= \lambda_0 E_z^2 \end{aligned} \tag{5}$$

in which E_z is the imposed electric potential gradient between the electrodes (expressed in V/m), ρ_e is the density of charge, λ_0 is the electrical conductivity (▶ electro-osmotic flow). These expressions underline that in an electro-osmotic flow where the fluid is moved by means of an imposed external electric potential gradient E_z there is a volumetric heat generation within the fluid linked to the Joule heating which is in turn related to the electric current induced in the fluid region.

Basic Methodology

Boundary Conditions

Velocity Problem

The boundary condition for the velocity problem (Eq. (2)) can be of three different kinds:

- The *no-slip condition*, valid for Newtonian liquids and for gases when the Knudsen number is less than 0.001 (▶ pressure-driven single-phase gas flows):

$$v_z|_\Gamma = 0 \tag{6}$$

  where Γ indicates the perimeter of the microchannel.
- The *slip condition*, valid for non-Newtonian liquids, like polymer solutions and surfactants, and for gases when the Knudsen number is greater than 0.001 (▶ pressure-driven single-phase gas flows):

$$v_{z,slip} = v_z|_\Gamma - v_{wall} = \xi \left.\frac{\partial v_z}{\partial n}\right|_\Gamma \tag{7}$$

  where ξ is a length commonly called the *coefficient of slip* and n is the normal direction, exiting the wall. The coefficient of slip is related to the nature of the fluid, to the status of the walls and to the temperature near the wall. For rarefied gases the slip condition can be written as follows:

$$v_z|_\Gamma - v_{wall} = \alpha \frac{2-\sigma_v}{\sigma_v}\lambda \left.\frac{\partial v_z}{\partial n}\right|_\Gamma \tag{8}$$

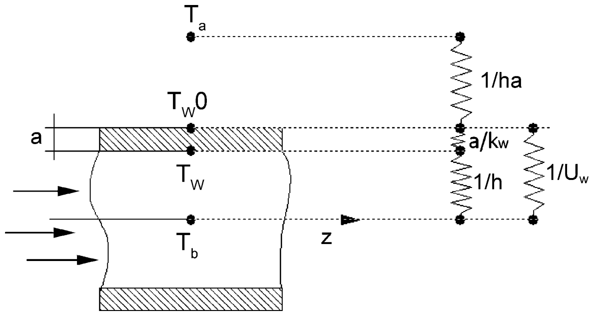
  in which σ_v is the momentum accommodation coefficient, λ is the molecular mean free path and α is a coefficient introduced by Cercignani to correct the original results of Maxwell. There exist more complicated expressions of this boundary condition (the so-called *second order slip boundary conditions*) but in this section these expressions are not taken into account.
- The *slug flow* condition for which the velocity field is considered as uniform in the whole cross-section:

$$v_z = W = const. \tag{9}$$

  This condition is particularly appropriate to analyze the convective heat transfer for ▶ electro-osmotic flows for which the velocity tends to become uniform on the cross-section.

Thermal Problem

In the *pure convection problem*, heat transfer through the wall is characterized by an appropriate thermal boundary condition directly or indirectly specified at the wall–fluid interface. In a pure convection problem the solution of the



Convective Heat Transfer in Microchannels, Figure 2 Thermal circuit representation of the resistance in a microchannel between the bulk temperature (T_b) and the outside temperature (T_a)

temperature problem for the solid wall is not needed: the velocity and temperature are determined only in the fluid region. However, the heat transfer through the solid walls of the microchannel by conduction may have significant normal and/or peripheral as well as axial components; or the wall may be of non-uniform thickness. In these cases the temperature problem for the solid wall needs to be analyzed simultaneously with that for the fluid in order to calculate the real wall–fluid interface heat flux distribution. In this case the wall–fluid heat transfer is referred to as *conjugate heat transfer*.

In a pure convection problem the thermal boundary conditions are the set of specifications describing temperature and/or heat flux at the inner wall of the microchannel.

The peripheral average heat transfer flux is strongly dependent on the thermal boundary conditions in the laminar regime, typical of microchannels, while very much less dependent in the turbulent flow regime. For this reason, for microchannels is very important to classify the thermal boundary conditions in order to model correctly the internal convective heat transfer.

In this work, the classification of the thermal boundary conditions proposed by Shah and London [2] will be used.

T Boundary Conditions

The thermal boundary condition in which the wall temperature is considered as axially constant and peripherally uniform is referred as the **T** boundary condition. In this case the boundary condition can be written as follows:

$$T|_{\Gamma} = T_{\mathrm{w}} = \text{const.} \tag{10}$$

This condition can be applied for micro-condensers and for micro-evaporators where an external two-phase flow sets as constant the wall temperature of the microchannels inside which a single-phase fluid flows.

With reference to Fig. 2, the thermal boundary condition for which the outer wall temperature ($T_{\mathrm{w},0}$) is considered axially constant while the wall heat flux is considered as linearly proportional to wall temperature peripherally is referred to as the **T3** boundary condition:

$$k\left.\frac{\partial T}{\partial n}\right|_{\Gamma} = U_{\mathrm{w}}\left(T_{\mathrm{w},0} - T|_{\Gamma}\right) \tag{11}$$

where U_{w} is the wall thermal transmittance. For a straight thin wall of uniform thickness a and thermal conductivity equal to k_{w}, U_{w} is given by

$$U_{\mathrm{w}} = \frac{k_{\mathrm{w}}}{a} \tag{12}$$

This boundary condition allows the analysis of micro-condensers and micro-evaporators with finite wall thermal resistance. It is evident that when U_{w} tends to infinity the **T3** boundary condition reduces to the **T** boundary condition.

With reference to Fig. 2, when the outer fluid (or the environment temperature) T_{a} can be considered axially constant while the wall heat flux is nonlinearly proportional to the wall temperature (*radiative heat transfer*) the boundary condition is referred to as **T4**:

$$k\left.\frac{\partial T}{\partial n}\right|_{\Gamma} = \varepsilon_{\mathrm{w}}\sigma_0\left(T|_{\Gamma}^4 - T_{\mathrm{a}}^4\right) \tag{13}$$

where ε_{w} is the emissivity of the external wall and σ_0 is the Stefan–Boltzmann constant.

In this case, the wall thermal resistance is considered negligible. This kind of thermal boundary condition can be used, for example, for micro-radiators working in space and manufactured with materials having a large value of thermal conductivity.

H Boundary Conditions

The thermal boundary conditions of approximately constant axial heat flow rate per unit length of the microchannel are referred as to **H** boundary conditions.

When the wall heat transfer rate is constant axially while the wall temperature at any cross-section z is constant in the peripheral direction, the boundary condition is referred to as **H1**:

$$\begin{aligned} q' &= \dot{m}c_{\mathrm{p}}\frac{\mathrm{d}T_{\mathrm{b}}}{\mathrm{d}z} = \text{const.} && \text{independent of z} \\ T|_{\Gamma} &= T_{\mathrm{w}} = \text{const.} && \text{independent of (x,y)} \end{aligned} \tag{14}$$

where $\dot{m}$ is the mass flow rate in the microchannel, q' is the wall heat transfer rate per unit of length of the microchannel and T_b is the bulk temperature defined as

$$T_b = \frac{1}{\dot{m}c_p} \int_{\Omega} \rho v_z c_p T \mathrm{d}\Omega \tag{15}$$

with Ω being the cross-sectional area of the microchannel (see Fig. 1).

This kind of boundary condition is very common in microchannels heated by means of electrical resistances and made of highly conductive materials like copper or silicon.

When the wall heat flux per unit of heat transfer area (q'') is constant in the axial as well the peripheral direction the boundary condition is referred to as **H2**:

$$\begin{aligned} q''\Gamma_h &= \dot{m}c_p \frac{\mathrm{d}T_b}{\mathrm{d}z} = \text{const.} \qquad && \text{independent of z} \\ k\frac{\partial T}{\partial n}\bigg|_{\Gamma} &= q'' = \text{const.} && \text{independent of (x,y,z)} \end{aligned} \tag{16}$$

where Γ_h is the heated perimeter of the microchannel. In this case the wall temperature is not constant peripherally but assumes the maximum value near the corner of the cross-section (if any).

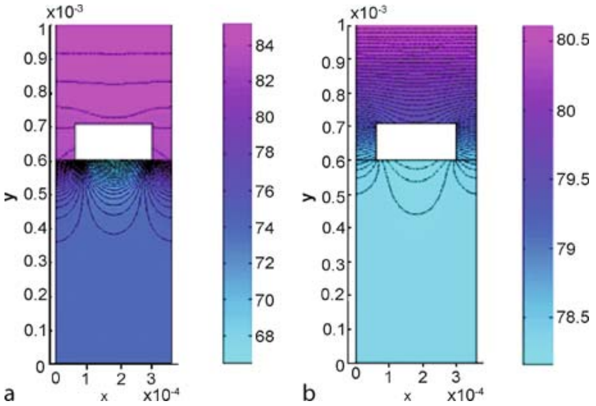
This kind of boundary condition enables one to model the convective heat transfer for microchannels heated electrically and made with very low conductive materials, like PMDS and so on, and with a uniform wall thickness.

For a constant wall heat transfer rate in the axial direction and the heat flux linearly proportional to the wall temperature in the peripheral direction the boundary condition is referred to as **H3**:

$$\begin{aligned} q' &= \dot{m}c_p \frac{\mathrm{d}T_b}{\mathrm{d}z} = \text{const.} \qquad && \text{independent of } z \\ k\frac{\partial T}{\partial n}\bigg|_{\Gamma} &= U_w \left(T_{w,0} - T|_{\Gamma}\right) \end{aligned} \tag{17}$$

The **H3** boundary condition contains the **H1** and **H2** boundary conditions as particular cases: in fact, when the wall transmittance U_w tends to zero the **H3** boundary condition reproduces the **H2** boundary condition. On the contrary, when the wall transmittance U_w tends to infinity the **H3** boundary condition approaches the **H1** boundary condition.

This kind of boundary condition is employed in modeling the convective heat transfer for microchannels heated electrically by taking into account a finite normal wall thermal resistance and negligible peripheral wall heat conduction.



Convective Heat Transfer in Microchannels, Figure 3 Temperature distributions in a ⟨110⟩ silicon wafer with a Pyrex glass cover (a) or a silicon cover (b)

When the axial wall heat flux varies exponentially along the flow length while the peripheral wall temperature is constant at a particular section z the boundary condition is referred to as **H5**:

$$\begin{aligned} q' &= q'_0 e^{m'z} \\ T|_{\Gamma} &= T_w = \text{const.} \qquad \text{independent of } (x, y) \end{aligned} \tag{18}$$

The **H5** boundary condition can be used to approximate parallel and counterflow micro-heat exchangers in which the fluid bulk temperature varies exponentially along the microchannel.

The thermal boundary conditions described above are schematically summarized in Tab. 1.

Temperature Jump Condition

For rarefied gases there exists a temperature discontinuity between the fluid and the walls of the channel. This temperature jump can be expressed as follows (*first-order condition*):

$$T|_{\Gamma} - T_w = \alpha_t \frac{2-\sigma_t}{\sigma_t} \frac{2\left(\frac{c_p}{c_v}\right)}{\left(\frac{c_p}{c_v}\right)+1} \frac{\lambda}{\Pr} \frac{\partial T}{\partial n}\bigg|_{\Gamma} \tag{19}$$

where α_t is a coefficient introduced by Cercignani to correct the original results of Maxwell and σ_t is the thermal accommodation coefficient that depends on the fluid and on the wall characteristics. This boundary condition has been used in order to study **T**, **H1** and **H2** boundary problems.

Convective Heat Transfer in Microchannels, Table 1 Thermal boundary conditions for internal forced convection in microchannels

	Description	Equations	Applications
T	Constant wall temperature peripherally as well as axially	$T\|_\Gamma = T_w = \text{const.}$	Micro-condensers, Micro-evaporators with negligible wall thermal resistance
T3	Constant axial wall temperature with finite normal wall thermal resistance	$k\left.\frac{\partial T}{\partial n}\right\|_\Gamma = U_w\left(T_{w,0} - T\|_\Gamma\right);\quad T_{w,0} = \text{const.}$	Micro-condensers, Micro-evaporators with finite wall thermal resistance
T4	Non linear radiant-flux	$k\left.\frac{\partial T}{\partial n}\right\|_\Gamma = \varepsilon\sigma_0\left(T\|_\Gamma^4 - T_a^4\right);\quad T_a = \text{const.}$	Micro-radiators in space power systems with negligible normal wall resistance
H1	Constant axial wall heat flux with constant peripheral wall temperature	$q' = \dot{m}c_p\frac{dT_b}{dz} = \text{const.}$ ind of z $T\|_\Gamma = T_w = \text{const.}$ ind of (x, y)	Microchannels heated by means of electrical resistances and made with highly conductive materials, like copper or silicon.
H2	Constant axial wall heat flux with uniform peripheral wall heat flux	$q''\Gamma = \dot{m}c_p\frac{dT_b}{dz} = \text{const.}$ ind of z $k\left.\frac{\partial T}{\partial n}\right\|_\Gamma = q'' = \text{const.}$ ind of (x, y, z)	Microchannels heated electrically and made with very low conductive materials, like PMDS and so on, and with a uniform wall thickness.
H3	Constant axial wall heat flux with finite normal wall thermal resistance	$q' = \dot{m}c_p\frac{dT_b}{dz} = \text{const.}$ ind of z $k\left.\frac{\partial T}{\partial n}\right\|_\Gamma = U_w\left(T_{w,0} - T\|_\Gamma\right)$	Microchannels heated electrically by taking into account a finite normal wall thermal resistance and a negligible peripheral wall heat conduction.
H5	Exponential axial wall heat flux	$q' = q_0' e^{mz}$ $T\|_\Gamma = T_w = \text{const.}$ ind of (x, y)	Parallel and counterflow micro heat-exchangers in which the fluid bulk mean temperature varies exponentially along the microchannel.

Heated Perimeter

The thermal boundary conditions can vary along the perimeter of a microchannel and the heated perimeter can differ for the wetted perimeter of the microchannel because some parts of it can be considered as adiabatic. In Fig. 3 the temperature distribution in a silicon substrate (k_s = 148 W/(m K)) having a thickness of 400 μm with a rectangular microchannel is depicted. The half distance between two adjacent microchannels is equal to 60 μm. The microchannel has a height (h) of 110 μm and a width (a) of 237 μm. Water (k = 0.607 W/(m K)) with a bulk temperature of 60° C flows through the channels in the laminar regime. The microchannels have an axially unchanging cross-section. A uniform wall heat flux q'' of 640 kW/m^2 is imposed as a boundary condition on the top of the silicon substrate while all the other outer walls are taken as adiabatic. In Fig. 3 are shown the temperature distributions in this device when the microchannel is closed by a cover with a thickness of 600 μm in Pyrex glass ($k_p = 1.13\, W/(m K)$) (Fig. 3a) or in silicon (Fig. 3b). As is evident, owing to the high thermal conductivity of the silicon, the temperature gradient in the silicon substrate is very limited and the temperature field is close to isothermal (see Fig. 3a). On the contrary, it is possible to observe that the isothermal lines in the Pyrex cover tend to become orthogonal to the microchannel wall; this means that the Pyrex wall of the rectangular microchannel can be considered *quasi-adiabatic* (Fig. 3a).

In conclusion, if a Pyrex cover is used to close silicon microchannels the silicon walls of the microchannels tend to work at constant temperature with an imposed constant heat flux; on the contrary, the Pyrex side can be considered adiabatic. Due to the high ratio between the thermal conductivity of the silicon and of the fluid (in this case $k_s/k = 247$) and its small hydraulic diameter, the microchannel can be conveniently studied as a *long duct* under a classical **H1** thermal boundary condition (theoretically valid for $k_s/k = \infty$). On the other hand, when a silicon cover is used to close the microchannel, all the boundaries can be considered as isothermal (see Fig. 3b); it is possible to use the **H1** thermal boundary condition, with the four sides at an imposed uniform temperature.

In Fig. 4 the most common combinations of adiabatic and heated walls in microchannels of different cross-sections (rectangular, trapezoidal and double trapezoidal) are depicted. Each combination is classified by means of a number that corresponds to the number of the heated sides of the microchannel.

Dimensionless Equations and Boundary Conditions

As highlighted by Shah and London [2], a natural tendency exists to use in convection problems a large num-

ber of different sets of dimensionless groups based on the analyst's particular normalization of the differential equations and boundary conditions. An effort to standardize the definitions of dimensionless groups for laminar flows through channels was made by Shah and London [2] some years ago. In this section, the normalization of the convection problems proposed by Shah and London will be followed.

The balance equations for steady-state, laminar, constant property (i. e. dynamic viscosity μ, specific heat c_p, thermal conductivity k) flow in a microchannel of constant cross-sectional area (see Fig. 1), in the absence of free convection, mass diffusion and change of phase, can be written in a dimensionless form by using the following dimensionless quantity:

$$\begin{aligned} &x^* = \frac{x}{D_\mathrm{h}};\; y^* = \frac{y}{D_\mathrm{h}};\; z^* = \frac{z}{D_\mathrm{h}\mathrm{RePr}} = \frac{z}{D_\mathrm{h}\mathrm{Pe}};\\ &v_z^* = \frac{v_z}{W};\; T^* = \frac{(T-T_0)}{\Delta T_\mathrm{ref}};\\ &\mathrm{Re} = \frac{\rho W D_\mathrm{h}}{\mu};\; \mathrm{Pr} = \frac{\mu c_\mathrm{p}}{k};\; f\mathrm{Re} = -\frac{D_\mathrm{h}^2}{2\mu W}\frac{\mathrm{d}p}{\mathrm{d}z};\\ &\mathrm{Br} = \frac{\mu W^2}{k\Delta T_\mathrm{ref}} \end{aligned} \tag{20}$$

in which Re is the Reynolds number, Pr the Prandtl number, Pe the Péclet number (= RePr), fRe is the Poiseuille number (defined as the product of the Fanning friction factor f and the Reynolds number Re, see ▶ pressure-driven single-phase liquid flows), Br is the Brinkman number, D_h is the hydraulic diameter $(= 4\Omega/\Gamma)$, and W is the average fluid velocity:

$$W = \frac{1}{\Omega}\int_\Omega v_z \,\mathrm{d}\Omega\,. \tag{21}$$

The dimensionless form of the momentum and of the energy balance is the following:

$$\nabla^{*2} v_z^* = -2f\mathrm{Re} + f^* \tag{22}$$

$$\begin{aligned} v_z^*\frac{\partial T^*}{\partial z^*} &= \frac{1}{\mathrm{Pe}^2}\frac{\partial^2 T^*}{\partial z^{*2}} + \nabla^{*2}T^*\\ &\quad - 2\mathrm{Br}f\mathrm{Re}\,v_z^* + \mathrm{Br}\Phi_\mathrm{inc}'^* + S_\mathrm{g}^* \quad \text{(ideal gases)} \end{aligned} \tag{23a}$$

$$\begin{aligned} v_z^*\frac{\partial T^*}{\partial z^*} &= \frac{1}{\mathrm{Pe}^2}\frac{\partial^2 T^*}{\partial z^{*2}}\\ &\quad + \nabla^{*2}T^* - 2\left(\beta\Delta T_\mathrm{ref}T^* + \beta T_0\right)\\ &\quad \times \mathrm{Br}f\mathrm{Re}\,v_z^* + \mathrm{Br}\Phi_\mathrm{inc}'^* + S_\mathrm{g}^* \quad \text{(liquids)} \end{aligned} \tag{23b}$$

where

$$\nabla^{*2} = \frac{\partial^2}{\partial x^{*2}} + \frac{\partial^2}{\partial y^{*2}};\quad S_\mathrm{g}^* = \frac{S_\mathrm{g}D_\mathrm{h}^2}{k\Delta T_\mathrm{ref}};\quad f^* = \frac{f_{\mathrm{ext},z}D_\mathrm{h}^2}{\mu W}. \tag{24}$$

The choice of ΔT_ref used to define the dimensionless temperature (T^*) and the Brinkman number is different for **T** and **H** thermal boundary conditions:

$$\Delta T_\mathrm{ref} = \begin{cases} (T_\mathrm{c} - T_0) & \text{with } T_\mathrm{c} = T_\mathrm{w} \quad [T]\,;\\ & \phantom{\text{with }} T_\mathrm{c} = T_{\mathrm{w},0} \quad [T3]\,;\\ & \phantom{\text{with }} T_\mathrm{c} = T_\mathrm{a} \quad [T4]\\ \frac{q_\mathrm{c}}{k} & \text{with } q_\mathrm{c} = q' \quad [H1, H3, H5]\,;\\ & \phantom{\text{with }} q_\mathrm{c} = q''D_\mathrm{h} \quad [H2] \end{cases} \tag{25}$$

As an example, by combining Eqs. (24) and (5) it is possible to demonstrate that a new dimensionless group must be introduced to study the velocity field for electro-osmotic flows:

$$F = \frac{\rho_e E_z D_\mathrm{h}^2}{\mu W} \tag{26}$$

where ρ_e is a characteristic value of the density of the electric charge $(\rho_e = ezn_0)$, and in order to study forced convection of electro-osmotic flows the source term in Eqs. (23a) and (23b) suggests the introduction of the following new dimensionless group:

$$M_z = \frac{E_z^2\lambda_0 D_\mathrm{h}^2}{k\Delta T_\mathrm{ref}} \tag{27}$$

in which ΔT_ref depends on the thermal boundary conditions by following Eq. (25).

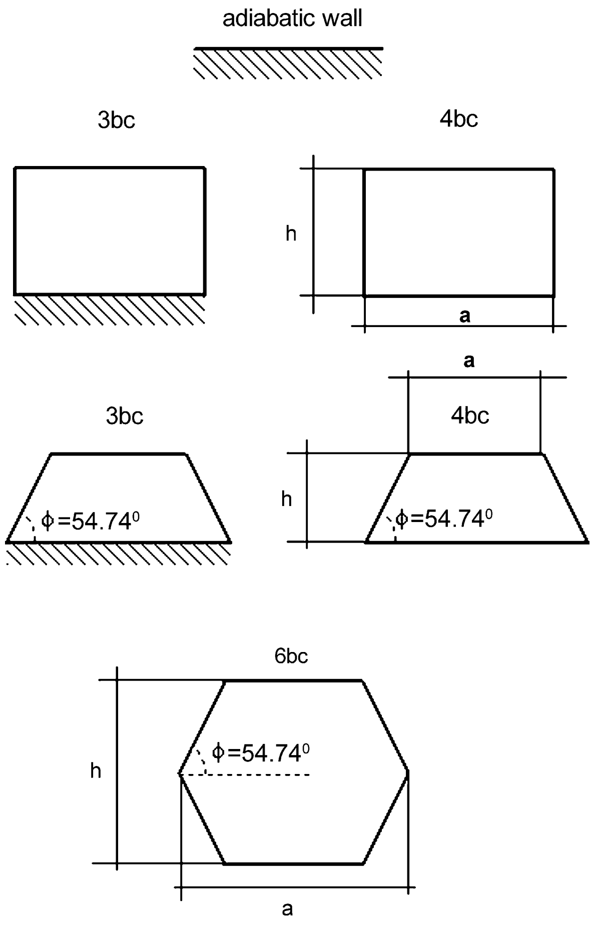
By using the dimensionless quantities of Eq. (20), it is possible to demonstrate that the boundary conditions written in dimensionless form introduce new dimensionless groups:

- The *slip flow* condition introduces the following dimensionless group:

$$\xi^* = \frac{\xi}{D_\mathrm{h}} \tag{28}$$

For rarefied gases, by using Eq. (8), it is possible to demonstrate that the slip flow condition leads to the Knudsen number, defined as the ratio between the molecular mean free path (λ) and the hydraulic diameter of the channel $(\mathrm{Kn} = \lambda/D_\mathrm{h})$.

C



Convective Heat Transfer in Microchannels, Figure 4 Combination of heated and adiabatic walls considered for each geometry investigated

- The **T3** and **H3** boundary conditions introduce the dimensionless wall thermal resistance:

$$R_{\mathrm{w}} = \frac{k}{U_{\mathrm{w}} D_{\mathrm{h}}} \tag{29}$$

- The **T4** boundary condition introduces the following dimensionless group:

$$\gamma = \varepsilon_{\mathrm{w}} \sigma_0 T_{\mathrm{e}}^3 D_{\mathrm{h}} / k \tag{30}$$

  where T_{e} is the absolute fluid inlet temperature.
- The **H5** boundary condition introduces the following dimensionless group:

$$m = m' D_{\mathrm{h}} \mathrm{RePr} = m' D_{\mathrm{h}} \mathrm{Pe} \tag{31}$$

The Nusselt Number

The main goal of the solution of the balance equations described above is to calculate the convective heat transfer coefficient defined as follows:

$$q'' = -k \left.\frac{\partial T}{\partial n}\right|_{\Gamma} = h \left(T|_{\Gamma} - T_{\mathrm{b}} \right) \tag{32}$$

in which T_{b} is the bulk temperature defined by Eq. (13) and $T|_{\Gamma}$ and $\partial T/\partial n|_{\Gamma}$ are the local values of the fluid temperature and the normal gradient at the wall respectively. The convective heat transfer coefficient makes it possible to describe the heat flux at a local point on the heated perimeter. The ratio of the convective heat transfer coefficient and the pure molecular thermal conductance is defined as Nusselt number:

$$\mathrm{Nu} = \frac{h}{k/D_{\mathrm{h}}} \tag{33}$$

If one knows the dimensionless temperature distribution in the fluid region, the local value of the Nusselt number in a point on the heated perimeter can be calculated from its operational definition:

$$\mathrm{Nu} = -\frac{\left.\frac{\partial T^*}{\partial n^*}\right|_{\Gamma^*}}{T^*|_{\Gamma^*} - T_{\mathrm{b}}^*} \tag{34}$$

where $\Gamma_{\mathrm{h}}^* = \Gamma_{\mathrm{h}}/D_{\mathrm{h}}$ is the dimensionless heated perimeter. The peripherally average, but axially local, Nusselt number is defined by

$$\overline{\mathrm{Nu}} = -\frac{\int_{\Gamma_{\mathrm{h}}^*} \left.\frac{\partial T^*}{\partial n^*}\right|_{\Gamma^*} \mathrm{d}\Gamma^*}{\Gamma_{\mathrm{h}}^* \left(T_{\mathrm{wm}}^* - T_{\mathrm{b}}^* \right)} \tag{35}$$

in which the dimensionless peripheral mean wall temperature T_{wm}^* has been used with

$$T_{\mathrm{wm}}^* = \frac{\int_{\Gamma_{\mathrm{h}}^*} T^*|_{\Gamma^*} \mathrm{d}\Gamma^*}{\Gamma_{\mathrm{h}}^*} \tag{36}$$

By observing the dimensionless form of the balance equations (Eqs. (22), (23)) and bearing in mind the dimensionless groups that can be introduced by the boundary conditions it is easy to demonstrate that the average Nusselt number in the laminar regime can be considered, for a fixed cross-sectional geometry, as a function of the following dimensionless quantities:

$$\overline{\mathrm{Nu}} = \overline{\mathrm{Nu}}(z^*, \mathrm{Br}, \mathrm{Pe}, \beta \Delta T_{\mathrm{ref}}, S_{\mathrm{g}}^*, f^*, \xi^*, R_{\mathrm{w}} |\, m |\, \gamma) \tag{37}$$

For example, for an incompressible liquid ($\beta = 0$) with negligible viscous dissipation ($\mathrm{Br} = 0$) and no-slip condition at the walls ($\xi^* = 0$) without significant fixed external forces ($f^* = 0$) and internal heat sources ($S_{\mathrm{g}}^* = 0$) under an **H3** thermal boundary condition, the average Nusselt

number can be considered as a function of the following dimensionless quantities:

$$\overline{\mathrm{Nu}} = \overline{\mathrm{Nu}}(z^*, \mathrm{Pe}, R_\mathrm{w}) \tag{38}$$

The laminar flow inside a microchannel is considered *thermally fully developed* when the following equation is satisfied by the fluid temperature:

$$\frac{\partial}{\partial z^*}\left[\frac{T^*_\mathrm{wm} - T^*}{T^*_\mathrm{wm} - T^*_\mathrm{b}}\right] = 0\,. \tag{39}$$

In this case $\overline{\mathrm{Nu}}$ becomes independent to z^*. It is important to remark that the flow is always thermally developing for *conjugate problems*.

The effects related to the thermal entrance region are not considered in this section *entrance Region and developing flows*.

For a thermally fully developed laminar flow, for a fixed dynamic and thermal boundary condition and by neglecting the fluid axial conduction ($\mathrm{Pe} \to \infty$), viscous dissipation ($\mathrm{Br} = 0$), the flow work ($\beta = 0$) and electro-osmotic phenomena ($S^*_\mathrm{g} = f^* = 0$), the Nusselt number depends on the cross-sectional geometry (through the Poiseuille number $f\mathrm{Re}$) only.

The Nusselt number (Nu) can be used in order to optimize the thermal performances of microchannels with different cross-section together with the Poiseuille number ($f\mathrm{Re}$); for this comparison, Shah and London have introduced the *area goodness factor* defined as follows:

$$\frac{j}{f} = \frac{\mathrm{Nu}\,\mathrm{Pr}^{-1/3}}{f\mathrm{Re}} \tag{40}$$

Under the hypotheses that $\mathrm{Pe} = \mathrm{Br} = \beta = S^*_\mathrm{g} = f^* = 0$, from the equality in Eq. (40) it is evident that this factor is a constant for the fully developed laminar flow of a specified fluid. Since the dimensionless quantities j and f are independent of the scale of the geometry (D_h), the area goodness factor j/f for different microchannels represents the influence of the geometric factors on the pressure losses and the heat transfer and allows the comparison of the thermal hydraulic performances of microchannels having different cross-sections. In the viscous dissipation section a comparison of the thermal performances of rectangular and trapezoidal microchannels by means of the *area goodness factor* is presented.

Laminar Flow

The solution of Eqs. (22)–(23) with the appropriate dynamic and thermal boundary conditions allows one to obtain the velocity and temperature distribution inside the microchannel for laminar fully developed flows. The analytical solution of Eqs. (22)–(23) has been obtained only for a few cross-sectional geometries. The numerical approach enables the calculation of the local and the average Nusselt number by means of which the internal convective heat transfer coefficients in microchannels can be computed.

Circular Cross-Section

T Boundary Conditions

For circular cross-sections the average value of the Nusselt number has been computed for different thermal boundary conditions. The value of the average Nusselt number for the **T** boundary condition can be found in many textbooks; $\overline{\mathrm{Nu}}_\mathrm{T} = 3.656735$ for the case of pressure driven with negligible external volume forces ($f_{\mathrm{ext,z}} = 0$), axial heat conduction ($\mathrm{Pe} \to \infty$), viscous dissipation ($\mathrm{Br} = 0$), flow work ($\beta = 0$) and thermal energy sources ($S_\mathrm{g} = 0$) within the fluid. In the same conditions but for a slug flow the value of the average Nusselt number is $\overline{\mathrm{Nu}}_{\mathrm{T,sf}} = 5.783$. By including the effect of axial conduction in the fluid the fully developed average Nusselt number becomes a function of the Péclet number. An approximate relation by means of which $\overline{\mathrm{Nu}}_\mathrm{T}$ can be calculated as a function of Péclet number is the following:

$$\overline{\mathrm{Nu}}_\mathrm{T} = \begin{cases} 3.6568\left(1 + \frac{1.227}{\mathrm{Pe}^2}\right) & \mathrm{Pe} > 5 \\ 4.1807\,(1 - 0.0439Pe) & \mathrm{Pe} < 1.5 \end{cases} \tag{41}$$

For the **T3** boundary condition the average Nusselt number for fully developed laminar flow with negligible external volume forces ($f_{\mathrm{ext,z}} = 0$), axial heat conduction ($\mathrm{Pe} \to \infty$), viscous dissipation ($\mathrm{Br} = 0$), flow work ($\beta = 0$) and thermal energy sources ($S_\mathrm{g} = 0$) within the fluid is a function of the dimensionless wall thermal resistance R_w; the values of $\overline{\mathrm{Nu}}_{\mathrm{T3}}$ as a function of R_w are quoted in Tab. 2. When R_w tends to zero the Nusselt number tends to the value taken under **T** boundary conditions. On the contrary, for $R_\mathrm{w} \to \infty$ the Nusselt number tends to the value of the **H** boundary condition (48/11). In Tab. 3 the values of $\overline{\mathrm{Nu}}_{\mathrm{T3}}$ are tabulated as a function of the dimensionless wall thermal resistance R_w and the Péclet number by taking into account the axial conduction in the fluid.

For radiant flux boundary condition **T4** the average value of the Nusselt number can be calculated by using the following relation:

$$\overline{\mathrm{Nu}}_{\mathrm{T4}} = \frac{8.728 + 3.66\gamma\left(\dfrac{T_\mathrm{a}}{T_\mathrm{e}}\right)^3}{2 + \gamma\left(\dfrac{T_\mathrm{a}}{T_\mathrm{e}}\right)^3} \tag{42}$$

1	4.223
∞	4.364

where T_a is the absolute outer fluid temperature (see Fig. 2), γ is defined by Eq. (30) and T_e is the absolute fluid inlet temperature.

Tunc and Bayazitoglu [3] have calculated for the **T** case the fully developed Nusselt numbers for microtubes through which a rarefied gas flows by taking into account the viscous dissipation but neglecting axial conduction in the fluid and the flow work. They defined the Brinkman number (Eq. (20)) with $\Delta T_{ref} = T_e - T|_\Gamma$ and used in the slip boundary conditions (Eqs. (8) and (19)) $\alpha = \sigma_v = \alpha_t = \sigma_t = 1$. The values of the Nusselt number for fully developed laminar flow determined by Tunc and Bayazitoglu [3] are quoted in Tab. 4 for $\mathrm{Br} = 0$ and $\mathrm{Br} = 0.01$ as a function of the Prandlt number and of the Knudsen number.

From the data it is clear that the Nusselt number decreases when the Knudsen number increases for a fixed Prandlt number. The rarefaction of the gas decreases the intensity of the heat transfer. When the Prandlt number increases for a fixed Knudsen number, the Nusselt number increases; this means that the convective heat transfer is enhanced for gases with larger Prandlt numbers. When the viscous dissipation increases the Nusselt number tends to increase. In fact, the increase of the viscous dissipation tends to increase the bulk temperature of the fluid. For a **T** boundary condition, since the Nusselt number is linked to the inverse of the difference between the wall temperature and the bulk temperature, an increase of the bulk temperature reduces this difference and increases the Nusselt number.

H Boundary Conditions

In the circular geometry there are no differences between **H1**, **H2** and **H3** boundary conditions in terms of Nusselt numbers. The Nusselt number can be expressed as

$$\overline{\mathrm{Nu}}_H = \frac{48}{11}\left(\frac{1}{1 + (3/44)\, S_g^* + (48/11)\,\mathrm{Br}}\right) \tag{43}$$

where S_g^* and Br are defined by Eqs. (24) and (20) respectively with ΔT_{ref} equal to $q'' D_h/k$. Axial conduction within the fluid is constant for the **H** boundary condition and consequently it does not affect the Nusselt number. Thus, in this case the Nusselt number is independent of the Péclet number.

The values of the Nusselt number for the **H5** boundary condition are quoted in Tab. 5 as a function of the parameter m defined by Eqs. (18) and (31). The data of Tab. 5 highlight how the **T** and **H** boundary conditions can be seen as particular cases of the H5 boundary condition for $m = -4\overline{\mathrm{Nu}}_T = -14.627$ and $m = 0$ respectively.

For slug flow the Nusselt number in the case of pressure-driven flow with negligible external volume forces ($f_{ext,z} = 0$), axial heat conduction ($\mathrm{Pe} \to \infty$), viscous dissipation ($\mathrm{Br} = 0$), flow work ($\beta = 0$) and thermal energy sources ($S_g = 0$) within the fluid is $\overline{\mathrm{Nu}}_{H,sf} = 8$.

Tunc and Bayazitoglu [3] have calculated in the **H** case the fully developed Nusselt numbers for microtubes through which a rarefied gas flows by taking into account the viscous dissipation but neglecting axial conduction in the fluid and flow work. They defined the Brinkman number (Eq. (20)) with $\Delta T_{ref} = q'' D_h/k$ and used in the slip boundary conditions (Eq. (8) and (19)) $\alpha = \sigma_v = \alpha_t = \sigma_t = 1$. The values of the Nusselt number for fully developed laminar flow determined by Tunc and Bayazitoglu [3] are quoted in Tab. 6 for $\mathrm{Br} = 0$, $\mathrm{Br} = -0.01$ and $\mathrm{Br} = 0.01$ as a function of the Prandlt number and of the Knudsen number. Negative values of the Brinkman number mean that the microchannel is cooled. By observing these data it is evident that the Nusselt number decreases when the Knudsen number increases for a fixed Prandlt number. The rarefaction of the gas decreases the intensity of the heat transfer. When the Prandlt number increases for a fixed Knudsen number the Nusselt number increases. The convective heat transfer is enhanced for gases with larger Prandlt numbers. When the viscous dissipation increases the Nusselt number tends to decrease; this trend is in disagreement with the behavior evidenced when the microtube is subjected to the **T** boundary condition.

The value of the Nusselt numbers obtained for the same conditions mentioned above but for slug flow can be calculated analytically as a function of the aspect ratio by means of the following relations for three and four heated walls:

$$\overline{\mathrm{Nu}}_{\mathrm{T,3bc,sf}} = \frac{\pi^2\left(4\delta^2+1\right)}{2\,(1+\delta)\,(1+2\delta)}$$
$$\overline{\mathrm{Nu}}_{\mathrm{T,4bc,sf}} = \frac{\pi^2\left(\delta^2+1\right)}{(1+\delta)^2} \qquad (44)$$

No data exist for **T3** and **T4** boundary conditions in the fully developed region.

H Boundary Conditions

In Tab. 8 the values of the Nusselt number for **H1** and **H2** boundary conditions (with three (3bc) and four (4bc) heated walls) in the case of pressure-driven flow with negligible external volume forces ($f_{\mathrm{ext,z}} = 0$), axial heat conduction ($\mathrm{Pe} \to \infty$), viscous dissipation ($\mathrm{Br} = 0$), flow work ($\beta = 0$) and thermal energy sources ($S_{\mathrm{g}} = 0$) within the fluid is quoted as a function of the aspect ratio δu.

For slug flow under **H1** boundary condition, in the case of pressure-driven flow with negligible external volume forces ($f_{\mathrm{ext,z}} = 0$), axial heat conduction ($\mathrm{Pe} \to \infty$), viscous dissipation ($\mathrm{Br} = 0$), flow work ($\beta = 0$) and thermal energy sources ($S_{\mathrm{g}} = 0$) within the fluid the Nusselt number can be calculated analytically as a function of the aspect ratio:

$$\overline{\mathrm{Nu}}_{\mathrm{H1,3bc,sf}} = \pi^6 \Big/ \left[128\,(1+\delta)\,(2\delta+1) \times \sum_{n=1,\mathrm{odd}}^{\infty} \sum_{m=1,\mathrm{odd}}^{\infty} \frac{1}{n^2 m^2\left(4m^2+\delta^2 n^2\right)}\right] \qquad (45)$$

$$\overline{\mathrm{Nu}}_{\mathrm{H1,4bc,sf}} = \pi^6 \Big/ \left[64\,(1+\delta)^2 \times \sum_{n=1,\mathrm{odd}}^{\infty} \sum_{m=1,\mathrm{odd}}^{\infty} \frac{1}{n^2 m^2\left(m^2+\delta^2 n^2\right)}\right] \qquad (46)$$

For slug flow under **H2** boundary conditions it is possible to demonstrate that the Nusselt number in the 4bc case (four heated sides) is independent of the aspect ratio and its value is 6. The Nusselt number for slug flow with three heated sides can be calculated by means of the following analytical expression:

$$\mathrm{Nu}_{\mathrm{H2,3bc,sf}} = 3\frac{(2\delta+1)}{(1+\delta)} \qquad (47)$$

In Tab. 9 the fully developed Nusselt numbers for rectangular microchannels in which rarefied gases flow under the **H1** boundary condition with four heated sides (4bc) are quoted. These values are obtained for a gas having $\mathrm{Pr} = 0.7$ by neglecting viscous dissipation, axial conduction and flow work and using in the slip boundary conditions (Eqs. (8) and (19)) $\alpha = \sigma_v = \alpha_t = \sigma_t = 1$. It is evident that the Nusselt number decreases when the Knudsen number increases and it tends to increase when the aspect ratio decreases.

Tunc and Bayazitoglu [4] have calculated in the case **H2** (4bc) the fully developed Nusselt numbers for rectangular microchannels through which a rarefied gas flows by neglecting the viscous dissipation, axial conduction in the fluid and the flow work. They used in the slip boundary conditions (Eqs. (8) and (19)) $\alpha = \sigma_v = \alpha_t = \sigma_t = 1$. The values of the Nusselt number for fully developed laminar flow determined by Tunc and Bayazitoglu [4] are quoted in Tab. 10 as a function of the aspect ratio δ, of the Prandlt number and of the Knudsen number for four sides heated (4bc). By observing these data it is evident that

the Nusselt number decreases when the Knudsen number increases for a fixed Prandlt number. The rarefaction of the gas decreases the intensity of the heat transfer. When the Prandlt number increases for a fixed Knudsen number, the Nusselt number increases. The convective heat transfer is enhanced for gases with larger Prandlt numbers and for square microchannels ($\delta \to 1$). By comparing Tab. 9 with Tab. 10 it is evident that the Nusselt number for the **H1** boundary condition is larger than those calculated for the **H2** boundary condition.

Convective Heat Transfer in Microchannels, Figure 5 Nusselt numbers as a function of the electro-osmotic diameter (kD_h) for rectangular microchannels. The filled symbols denote an aspect ratio $\delta = 0.25$, whereas the open symbols are for $\delta = 0.50$.The superscript sf stands for 'slug flow'

a rectangular cross-section with four sides heated (4bc) are depicted in Fig. 5 as a function of M_z (*Joule heating*) and the dimensionless electro-osmotic diameter:

$$kD_h = D_h \sqrt{\frac{2 n_0 z^2 e^2}{\varepsilon_r \varepsilon_0 k_B T}} \tag{48}$$

This parameter gives the magnitude of the diffuse layer thickness. It can be demonstrated that the value of the dimensionless electrokinetic potential for a given cross-section is strongly dependent on the product kD_h. Viscous dissipation, axial conduction and flow work are considered negligible.

It can be noticed how the presence of Joule heating reduces the value of the Nusselt number dramatically, while a decrease in the value of the aspect ratio δ dampens this effect. The value of the Nusselt number for a perfectly flat velocity profile (*slug flow*) for a rectangular duct, Nu_{sf}, is also plotted in Fig. 5 for the rectangular cross-section

considered. It is evident that the values of the Nusselt number approach the corresponding $\mathrm{Nu_{sf}}$ when kD_h increases, so much more so the lower the value of M_z.

Trapezoidal Cross-Section

It is well known that with photo-lithographic-based process one can obtain microchannels having a cross-section fixed by the orientation of the wafer crystal planes; for example, the microchannels etched in ⟨100⟩ silicon using a KOH solution have a trapezoidal cross-section with an apex angle of 54.74° imposed by the crystallographic morphology of the ⟨100⟩ silicon. By gluing together two KOH-etched trapezoidal silicon microchannels one can obtain microchannels having a double-trapezoidal cross-section (see Fig. 4). This kind of microchannel is investigated in this section.

Only numerical solutions have been published in the open literature for this kind of geometry.

T Boundary Conditions

Nonino et al. [5] computed numerically the value of the laminar fully developed average Nusselt number for trapezoidal and double trapezoidal KOH-etched microchannels under the **T** boundary condition with four and six heated sides respectively. They found that $\overline{\mathrm{Nu}}_\mathrm{T} = 2.7701$ for a trapezoidal microchannel with $\delta = 1$ and $\overline{\mathrm{Nu}}_\mathrm{T} = 3.3247$ for a double trapezoidal microchannel with $\delta = 0.828$. Further numerical investigations are required in order to investigate the role of the aspect ratio on the Nusselt number.

H Boundary Conditions

In Tab. 11 the values assumed by the Nusselt number for **H1** boundary conditions with three (3bc) and four (4bc) heated walls in the case of pressure-driven flow with negligible external volume forces ($f_{\mathrm{ext,z}} = 0$), axial heat conduction ($\mathrm{Pe} \to \infty$), viscous dissipation ($\mathrm{Br} = 0$), flow work ($\beta = 0$) and thermal energy sources ($S_\mathrm{g} = 0$) within the fluid is quoted as a function of the aspect ratio δ defined as h/a ratio (see Fig. 4).

In Tab. 12 the fully developed value of the Nusselt number for double-trapezoidal KOH-etched microchannels with six sides heated (6bc) are presented as a function of the aspect ratio δ defined as h/a ratio (see Fig. 4). For slug flow under **H1** boundary conditions, in the case of pressure-driven flow with negligible external volume forces ($f_{\mathrm{ext,z}} = 0$), axial heat conduction ($\mathrm{Pe} \to \infty$), viscous dissipation ($\mathrm{Br} = 0$), flow work ($\beta = 0$) and thermal energy sources ($S_\mathrm{g} = 0$) within the fluid the Nusselt numbers for KOH-etched trapezoidal and double-trapezoidal

Convective Heat Transfer in Microchannels, Table 11 Nusselt numbers $\overline{Nu}_{H1}$ for laminar fully developed flow for a KOH-etched trapezoidal cross-section with three (3bc) and four (4bc) heated sides as a function of the aspect ratio δ for the **H1** boundary condition

microchannels are quoted in Tab. 13 and 14 respectively as a function of the aspect ratio δ.

In Tab. 15 the fully developed Nusselt numbers for trapezoidal microchannels in which rarefied gases flow under the H1 boundary condition with four heated sides (4bc) are quoted. These values are obtained for a gas having $\mathrm{Pr} = 0.7$ by neglecting viscous dissipation, axial conduction and flow work and using in the slip boundary conditions (Eq. (8) and (19)) $\alpha = \sigma_v = \alpha_t = \sigma_t = 1$.

Laminar-to-Turbulent Transition

Heat transfer results are uncertain in the transition region because of the large number of parameters which determine when and how transition occurs (wall roughness, cross-sectional geometry, compressibility, Reynolds number and so on). Experimental results indicate that in smooth microchannels below Reynolds numbers of 1800–2000 the heat transfer results will be laminar and above 10 000 the results will be normally turbulent. The results in between are difficult to predict (see ▶ pressure-driven single-phase flow): unfortunately, this region is largely used when microchannels having hydraulic diameters less than 500 μm are considered (Re < 30 000).

Convective Heat Transfer in Microchannels, Table 12 Nusselt numbers $\overline{Nu}_{H1}$ for laminar fully developed flow for a KOH-etched double-trapezoidal cross-section with six (6bc) heated sides as a function of the aspect ratio δ for the **H1** boundary condition

Turbulent Regime

The thermal behavior of turbulent flows in a microchannel, under conditions of constant properties and moderate velocity can be described by means of the Nusselt number. Under certain thermal boundary conditions the Nusselt number in the turbulent regime becomes independent on the channel length. As in the case of laminar flow the

two thermal boundary conditions of most technical interest for which such an asymptotical Nusselt number is obtained are for a constant heat flux (**H** boundary conditions) and for a constant surface temperature (**T** boundary condition). In the turbulent regime as well as in the laminar regime the **H** Nusselt numbers are always greater than **T** Nusselt numbers but in turbulent regime the difference is generally much smaller than for laminar flow and becomes negligible for fluids having $\mathrm{Pr} > 1$ (e. g. water).

For turbulent flow the thermal entrance region is shorter than for laminar flow (with the exception of liquid metals which have a very low Prandtl number) and thus the fully developed values of the Nusselt number are frequently used directly in heat transfer design without reference to the thermal entrance effects. The turbulent fully developed Nusselt number in a smooth channel can be expressed as a function of the Reynolds number and of the Prandtl number.

Algebraic correlations are used extensively to represent turbulent convective heat transfer data. One of the earliest correlations used for fully developed turbulent flow heat transfer is the *Dittus–Boelter correlation*:

$$\overline{\mathrm{Nu}} = 0.023\ \mathrm{Re}^{0.8}\mathrm{Pr}^{n} \tag{49}$$

where $n = 0.4$ for heating and $n = 0.3$ for cooling. This correlation can be employed for both **H** and **T** boundary conditions when $\mathrm{Re} > 10\,000$, $0.7 < \mathrm{Pr} < 160$ and $L/D_{\mathrm{h}} > 10$.

For fluids with Prandtl numbers less than 1 (e. g. gases) the difference among the thermal boundary conditions becomes important and the Nusselt number has to be calculated in a different way for **H** and **T** problems. In the range of the Prandtl number between 0.5 and 1 the turbulent fully developed Nusselt number can be calculated by using the following correlations:

$$\begin{aligned}\overline{\mathrm{Nu}}_{\mathrm{T}} &= 0.021\ \mathrm{Re}^{0.8}\mathrm{Pr}^{0.6}\\ \overline{\mathrm{Nu}}_{\mathrm{H}} &= 0.022\ \mathrm{Re}^{0.8}\mathrm{Pr}^{0.6}\end{aligned} \tag{50}$$

Another very common correlation used in order to predict the turbulent convective heat transfer in channels is the *Sieder and Tate correlation*:

$$\overline{\mathrm{Nu}} = 0.027\ \mathrm{Re}^{0.8}\mathrm{Pr}^{\frac{1}{3}}\left(\frac{\mu}{\mu_{\mathrm{w}}}\right)^{0.14} \tag{51}$$

The use of this correlation is recommended when the temperature variation inside the microchannel is large; in this case it is not possible to consider the thermophysical properties of the fluid as constant, and in particular it is necessary to take into account the variation of the viscosity with temperature. In this correlation all the properties must be computed at the average fluid bulk temperature except μ_{w} that is evaluated at the wall temperature. This correlation is valid for $\mathrm{Re} > 10\,000$; this range of Reynolds numbers is not commonly encountered when microchannels having a hydraulic diameter less than 500 μm are considered. For this reason, in many experimental works conducted with microchannels the data obtained in the turbulent regime have been compared with the predictions of the *Gnielnski correlation*:

$$\overline{\mathrm{Nu}} = \frac{(f/2)(\mathrm{Re}-1000)\mathrm{Pr}}{1+12.7(f/2)^{1/2}(\mathrm{Pr}^{2/3}-1)} \tag{52}$$

where f is the Fanning friction factor (see ► pressure–driven single-phase flow).

This correlation is valid for moderate Reynolds number ($3000 < \mathrm{Re} < 5\times10^{6}$) and for this reason can be considered as appropriate for microchannels where larger Reynolds numbers are hard to obtain. The experimental data obtained by Celata et al. [6] confirmed that this kind of correlation agrees well with the data obtained with microtubes having an inner diameter between 500 and 120 μm.

Experimental Determination of the Nusselt Number

Since the local value of the bulk temperature is not easy to measure along a microchannel, the local value of the Nusselt number cannot be calculated in general. Only the

mean value of the Nusselt number can be gained from the experimental data by means of the following equation:

$$\mathrm{Nu}_{\mathrm{m}} = \frac{Q}{k\Gamma_{\mathrm{h}}^{*} L(T_{\mathrm{m,w}} - T_{\mathrm{m,b}})} \tag{53}$$

in which Q is the power removed by the working fluid, Γ_{h}^{*} is the dimensionless heated perimeter of the microchannel ($\Gamma_{\mathrm{h}}/D_{\mathrm{h}}$) and L the microchannel length.

The average wall temperature ($T_{\mathrm{m,w}}$) is in general calculated as the mean of N temperature measures made along the microchannel and the average bulk temperature ($T_{\mathrm{m,b}}$) is usually interpolated by using the inlet and outlet temperatures because it is hard to provide local measurements of bulk temperature along the microchannel.

It is necessary to remark that a large number of comparisons between experimental and theoretical results for microchannels have revealed a deep mismatch in the thermal boundary and inlet conditions that can preclude the use of the conventional correlations. In addition, in experiments on flow and heat transfer in microchannels, some parameters, like the channel dimensions, the average roughness, the local convective heat transfer, the local value of the static pressure along a microchannel, and so on, are difficult to measure accurately. For this reason, a large number of inconsistencies in published data are very likely to be due to experimental inaccuracies.

In this section, the main effects that can be invoked in order to justify the eventual discrepancies between the theoretical and the experimental results in terms of Nusselt numbers are listed and systematically discussed.

Entrance Effects

First of all, the difference between the theoretical values of the Nusselt number and the experimental ones evaluated by means of Eq. (53) can be eliminated by taking into account the effects related to the entrance region. Since the length of the thermal entrance region can be very short for turbulent flow, the entrance effects become more important in microchannels in which the flow is laminar but with large Reynolds numbers ($\mathrm{Re} > 1500$). Theoretically, the mean Nusselt number along a channel having a length equal to L can be predicted by means of the following generalized *Hausen correlation*, valid for $\mathrm{Re} < 3000$:

$$\mathrm{Nu}_{\mathrm{m}} = \overline{\mathrm{Nu}} + K_1 \frac{\left(\frac{\mathrm{Re}\,\mathrm{Pr}\,D_{\mathrm{h}}}{L}\right)}{\left(1 + K_2\left(\frac{\mathrm{Re}\,\mathrm{Pr}\,D_{\mathrm{h}}}{L}\right)^{b}\right)} \tag{54}$$

In the *Hausen correlation* the mean Nusselt number is calculated as a sum of two terms: the first term ($\overline{\mathrm{Nu}}$) is the fully developed value of the Nusselt number; its value can be calculated by using the data quoted in the above sections. The second term takes into account the effects of the thermal **entrance region**. Rosehnow and Choi [7] give the value of the coefficients K_1, K_2 and b for circular channels; in the case of prescribed wall heat flux (**H** boundary condition) and developed profile of velocity, $\overline{\mathrm{Nu}}$ is equal to 48/11 (see Eq. (43)) with $\mathrm{Br} = S_{\mathrm{g}}^{*} = 0$, $K_1 = 0.023$, $K_2 = 0.0012$ and $b = 1$. Recently Li et al. [8] proposed to use in Eq. (54) for rectangular microchannels with four sides heated the following values: $K_1 = 0.14$, $K_2 = 0.05$ and $b = 2/3$. Equation (54) brings to the fore the effect of the entrance region on the mean value of the Nusselt number along a channel. If the Reynolds number increases, the length of the entrance region increases and the second term in Eq. (54) increases too. It is possible to demonstrate that the entrance effects in tubes become negligible if the following inequality is satisfied:

$$\frac{\mathrm{RePr}D_{\mathrm{h}}}{L} < 10 \tag{55}$$

Viscous Dissipation

When the Reynolds number increases the Brinkman number increases too; this means that the effect of the ▶ viscous dissipation gains in importance. When the fluid is heated by viscous dissipation the fully developed value of the Nusselt number tends to decrease for **H1** boundary condition; in fact, its value depends on the Brinkman number as follows:

$$\overline{\mathrm{Nu}}_{\mathrm{H1}}(\mathrm{Br}) = \frac{\overline{\mathrm{Nu}}_{\mathrm{H1}}}{1 + \sigma\,\mathrm{Br}} \tag{56}$$

where $\overline{\mathrm{Nu}}_{\mathrm{H1}}$ is the fully developed Nusselt number when $\mathrm{Br} = 0$ and σ is a parameter depending on the geometry of the channel cross-section and on the combination of heated and adiabatic sides of the channel. The values assumed by σ for rectangular, circular and KOH-etched trapezoidal cross-sections are quoted in the section on viscous dissipation.

Equation (56) states that when the Brinkman number increases the Nusselt number decreases; in other words, the viscous dissipation tends to reduce significantly the value of the convective heat transfer at large Reynolds numbers when the hydraulic diameter decreases. On the contrary, for low values of the Reynolds number, the mean value of the Nusselt number coincides theoretically with the fully developed value of the Nusselt number because the entrance region is very short and the effects of the viscous dissipation are unimportant in this region.

A theoretical criterion to draw the limit of significance of the viscous dissipation in adiabatic and in heated

microchannels is described in the section on viscous dissipation.

Wall–Fluid Conjugate Heat Transfer

In the region of low Reynolds numbers the effects of the *conjugated heat transfer* on the mean value of the Nusselt number are very important because the conduction along the walls (especially for silicon microchannels) becomes a competitive mechanism of heat transfer as compared to internal convection. As evidenced theoretically by Maranzana et al. [9], when the effects of conjugate heat transfer are predominant, the bulk temperature distribution along the microchannel is not linear at all even in the **H1** boundary condition. For this reason, the Nusselt number calculated by using Eq. (53) is underestimated because the mean value of the bulk temperature ($T_{m,b}$) along the microchannel is underestimated. For this reason if the experimental values of the Nusselt number calculated by means of Eq. (53) are compared with their theoretical fully developed value a difference can be noted. This difference decreases when the Reynolds number increases because the effects of conjugate heat transfer are limited for large Reynolds numbers. This fact explains the dependence of the Nusselt number evaluated by means of Eq. (53) on the Reynolds number especially when low values of the latter are considered. In other words, the mean Nusselt number evaluated through Eq. (53) can exhibit a dependence on the Reynolds number even in the laminar regime due to the axial conduction along the solid walls of the microchannel. The conjugate wall-fluid effects are predominant for low Reynolds numbers and therefore not in direct competition with the effects related to viscous heating.

The limit of significance of the wall axial heat conduction in comparison with the convective heat transfer can be drawn by using the following inequality:

$$\left(\frac{\lambda_s}{\lambda_f}\right)\left(\frac{D_h}{L}\right)\left(\frac{\Omega_w}{\Omega}-1\right)\frac{1}{\mathrm{RePr}} > 0.01 \qquad (57)$$

in which Ω and Ω_w are the areas depicted in Fig. 1. This dimensionless quantity allows the comparison of the heat transfer by axial conduction in the wall with the convective heat transfer in the flow. When Eq. (57) is satisfied the wall axial heat conduction cannot be neglected.

Temperature-Dependent Fluid Properties

Since the temperature rise along the microchannel can be very large at very low values of the Reynolds number, for a fixed value of the wall heat flux, the thermophysical properties cannot be considered as constants; in other words, the effects related to the *variation of the thermophysical properties with temperature* tend to be in general coupled with conjugate effects. It has been numerically demonstrated that in microchannel flows it becomes very important to take into account the variation of the fluid viscosity with the temperature; in contrast, the other thermophysical properties can be considered as constant.

In addition, for large Reynolds numbers and very small diameters, the pressure drop along the microchannel can be very high. In this case, the effect of the pressure on the thermophysical properties has to be taken into account. Since the viscosity tends to increase with pressure, the effect of a large pressure drop along a microchannel is similar to a temperature rise: the viscosity decreases along the microchannel. This means that the effects of the pressure on the fluid viscosity can be coupled with viscous dissipation effects at large Reynolds numbers. Experimentally it has been demonstrated that the variation of the thermophysical properties with the pressure can in general be considered negligible for pressure differences less than 50 MPa between the inlet and the outlet.

Convective Heat Transfer in Microchannels, Table 15 Nusselt numbers $\overline{\mathrm{Nu}}_{H1}$ for a rarefied gas with Pr = 0.7 in laminar fully developed flow in a KOH-etched trapezoidal microchannel with four sides heated as a function of the Knudsen number and of the aspect ratio δ for the **H1** boundary condition

	$\overline{\mathrm{Nu}}_{H1}$				
Kn	$\delta = 10$	$\delta = 5$	$\delta = 1$	$\delta = 0.5$	$\delta = 0.1$
0.02	2.98	3.02	3.18	3.68	5.59

0.08	2.38	2.41	2.50	2.73	3.66
0.1	2.22	2.24	2.32	2.50	3.26

Surface Roughness

It is well known that the friction factor and the convective heat transfer coefficient can be influenced by the relative roughness of the walls of a channel. For microchannels the relative roughness, defined as the ratio between the mean height of the surface asperities and the hydraulic diameter of the channel, can assume large values. Especially for stainless steel commercial microtubes the relative roughness can reach values equal to 2–8%.

Numerical works have demonstrated that the effect of the roughness on the Nusselt number is in general less pronounced than its effect on the friction factor: its influence on the heat transfer is mostly of the same order of magnitude as the accepted experimental uncertainty. A large relative roughness can increase or decrease the

value of the Nusselt number as compared to the value of Nu in a smooth microchannel and the effect of the roughness seems to be highly dependent on the channel shape.

Rarefaction Effects

A very accurate and recent review of the main results on this topic has been published [10]. In that review it is demonstrated that the slip-flow regime has been much studied in the last few years from theoretical and experimental points of view. The gas rarefaction decreases the value of the convective heat transfer, as evidenced by the results quoted in Tab. 6, 9, 10 and 15. The convective heat transfer for rarefied gases in microchannels depends on the kind of interactions between the gas and the walls; in fact, these interactions determine the value of the finite 'temperature jump' between walls and gas (see ▶ pressure-driven single phase gas flows). Rarefaction effects tend to influence the heat transfer for Knudsen numbers greater than 0.001.

Compressibility Effects

The conventional theory states that if the average value of the Mach number (Ma_m, defined as the ratio between the fluid velocity and the speed of sound) along a channel is less than 0.3 the flow can be modeled locally as incompressible. In addition, when the pressure drop along the tube length is lower than 5% of the inlet pressure, the effect of the acceleration of the gas flow in the axial direction can be neglected (in other words, the variation of the gas density along the channel can be neglected).

Since the pressure drop along the tube length is much larger in microchannels than in conventional-sized tubes, the effects of the gas acceleration cannot in general be neglected, even for very low values of the Mach numbers as observed theoretically and experimentally by several authors.

When $Ma_m > 0.3$ the hypothesis of incompressibility no longer holds and the gas acceleration leads to changes in the velocity profile not only in magnitude but also in shape. The magnitude increments produce additional pressure drop while the shape changes alter the friction factor at the walls. The continuous variation in shape of the velocity profile means that neither fully developed nor locally fully developed flows occur. This fact influences the convective heat transfer coefficient since no fully developed temperature profiles can occur if the flow is developing and the experimental Nusselt numbers differ by the theoretical values for fully developed flow. It is possible to demonstrate numerically that when the Mach number increases the Nusselt number decreases along the tube and it can become negative if the resulting temperature decrease along the microchannel is large enough.

Electric Double Layer Effects

One aspect which has been evidenced in numerical and experimental works is the influence of electrostatic interaction between fluid and channel walls on the friction factor and on the Nusselt number. In particular, it has been observed that in the presence of an electric double layer the Nusselt number increases because the temperature and the velocity gradients at the walls tend to be increased. The electro-osmotic interactions between the fluid and the walls could explain, for microchannels with a hydraulic diameter less than 20 μm, the dependence of the Nusselt number on the Reynolds number, even in the laminar regime.

Future Directions for Research

Convective heat transfer in microchannels has been studied extensively in the last decade both experimentally and theoretically. From a chronological analysis of these experimental works it is possible to note that the discrepancy between the experimental data obtained for microchannels and the predictions of the conventional theory is decreasing. This fact can be partially explained by considering the dramatic improvements in microfabrication techniques with the consequent more appropriate control of the roughness and geometry of the microchannel and with the increase in the accuracy of the experimental tests made. For this reason the results of the older studies are sometimes fraught with errors and can be misleading.

In the future it will be very important to study the role played by the main scaling effects (i. e. viscous dissipation, flow work, compressibility) and micro-effects (rarefaction, electric double layer effects) on the convective heat transfer for single-phase flows in microchannels with the aim to explain that many experimental results published in the open literature can be justified by using correctly the conventional theory.

Covalent Bonding

Definition

Covalent bonding is a description of chemical bonding that is characterized by the sharing of one or more electrons between two atoms. In general, bonds are defined by a mutual attraction that holds the resultant molecule together. Often, bonding occurs in such a way that the outer electron shells of the participating atoms become filled. In contrast to electrostatic interactions labeled as "ionic bonds,"the strength of covalent bond depends on the angular relation between atoms in polyatomic molecules. Covalent bonding is most important between atoms with similar electronegativities. Covalent bonding is often delocalized. Covalent bonding is a broad concept and includes many kinds of interactions, including σ-bonding, π-bonding, metal-metal bonding, agostic interactions, and three-center two-electron bonds.

Definition

It is often necessary to drive fluids from one part of a microfluidic device to another, to control the fluid motion, to enhance mixing, or to separate fluids. The fluids are transported through channels with characteristic cross-section dimensions in the micrometer range. A channel of this size is called microchannel. If the channels are not in a straight line, then they are called a curved microchannel.

Overview

The channel geometry of a microfluidic device is commonly characterized by a rectangular curved microchannel. The flow field conditions within such a microchannel have a significant influence upon the performance of the device when conducting the separation, extraction, and mixing of chemical or biological components.

Compared to the classical flow phenomena observed in macroscopic devices, microfluidic systems generally involve laminar flows. Schönfeld and Hardt [1] developed a simple micromixer. They showed that the secondary flows (known as "Dean vortices") induced in a curved microchannel generate a mixing effect in micro devices. They analyzed the secondary flow patterns in curved square channels of various dimensions and compared the relative transverse flows of bas-relief structured channels with those of curved square channels. Particular attention was paid to the formation of additional vortices close to the center of the outer channel wall. Based on the analytical results, a novel micromixer was proposed whose mixing action was generated by transitions of the secondary flow pattern. Jiang et al. [2] investigated helical flows and chaotic mixing in curved microchannels and performed a series of experimental evaluations to verify the predicted mixing results. The experimental and numerical results both revealed that the mixing performance was highly dependent on the structure of the helical flow patterns formed within the microchannels. Howell et al. [3] used a similar helical structure of microchannel to develop a Dean vortex-based micromixer. In their design, Dean vortices appeared at Reynolds numbers between 1 and 10 which became stronger with the increase in flow velocity. The vortex formation was investigated in various microchannels with different aspect ratios. Yamaguchi et al. [4] performed three-dimensional computational fluid dynamics simulations to investigate fluidic behavior in a microchannel containing hairpin curves. The authors also performed an experimental study to observe the 3-D flow patterns generated in a hairpin microchannel fabricated on a PMMA plate. The experimental data were found to be in good agreement with the numerical results. Yamaguchi et al. [5] investigated the interface configuration of two-layered laminar flow in a curved microchannel and showed that the configuration is heavily distorted by the curved structure, leading to an increased interfacial area and hence an improved mixing performance. They reported that the interface configuration of the two liquids was affected by the secondary flows induced by inertial forces acting at the corners of the microchannel. The results showed that the interface configuration was also dependent on the velocity, the density and the viscosity of the fluid, as well as on the curvature radius and aspect ratio of the cross-sectional plane of the channel. Ookawara et al. [6] proposed a novel application for curved microchannels in which the curved channels were used to classify contained particles. The feasibility of the proposed micro-separator/classifier was verified both numerically and experimentally. Ueda et al. [7] investigated the curvature effect on the dynamics of long DNA in microfluidic devices. It was shown that under weak hydrodynamic flow,

Curved Microchannel Flow, Figure 3 Velocity distributions along X-direction in microchannels with different curvature ratios. (The DC electric field intensity is 450 V/cm

long DNA exhibited a curvature entropy trapping effect. However, this effect disappeared as the hydrodynamic flow was increased.

Most studies mentioned above focus on the pressure-driven microfluidic flow in the microchannels. Recently, electrokinetically driven flows in curved microchannels have received much attention. Luo et al. [8, 9] investigated the transient electro-osmotic secondary flows which provide evidence of the growth and decay of vortices in the transverse section in a curved microchannel. They explored the small vortices that appear in each corner of the micro-channel as the AC electric field intensity is applied. Both upper and lower corner vortices gradually grow in size and strength and finally merge to form a single vortex, which compresses the original recirculation in the upper and lower half of the transverse section. Chen et al. [10] investigated the velocity distribution and secondary flow patterns induced by a DC electric field or an AC electric field in microchannels with various curvature ratios and driving frequencies.

Basic Methodology

This section focuses on the electrokinetically-driven flow in a rectangular curved microchannel. It is assumed that the fluid in the microchannel is filled with an incompressible Newtonian electrolyte of uniform dielectric constant, ε, and viscosity, μ. A fully developed flow field is then established in which the flow is driven by an applied DC or by an AC electric field. Since the characteristic length of the microchannel is of the order of magnitude of 10 microns, the interaction of the fluid and the wall is significant and must therefore be considered in the theoretical model. A review of the related literature reveals the widespread use of a theoretical microchannel model in previous studies. This model is described by the following set of equations: the Poisson–Boltzmann equation and the Navier–Stokes equation, which comprises the body force terms from the Guoy–Chapman model. When applying this model, it is convenient to transform the toroidal coordinate system (R, Y, θ) to the related coordinate system $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$, where $X = R - C$, $\mathrm{d}Z = C\mathrm{d}\theta$, and C is the radius of, as shown in Fig. 1.

When an external electric field is applied, the liquid flow induced by electroosmosis is governed by the general incompressible the equations of motion, i. e.

$$\nabla \cdot \boldsymbol{V} = 0 \tag{1}$$

and

$$\rho \frac{\partial \boldsymbol{V}}{\partial t} + \rho\,(\boldsymbol{V} \cdot \nabla)\,\boldsymbol{V} = -\nabla P + \boldsymbol{F} + \mu \nabla^2 \boldsymbol{V} \tag{2}$$

where $\boldsymbol{V}$ is the velocity, ρ is the fluid density, p is the static pressure, μ is the fluid viscosity, $\boldsymbol{F} = \rho_e \boldsymbol{E}$, If the gravity effect is neglected, the body force, $\boldsymbol{F}$, occurs only as a result of the action of the applied electric field on the free ions within the EDL. This body force induces a bulk fluid motion generally referred to as electroosmotic flow.

ρ_e is the net electric charge density and $\boldsymbol{E}$ is the electric field, which is given by

$$\boldsymbol{E} = -\nabla\Psi \tag{3}$$

where Ψ is the electric potential.
According to electrostatics theory, the potential is governed by the Poisson equation, i. e.

$$\nabla^2\Psi = -\frac{\rho_e}{\varepsilon\varepsilon_0} \tag{4}$$

where ε is the dielectric constant of the electrolyte solution and ε_0 is the permittivity of vacuum. Since, the Debye length of the EDL is typically very small compared to the microchannelwidth, the ion distribution is influenced primarily by the ζ potential. It is reasonable to assume that the electric potential, Ψ, is given by the linear superposition of the electrical double layer potential and the externally applied potential, i. e. $\Psi = \psi + \phi$. Therefore, equation (4) can be represented as

$$\nabla^2\psi = -\frac{\rho_e}{\varepsilon\varepsilon_0} \tag{5}$$

and

$$\nabla^2\phi = 0 \tag{6}$$

Under conditions of thermodynamic equilibrium, the ion concentration is described by the Boltzmann distribution. The electric potential distribution in the EDL can be described by the nonlinear Poisson–Boltzmann equation,

$$\nabla^2\psi = \frac{2n_0 ze}{\varepsilon\varepsilon_0}\sinh\left(\frac{ze\psi}{k_b T}\right) \tag{7}$$

The momentum expression of Eq. (2) can be rewritten in the following form:

$$\rho\frac{\partial \boldsymbol{V}}{\partial t} + \rho\left(\boldsymbol{V}\cdot\nabla\right)\boldsymbol{V} = -\nabla P + 2n_0 ze \sin\text{h}\left(\frac{ze\psi}{k_b T}\right) \times \left[\nabla\left(\psi+\phi\right)\right] + \mu\nabla^2\boldsymbol{V} \tag{8}$$

For fully developed flow field in the curved micro-channel, the Eqs. (1), (7) and (8) were transformed the toroidal coordinate system (R, Y, θ) to the related coordinate system $(\boldsymbol{X}, \boldsymbol{Y}, \boldsymbol{Z})$ and can be expressed as:

$$\frac{1}{(x+c)}\frac{\partial}{\partial x}\left[(x+c)\,u\right] + \frac{\partial v}{\partial y} = 0 \tag{9}$$

and

$$\frac{1}{(x+c)}\frac{\partial}{\partial x}\left[(x+c)\frac{\partial\psi}{\partial x}\right] + \frac{\partial^2\psi}{\partial y^2} = \frac{2n_0 ze}{\varepsilon}\sin\text{h}\left(\frac{ze\psi}{k_b T}\right) \tag{10}$$

and

$$\frac{\partial u}{\partial t} + u\frac{\partial u}{\partial x} + v\frac{\partial u}{\partial y} - \frac{w^2}{(x+c)} = -\frac{1}{\rho}\frac{\partial p}{\partial(x+c)} + \frac{\mu}{\rho}\left[\frac{\partial^2 u}{\partial\,(x+c)^2} + \frac{1}{(x+c)}\frac{\partial u}{\partial\,(x+c)} + \frac{\partial^2 u}{\partial y^2} - \frac{u}{(x+c)^2}\right] + \frac{1}{\rho}2n_0 ze\sin\text{h}\left[\frac{ze\psi}{k_b T}\right]\left[\frac{\partial\psi}{\partial\,(x+c)}\right] \tag{11a}$$

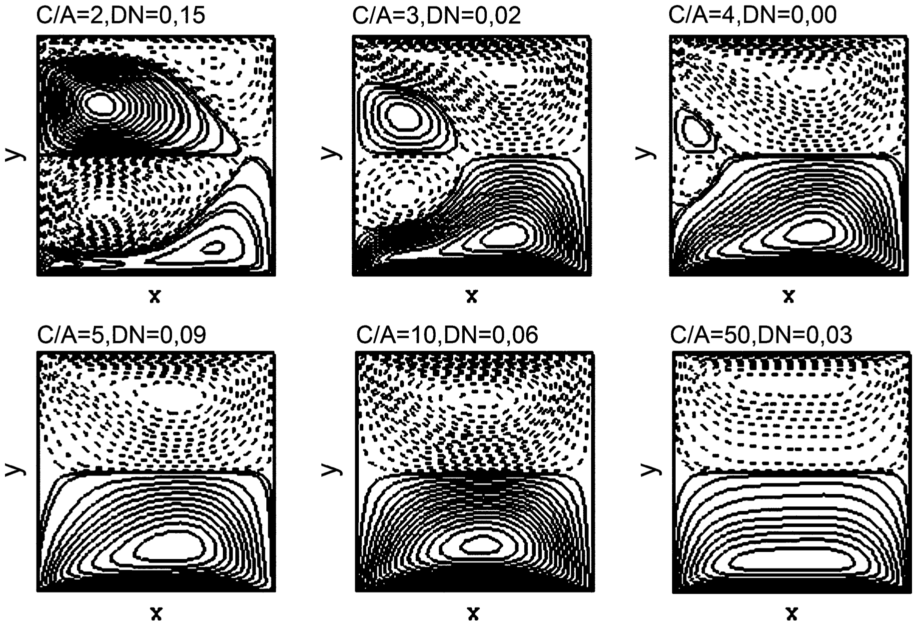
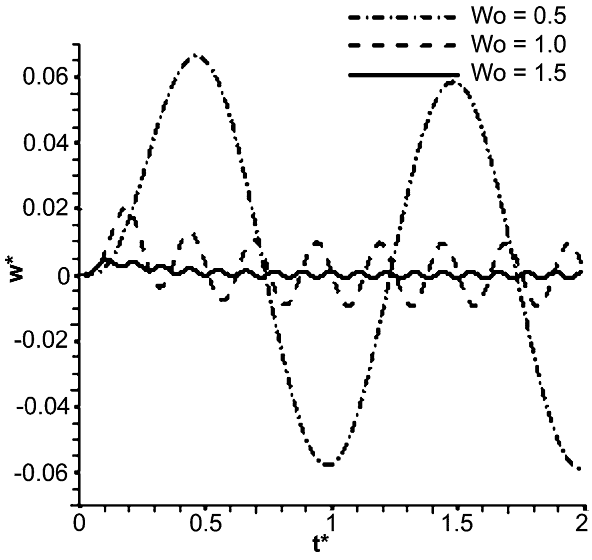
where $\kappa=AK$, $K=\left(2n_0z^2e^2/\varepsilon\varepsilon_0k_bT\right)^{1/2}$ is the Debye–Huckel parameter, the curvature ratio is given by $\beta=C/A$ and $Gx=2n_0k_bT/\left(\rho v^2/A^2\right)$ is the ratio of the EDL energy to the mechanical kinetic energy.

Key Research Findings

Figure 1 illustrates the geometry and related coordinate system of a curved microchannel. Figure 2 shows the axial velocity component distributions along the Y-direction of a microchannel with a curvature ratio of $C/A=50$ when a DC electric field with an intensity of 450 V/cm is applied. It can be seen that the axial velocity stabilizes after a dimensionless time of $t^*=1.0$. At this particular curvature ratio, the radius of curvature is so large that the curved channel approximates a straight channel, and hence the flat velocity profile is similar to that of the electro-osmotic flow observed in a straight microchannel. Figure 3 illustrates the axial velocity component distributions along the X-direction of microchannels with various curvature ratios $\left(2\le C/A\le 50\right)$. Due to the shorter turning arc-length along the inner wall, the electric field strength along the inner wall is much larger than that along the outer wall. Consequently, the electrokinetic force is larger along the inner wall resulting in a faster axial velocity w^* near the inner wall. A ratio of C/A=2 implies that the curvature of the microchannel resembles that of a hairpin curve, and hence the velocity near the inner wall is 2 times that near the outer wall of the microchannel. In the case of $C/A>10$, the velocity profile of the electro-osmotic flow is nearly flat. Figure 4 shows the secondary flow patterns in microchannels with different curvature ratios. The Dean number D_n, is defined as $\mathrm{D}_n=\mathrm{Re}\beta^{-\frac{1}{2}}$, where $\mathrm{Re}=(\mathrm{D}\bar{w})/A$ is the Reynolds number. $\mathrm{D}=(4AB)/(A+B)$, $A=B$, D is the hydraulic diameter, and $\bar{w}$ is the non-dimensional mean axial velocity, where $\bar{w}=\left(\int w(x,y)(x+\beta)\mathrm{d}x\mathrm{d}y\right)/\left(\int(x+\beta)\,\mathrm{d}x\mathrm{d}y\right)$, and $\beta=C/A$ is the radius of curvature. It is evident from Fig. 4 that when the ratio of C/A is smaller, the microchannel becomes more of a hairpin. When the secondary flows increase in strength the result is that vortices are induced near the inner walls. When the ratio of C/A is larger than 4, the curvature effect becomes weaker, and the inner vortices almost disappear. Figure 5 shows the velocity responses of the electro-osmotic flows induced by an AC electric field with an increasing Wo in curved microchannels. A dimensionless parameter, the Womersley number ($\mathrm{Wo}=(A/2)\sqrt{n/\upsilon}$, A is the characteristic length of the curved channel, n is the angular velocity of the applied electric field ($n=2\pi f$ where $f$is frequency in cycle/sec), υ is the kinematic viscosity of the fluid), is used to describe the transient fluid phenomena in an AC electric field. For a higher AC frequency (i. e., a larger Wo number), the fluid in the channel has nearly no effect due to the dragging force from the channel walls. This is because for a higher frequency the faster forward and backward electrokinetic force reverses itself and does not have sufficient time to diffuse to the center of the channel. Under this condition the w^* velocity in the center behaves with a very small amplitude of oscillation. Figure 6 shows the streamlined contours for the half-periods of applied sinusoidal electric fields with frequencies of 1.0 kHz (Wo = 0.50). The cyclic nature of the electro-osmotic flow evolution results



Curved Microchannel Flow, Figure 4 Secondary flow contours in microchannels with different curvature ratios. (The DC electric field intensity is 450 V/cm)

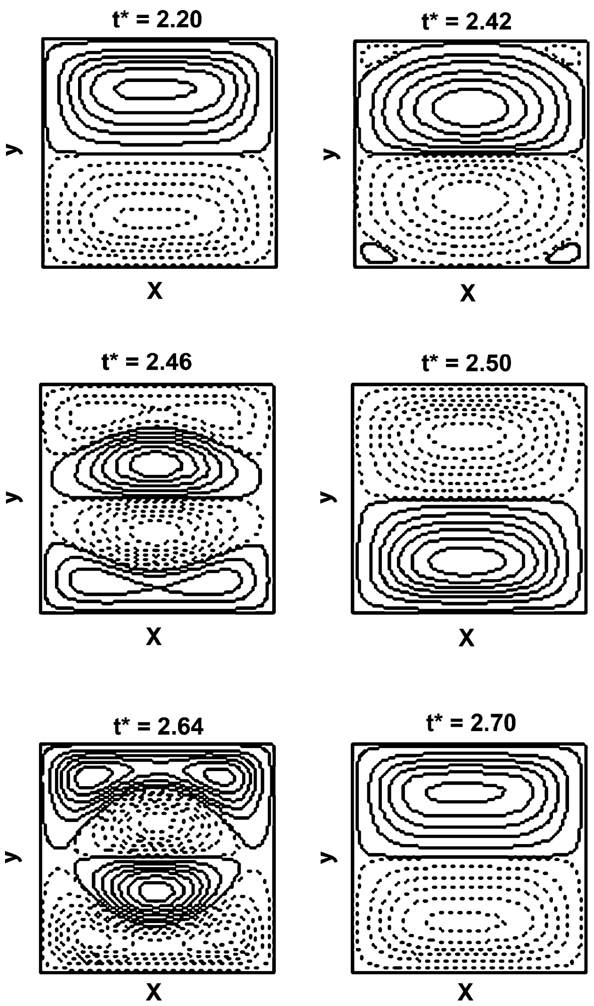


Curved Microchannel Flow, Figure 5 Transient velocity response in center of microchannel with Wo = 0.5, 1.0, and 1.5

in the growth and subsequent decay of vortices in each half of the transverse section. The greater net charge density within the double layer of the microchannel results in local maximum or minimum axial velocities near the upper and lower walls as the intensity of the applied electric field increases or decreases in either the positive or negative direction. The peak values of the axial velocity increase the force drops between the flows near the upper and lower walls as well as those in the central region, and hence prompt the formation of small vortices near the upper and lower walls. The force drops increase as the electric field intensity increases in either the positive or negative direction. Therefore, these vortices increase in size and strength as the intensity of the electric field increases, and finally merge to form one vortex in the upper half of the microchannel and a second vortex in the lower half. These vortices compress their respective neighboring recirculations as they continue to expand. Once the maximum, or minimum, electric field intensity has been attained, the original recirculations are compressed to such an extent that they vanish completely, and consequently the flow reverts to a two-vortex state. In the case with a higher applied electric field frequency 3.0 kHz (Wo = 0.87), during one period of the sinusoidal electric field, the momentum resulting from electro-osmosis near the walls has only enough time to affect a finite region near the corners of the microchannel. The induced vortices near the corners are very weak and are not strong enough or large enough to compress the original circulations. These vortices appear for a short period of time only.

Future Directions for Research

Microfluidic devices require a mixing operation for complex chemical synthesis and analysis. However, diffusive



Curved Microchannel Flow, Figure 6 Streamline contours in transverse section of curved microchannel over half-period from t* = 2.20 to 2.70 for driving frequency of 1.0 kHz (Wo = 0.50)

mixing tends to be slow, and hence requires a relatively long mixing channel. A curved microchannel can be fabricated to save chip material. The formation of the vortices in the curved microchannel can be crated by the application of a periodic external electric field, which to increase the contact area of the different fluids in order to accelerate the mixing process. The induced secondary flow field in the curved microchannel may provide a rapid stirring mechanism or increase unwanted dispersion of the sample. The geometry of a microfluidic device is commonly characterized by a helical rectangular curved microchannel. In the future, 3-D induced electro-osmotic helical flows and chaotic mixing in curved microchannels should be investigated with a series of experimental evaluations and numerical analysis in order to further understanding of the relationship between the mixing performance and the structure of the helical flow patterns formed within microchannels.

Cy3/Cy5-Dye

Definition

These two dye molecules of the cyanine dye family are the most frequently used fluorescent dyes for DNA microarray analysis. Cy3 (green color) is exited at 550 nm and emits at 570 nm, Cy5 (red color) is exited at 649 nm and emits at 670 nm. However, the microarray scanners that are used to detect these dyes use different laser emission wavelengths (typically 532 nm and 635 nm) and filter wavelengths (550-600 nm and 655-695 nm) to avoid background contamination.

Definition

Direct current (DC) dielectrophoresis (DEP) is an efficient means to move and thus separate particles or cells with the force of a stationary electric field. This is accomplished with a nonuniform electric field, which is created using insulator objects as obstacles in the path of the DC field. DC-DEP is then the induced motion of polarizable, dielectric objects of micron and smaller size, in a DC electric field that is modified by Lab-on-a-Chip geometry (or other means) to be spatially nonuniform.

Overview

Dielectrophoresis has a number of advantages over linear electrophoresis. Electrophoresis only works for samples having a narrow range of properties (significant surface charge, electrically conductive, measurably dense or with discernable radius). However, DEP enables precise manipulation of particles with widely varying electrical properties (particle only needs to be polarizable) while still interfacing with electronically controllable, microfluidics based applications. Dielectrophoresis can also directly manipulate native, unlabeled cells, thus eliminating the expense, labor, and time of labeling and tagging, as well as the development and validation of such labels and tags. The same basic DEP method has the capability of isolating and analyzing a wide range of particle types (polymer microparticles, metallic particles, cells, bacteria, viruses, DNA and proteins) using one basic procedure.

The field of dielectrophoresis is relatively recent. Herbert Pohl did dielectrophoretic research in the 1950s although this area did not gain visibility until his groundbreaking book was published in 1978 [1]. In this book, the two main components of the electric field in alternating current (AC) dielectrophoresis were extensively discussed, namely (i) a spatially nonuniform electric field and (ii) an alternating current electric field, both of which contribute to the nonlinear DEP force. Within the last 5 years, direct current dielectrophoresis has been explored. DC-DEP only utilizes the spatially nonuniform electric field component (part i), thus creating gradients in the electric field and enacting motion of cells. A brief background on the dielectrophoretic force is provided here followed by the contributing term for frequency dependent AC-DEP and then non-frequency dependent DC-DEP.

A significant boom in AC dielectrophoretic research occurred when microfabrication became widely available. This enabled precise fabrication of electrode systems (interdigitated electrodes, etc.), which created very symmetric, reproducible nonuniform electric fields enabling cellular responses to such fields to be more precisely quantified. It became apparent that at radio frequencies, cells were selectively controlled due to their inherent intra membrane polarizability characteristics. This attribute was exploited to sort cells because one cell type responded in a unique fashion from other cells at specific AC frequencies. Genetically or geometrically similar cells were found to have more similar, but still distinct, responses at given frequencies [2].

In AC and DC dielectrophoresis, the dielectrophoretic force acting on the polarized cell causes it to move either up or down the induced electric field gradient. This electric field gradient is created by a nonuniform electrode geometry in AC fields, or by a nonuniform insulator geometry of obstacles in an otherwise uniform DC field. This nonuniform field force can be derived from the net dielectric force:

$$\boldsymbol{F} = (\boldsymbol{p} \cdot \nabla)\,\boldsymbol{E} \tag{1}$$

Where $\boldsymbol{p}$, the dipole moment vector, can be broken down into the particle's effective polarizability, α, volume, v, of the particle, and the applied electric field, $\boldsymbol{E}$ ($\boldsymbol{p} = \alpha v \boldsymbol{E}$). This effective polarizability term is most commonly estimated using the Clausius–Mosotti factor for perfectly spherical particles as follows [1, 2]:

$$\mathrm{K}(\omega) = \frac{\tilde{\varepsilon}_\mathrm{p} - \tilde{\varepsilon}_\mathrm{m}}{\tilde{\varepsilon}_\mathrm{p} + 2\tilde{\varepsilon}_\mathrm{m}} \tag{2}$$

This frequency, ω, dependent factor, $\mathrm{K}(\omega)$, dynamically reflects the polarizability of a particle (subscript p) in a conductive medium (subscript m). The Clausius–Mosotti factor is a ratio of complex permittivities, $\tilde{\varepsilon}$, of the form $\tilde{\varepsilon} = \varepsilon - i\sigma/\omega$, where ω is the frequency, ε is the dielectric constant, and σ is the electrical conductivity of the medium. As can be seen, the complex $\mathrm{K}(\omega)$ factor has an imaginary component, which is out of phase with the applied electric field while the real component is in phase [2]. The imaginary component manifests itself as a torque on the particle and is detected in electrorotation or impendence measurements. However, the traditional dielectrophoretic force is dependent on the in-phase, or real component of the Clausius–Mosotti factor. In order to examine the special case when no frequency component is involved, DC-DEP can be estimated as the residual of this factor when frequency goes to zero [3]:

$$\lim_{\omega \to 0} \mathrm{K}(\omega) = \frac{\sigma_\mathrm{p} - \sigma_\mathrm{m}}{\sigma_\mathrm{p} + 2\sigma_\mathrm{m}} \tag{3}$$

Combining this all together and simplifying the gradient, one obtains an expression for the dielectrophoretic force:

$$\boldsymbol{F}_\mathrm{DEP} = \frac{1}{2} v \frac{\sigma_\mathrm{p} - \sigma_\mathrm{m}}{\sigma_\mathrm{p} + 2\sigma_\mathrm{m}} \nabla \boldsymbol{E}^2 \tag{4}$$

This dielectric force pushes particles toward regions of high field density or low field density depending on whether the Clausius–Mosotti factor is positive or negative, respectively. In other words, if $\sigma_\mathrm{p} < \sigma_\mathrm{m}$, then negative dielectrophoretic motion away from sharp points in electrodes or insulator obstacles is observed; the converse is true for positive dielectrophoresis. For a truly insulating particle, $\sigma_\mathrm{p} = 0$, the Clausius–Mosotti factor is simply $-1/2$, and motion away from high field density regions is observed [4]. Limiting further to a spherical particle yields:

$$\boldsymbol{F}_\mathrm{DEP} = -\frac{1}{3} \pi r^3 \nabla \boldsymbol{E}^2 \tag{5}$$

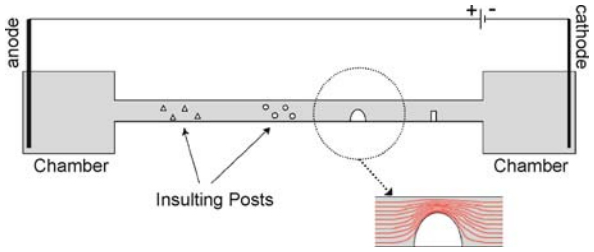
As a result of the complexity of this dielectric force phenomenon, many configurations and electric field operating conditions are possible. Specifically in DC fields, the nonuniform insulator geometry of obstacles results in a dielectrophoretic force acting on the polarized cell, which causes the cell to move either towards or away from electric field intensity without having the cells in direct contact with the electrode. Kang et al. noted the following advantages to direct current dielectrophoretic techniques [4]:

- insulators are less prone to fouling, thus they generally retain their function despite surface changes;
- no metal components are involved which greatly reduces the complexity of fabrication ...
- the structure is mechanically robust and chemically inert; and
- gas evolution due to electrolysis around the metal electrodes is avoided inside the channel.

Further, it is possible to simultaneously manipulate the particles via DC-DEP as well as linear electrophoresis in the same DC field. It should be noted that non-uniformities in the electric field are most effective when they occur over length scales comparable to a cell ($< 10\,\mu$m) in order for the cell to experience a significant dielectrophoretic force. Methods to embed insulators in the path of direct current electric field lines have varied. The next section will discuss these strategies.

Basic Methodology

Spatial non-uniformities in the electric field (i. e. gradients) can be created using any number of insulating protrusions or obstacles into a Lab-on-a-Chip device channel or chamber through which a DC field is being conducted. An insulator is a material that has a high resistance to flow of electrical current. DC field lines will naturally follow paths of least resistance through conducting fluid in channels and chambers. A characteristic of DC fields is that the field lines (paths of equal current) are parallel and follow a linear path with the flow of free electrons going from negative to positive. When an insulator is placed in the path of a DC field, the electric field lines diverge around the insulator and thus are densely compressed around insulator points and sharp edges. This results in a varying den-



DC Dielectrophoresis in Lab-on-a-Chip Devices, Figure 1 The diagram depicts chambers holding a reservoir of fluid (shaded) at either end of a Lab-on-a-Chip linear channel. The electrodes are immersed in the chamber liquid and deliver a linear DC electric field. Insulating posts or protrusions of varying geometries (triangular posts, cylindrical posts, protruding oil menisci, or rectangular protrusion) are depicted. The bottom inset shows the equally spaced parallel field lines diverging around a protruding oil meniscus. Highest field density occurs where the field lines are most densely packed

sity of the electric field and thus what is termed an electric field gradient.

A number of creative ways have been developed to create non-uniformities in an electric field using insulators. Initial efforts simply used prefabricated posts embedded in the channels or rectangular protrusions into the channels. These were typically made out of polydimethylsiloxane (PDMS), or polymethylmethacrylate (PMMA), which are common polymers for photolithography or hot embossing fabrication techniques, respectively [4]. More recently, oil menisci have been used. Please see Fig. 1.

The shapes of such insulator protrusions have varied enabling slightly modified electric field gradients. In all cases, highest field intensity occurs at sharp points or areas of highest curvature on the insulator as well as through areas of constriction in channels. A key attribute of direct current dielectrophoresis is that the electrodes supplying the electric field can be located more remotely on the Lab-on-a-Chip device. Electrodes can be immersed in fluid in chambers at either end of the test channel (Fig. 1).

Key Research Findings

Initial work in this area was conducted by Cummings and Singh and is described in their seminal paper [5]. In this work, two operating regimes were observed. The first, named *streaming DEP* occurred when the dielectrophoretic forces from the spatially non-uniform field dominated over diffusive forces, but not over electrophoresis or electroosmotic flow. In this case, the particle motion observed was due to dielectrophoretic motion into specified streamlines of electrokinetic flows. The second regime was titled *trapping DEP*; the dielectrophoretic force in this regime was greater than the diffusive forces and electrokinetic forces combined and as a result, particles were trapped at the insulating post surfaces. It is noted that this regime allows for *inexpensive and embedded batch filter/concentrator devices* [5].

Insulating post dielectrophoresis was then adopted in 2004 to concentrate and sort live and dead *E.coli* [3]. The batch concentrator strategy was employed for this work; results showed that at a DC fields of 16 V/mm, live *E.Coli* cells were concentrated between insulating posts. Bands of dead cells and then live cells were accomplished at 60 V/mm with the dead cells preferentially concentrating at the electric field maxima region [3]. Particle trajectories were carefully explored via experiments and simulations and elucidated repulsive effects to due dielectric wall/particle interactions. It was shown in this work that changes in the conductivity of the aqueous media did not effect changes in the trajectory of the particles while particle size did effect trajectories [6]. This is supported by Eq. (5) above.

Efforts then turned to exploring other insulative materials for electrodeless DEP. Cyclo-olefin polymers (Zeonor®) were used as the construction materials for microchannels and the resulting wall zeta potentials were correlated with DC-DEP particle behaviors [7]. It was found that DC-DEP trapping voltages for polystyrene beads were lower with this polymeric insulating post array than with previously explored glass posts [3, 5]. The next major advance in insulator materials for this class of devices was an oil droplet obstacle [8]. This was accomplished by pushing oil through an intersecting channel such that it protruded into the main channel to create an oil meniscus as depicted in Fig. 1. This strategy resulted in an insulating barrier without a sharp point, and it was shown to be effective at modifying the electric field to be nonuniform. Thus particles of different sizes were separated into different trajectories as they passed by the oil obstacle [8]. The newest unique accomplishment at this date is the extension of DC-DEP from aqueous media to a viscous media of silicone oil [9]. This work found that joule heating let to density gradients in the liquid and buoyancy forces, which significantly effected particle and water droplet velocities. It was found that these velocities increased with particle/droplet size. Research in this area continues to net interesting results applicable to future Lab-on-a-Chip devices [9].

Future Directions for Research

Insulator materials and configurations, which may be tailored to the given application, are the basis for future research in this area. Since traditional AC dielectrophoresis requires precise metallization of embedded electrodes, a DC dielectrophoretic approach eliminates this time consuming and expensive process. This will facilitate rapid

prototyping of ideas and streamlined fruition of devices to the marketplace. Further, the use of oil as insulating barriers in the chambers will allow for dynamic control of the electric field gradient within the channel. This opens up opportunities for separations or sorting of cells via feedback control mechanisms.

Of course, as this avenue of research progresses, further work on how various cell populations respond to field nonuniformities will also be explored. Integration of this technique within a complete Lab-on-a-Chip device capable of sample preparation, dilution, mixing, quantified sensing, etc. is another major milestone to be attained. One thing is clear, there is significant promise in this area because of the wide applications of dielectrophoresis and the advantages that arise when embedded electrodes are no longer a concern in Lab-on-a-Chip devices.

Synonyms

Phase separation kinetics; Unmixing; Spinodal decomposition

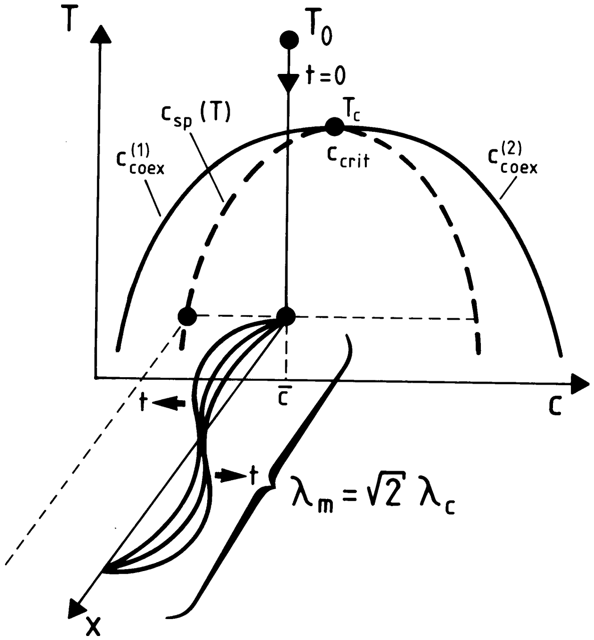
Definition

When a binary (or multicomponent) mixture by some fast change of external conditions (e. g. rapid change of temperature or pressure, etc.) is brought from the one-phase region into a state inside the miscibility gap of the equilibrium phase diagram, demixing occurs. That is, the system develops from a homogeneous state towards an arrangement of (macroscopic) domains of different chemical composition.

Overview

The basic mechanisms of phase separation of bulk binary fluid mixtures are either nucleation and growth, if the initial state from which the process starts is close to one of the branches of the coexistence curve which describe the concentrations of the phases coexisting in thermal equilibrium, or spinodal decomposition and subsequent coarsening, if the process starts from a state inside the unstable region of the equilibrium phase diagram. *Spinodal decomposition* means the spontaneous growth of long-wavelength concentration fluctuations, which are already present in the initial state. However, the so-called *spinodal curve*, separating the *metastable* region of the phase diagram (where phase separation starts by nucleation) from the *unstable* region, is not a well-defined concept, and the transition between these two mechanisms describing how concentration inhomogeneities develop is completely gradual.

After a brief review of these concepts, the effects of external boundaries on phase separation will be discussed. Confining a fluid mixture into a slit pore already modifies the static phase diagram of the system, precursors of wetting layers (surface layers where one component gets enriched)



Demixing, Figure 1 Schematic description of a quenching experiment which leads to spinodal decomposition of a binary mixture: one starts at a temperature T_c such that the system is in thermal equilibrium for times $t < 0$ at the chosen average concentration $\bar{c}$ of one species (say, B). At time $t = 0$ the system is *quenched* (i. e. suddenly cooled) to a temperature T underneath the coexistence curve (consisting of two branches $c_{coex}^{(1)}$, $c_{coex}^{(2)}$ which merge at an upper critical solution point T_c, c_{crit}). If the state point $(\bar{c}, T)$ at which the quench ends lies inside of the spinodal curve $c_{sp}(T)$, then the linear theory of spinodal decomposition predicts that in the bulk of the system long-wavelength concentration fluctuations which exceed a critical wavelength λ_c are unstable, their amplitude grows spontaneously with time t after the quench. Initially the maximum growth rate occurs for a wavelength $\lambda_m = \sqrt{2}\lambda_c$. This spontaneous amplification of concentration fluctuations is schematically indicated in the figure, where a growth of a single concentration wave in the x-direction is shown

may form at the walls of the pore, and in the direction normal to the confining walls the system always is inhomogeneous. *Surface-directed spinodal decomposition* (i. e. a concentration variation like a damped sinusoidal wave with wavevector oriented normal to the surface) then occurs as a transient initial stage before lateral phase separation sets in. Additional complications arise for demixing of fluid mixtures inside porous materials due to the randomness of the structure.

Basic Methodology

Spinodal Decomposition

For simplicity, we consider here only a binary mixtures (A,B), and do not discuss the complications posed by extensions to multicomponent systems. Figure 1 shows a schematic phase diagram in the plane of variables temperature T and concentration c of species B. Kinetics of phase separation in bulk fluid mixtures is triggered by a rapid quench (at time $t = 0$) from the one-phase region into the miscibility gap. The initial equilibrium state ($t \leqslant 0$) is spatially homogeneous, apart from small-scale concentration inhomogeneities. The final equilibrium state towards which the system ultimately evolves ($t \to \infty$) consists of macroscopic domains of the two coexisting phases, with concentrations $c_{coex}^{(1)}(T)$ and $c_{coex}^{(2)}(T)$, given by the coexistence curve. The relative amounts X, $1 - X$ are given by the lever rule,

$$\bar{c} = c_{coex}^{(1)}(T)X + c_{coex}^{(2)}(T)(1 - X) \qquad (1)$$

We are interested in the time evolution of the system from the initial homogeneous state to the final segregated state. According to the most simple-minded theoretical concepts on this process, the initial stages of phase separation depend on the question whether the considered state point $(T, \bar{c})$ to which the quench leads lies inside or outside a special curve in the phase diagram, the so-called spinodal $c_{sp}(T)$, which will be defined below. If the state point falls in between the spinodal and the coexistence curve, phase separation is started by (homogeneous or heterogeneous) nucleation [1], i. e. a nanoscopically small droplet of the new phase appears on the background of the old phase. If the state point falls underneath the spinodal curve, however, phase separation does not need to be triggered by such *heterophase fluctuations* but long-wavelength fluctuations with arbitrarily small amplitudes (so-called *homophase fluctuations*) suffice to start the phase separation (see Fig. 1). Of course, one should not misunderstand this figure assuming that a periodic concentration distribution forms in the system: there is a whole *wave packet* of unstable *concentration waves*, with wavelengths $\lambda_c < \lambda < \infty$, and random orientations of their wavevectors, and so the concentration pattern which forms rather has the character of a randomly interconnected structure, like in a sponge or in a seaweed [2].

Assuming that one can associate with the initial homogeneous but unstable state a free energy $F'(c)$, the instability of this state is attributed to a negative second derivative, $\left(\partial^2 F'(c)/\partial c^2\right)_T < 0$. In the metastable region, on the other hand, one has $\left(\partial^2 F'(c)/\partial c^2\right)_T > 0$, while the curve in the (T, c) plane where $\left(\partial^2 F'(c)/\partial c^2\right)_T = 0$ defines the spinodal (or *limit of metastability*). This notion is familiar also from the van der Waals theory of the vapor–liquid transition of a simple fluid.

At the outset we emphasize, however, that $F'(c)$ is not a well-defined quantity: thermodynamic potentials are well defined for thermal equilibrium states only, states

with $\left(\partial^2 F'(c)/\partial c^2\right)_T < 0$ violate the basis laws of statistical thermodynamics. For $c_{\text{coex}}^{(1)} < c < c_{\text{coex}}^{(2)}$ the only well-defined free energy is the free energy which corresponds to the lever rule, i. e. $F(c) = F\left(c_{\text{coex}}^{(1)}(T)\right)X + F\left(c_{\text{coex}}^{(2)}(T)\right)(1-X)$, i. e. a linear function of the concentration. The double-well shape of $F(c)$ obtained from mean-field theories, such as the Bragg–Williams approximation of binary mixtures, is an artifact of an uncontrolled approximation. So the singular behavior resulting at the spinodal should not be taken seriously.

Nevertheless, the linearized theory of spinodal decomposition, based on the assumption that $\left(\partial^2 F'(c)/\partial c^2\right)_T < 0$ inside of the spinodal curve, provides a useful first orientation, and shall be described here. One considers the dynamics of a time-dependent local concentration field $c(\boldsymbol{x}, t)$. Since the average concentration $\bar{c} = (1/V)\int dx c(\vec{x}, t)$ is conserved, $c(\boldsymbol{x}, t)$ satisfies a continuity equation:

$$\frac{\partial c(\boldsymbol{x}, t)}{\partial t} + \nabla \cdot \boldsymbol{j}(\boldsymbol{x}, t) = 0 \tag{2}$$

where $\boldsymbol{j}(\boldsymbol{x}, t)$ is the concentration current density. Following standard nonequilibrium thermodynamics, $\boldsymbol{j}(\boldsymbol{x}, t)$ is set proportional to the gradient of the local chemical potential difference $\mu(\boldsymbol{x}, t)$,

$$\boldsymbol{j}(\boldsymbol{x}, t) = -M\nabla\mu(\boldsymbol{x}, t) \tag{3}$$

where M is a mobility. Since in thermal equilibrium $\mu = (\partial F/\partial c)_T$, we generalize this relation for an inhomogeneous situation out of equilibrium in terms of a functional derivative,

$$\mu(\boldsymbol{x}, t) = \delta\Delta F\left[c(\boldsymbol{x}, t)\right]/\delta c(\boldsymbol{x}, t) \tag{4}$$

where the free energy functional describing the inhomogeneous situation out of equilibrium is given as follows ($f' = F'/V$):

$$\Delta F\left[c(\boldsymbol{x}, t)\right] = \int dx \left\{ f'\left[c(\boldsymbol{x}, t)\right] + \frac{1}{2} r^2 k_{\mathrm{B}} T \left[\nabla c(\boldsymbol{x}, t)\right]^2 \right\} \tag{5}$$

Here the *gradient square* term describes the extra free energy cost due to concentration inhomogeneities. Boltzmann's constant is denoted as k_{B}, and the parameter r then has dimensions of length (in microscopic models, e. g. lattice models of binary mixtures treated in mean field approximation, r has the meaning of the range of pairwise interactions among the particles).

Equations (4) and (5) lead to

$$\mu(\boldsymbol{x}, t) = (\partial f'/\partial c)_T - r^2 k_{\mathrm{B}} T \nabla^2 c(\boldsymbol{x}, t) \tag{6}$$

and using this result in the continuity equation one obtains a generalized nonlinear diffusion equation [3]:

$$\frac{\partial c(\boldsymbol{x}, t)}{\partial t} = M\nabla^2 \left\{ \left(\frac{\partial f'\left[c(\boldsymbol{x}, t)\right]}{\partial c} \right)_T - r^2 k_{\mathrm{B}} T \nabla^2 c(\boldsymbol{x}, t) \right\} \tag{7}$$

Now it is assumed that in the initial state the fluctuation $\delta c(\boldsymbol{x}, t) = c(x, t) - \bar{c}$ is very small everywhere in the system (since on small length scales fluctuations can be large, this assumption typically is not true, but it is necessary to allow a simple analysis of Eq. (7)). Linearizing then Eq. (7) in $\delta c(\boldsymbol{x}, t)$ yields the equation

$$\frac{\partial \delta c(\boldsymbol{x}, t)}{\partial t} = M\nabla^2 \left\{ \left(\frac{\partial^2 f'\left[c(\boldsymbol{x}, t)\right]}{\partial c^2} \right)_{T,\bar{c}} - r^2 k_{\mathrm{B}} T \nabla^2 \right\} \delta c(\boldsymbol{x}, t) \tag{8}$$

which is solved by introducing Fourier transforms ($\boldsymbol{k}$ is the wavevector):

$$\delta c_k(t) = \int \mathrm{d}\boldsymbol{x} \exp(i\boldsymbol{k} \cdot \boldsymbol{x}) \delta c(\boldsymbol{x}, t) \tag{9}$$

to obtain

$$\delta c_k(t) = \delta c_k(0) \exp\left[A(k)t\right] \tag{10}$$

with the rate factor for the amplification of fluctuations

$$A(k) = -Mk^2 \left[\left(\partial^2 f'/\partial c^2 \right)_{T,\bar{c}} + r^2 k_{\mathrm{B}} T k^2 \right] \tag{11}$$

The equal-time structure factor $S(k, t)$ at the time t after the quench is

$$S(k, t) \equiv \left\langle \delta c_{-k}(t) \delta c_k(t) \right\rangle_T \tag{12}$$

where $\langle \ldots \rangle_T$ denotes a thermal average. Note that $S(k, t)$ is readily found experimentally by scattering of neutrons, X-rays or light, depending on the length scales of interest. Equations (10)–(12) imply that $S(k, t)$ has a simple exponential variation with time:

$$S(k, t) = S_{T_0}(k) \exp\left[2A(k)t\right] \tag{13}$$

where $S_{T_0}(k) = \left\langle \delta c_{-k}(0) \delta c_k(0) \right\rangle_T = \left\langle \delta c_{-k} \delta c_k \right\rangle_{T_0}$ is simply the equal-time structure factor in thermal equilibrium at temperature T_0 before the quench.

Note that $A(k)$ is positive for $0 < k < k_c$, with

$$k_c = 2\pi/\lambda_c = \left[-\left(\partial^2 f'(c)/\partial c^2\right)_{T,\bar{c}} / \left(r^2 k_B T\right)\right]^{1/2} \quad (14)$$

and hence the structure factor during the initial stages of phase separation (where the above linearization approximation is hoped to work) grows exponentially with time. This mechanism of phase separation, spontaneous amplification of fluctuations, is termed *spinodal decomposition*. Of course, this exponential growth is limited by nonlinear effects, which imply that the linearization of Eq. (7) yielding Eq. (8) no longer is valid, and those nonlinear effects cause an onset of *coarsening*: rather than observing a peak of $S(k,t)$ growing at a fixed wavenumber $k_m = 2\pi/\lambda_m$, where $A(k)$ is maximal (note $k_m = k_c/\sqrt{2}$ is easily derived from Eq. (9), with $dA(k)/dk = 0$ for $k = k_m$), the position $k_m(t)$ of the peak of $S(k,t)$ shrinks to zero as time $t \to \infty$, $k_m(t) \propto t^{-a}$, where a is a characteristic exponent describing this domain growth. The physical interpretation is that the growing concentration inhomogeneities develop into domains, separated by interfaces, and the length scale $\ell(t)$ of these domains increases with time: $\ell(t) \propto 1/k_m(t) \propto t^a$. The driving force of this *coarsening* of the domains which have formed is the reduction of total interfacial area and thus interfacial free energy cost in the system.

Another spectacular prediction of this linear theory, Eqs. (8)–(13), would originate from the presence of a special wavenumber k_c where $S(k = k_c, t)$ is strictly independent of time since $A(k = k_c) = 0$. Such a behavior is not at all observed, and the reason is that Eqs. (2) and (3) are completely deterministic, and lack the presence of statistical thermal fluctuations that physically should occur for the system in its states at the temperature $T > 0$. This problem can be remedied by adding a suitable random force term at the right-hand side of Eq. (3).

Finally, we draw attention to the special role played by the spinodal $c_{sp}(T)$. We expect that $-(\partial^2 f'(c)/\partial^2 c)_{T,\bar{c}} \propto \bar{c} - c_{sp}(T)$ for $\bar{c}$ close to $c_{sp}(T)$, and hence k_c exhibits for $\bar{c} \to c_{sp}(T)$ a critical vanishing, $k_c \propto [c - c_{sp}(T)]^{1/2}$, implying a divergence of the critical wavelength $\lambda_c = 2\pi/k_c$ (Fig. 2a). Similarly, when one approaches the spinodal from the metastable region of the phase diagram, the prediction of the mean-field theory of nucleation is that the radius R^* of the *critical droplet* (necessary to effect the creation of a nucleus of the stable phase on the background of the metastable phase) exhibits a similar critical divergence (Fig. 2a), $R^* \propto [c_{sp}(T) - \bar{c}]^{-1/2}$. However, there is no clear evidence for such a divergent length scale when one carries out quenches into the region of the phase diagram where the spinodal is expected to occur [3]. Rather, there is compelling evidence from both experiments and computer simulations that the transition from nucleation to spinodal decomposition is completely gradual [3] (Fig. 2a).

Nucleation and the Spinodal Curve

Before we comment on the reasons for this lack of a nonexistence of singularities associated with the spinodal, we recall the basic ideas about nucleation. One assumes that the critical fluctuation to consider is a spherical droplet (of the B-rich phase on the background of the A-rich metastable phase), and this droplet is described like a macroscopic object despite its nanoscopic size. Thus, considering the droplet formation free energy $\Delta F(R)$ as a function of droplet radius R,

$$\Delta F(R) = \Delta g(\bar{c})\left(4\pi R^3/3\right) + \gamma_{int}\left(4\pi R^2\right), \quad (15)$$

where the first term describes the contribution proportional to the droplet volume and the second term is a surface correction, γ_{int} being the interfacial free energy per unit area, taken for a flat planar interface. If $\bar{c}$ exceeds $c^{(1)}_{coex}$ only slightly, we may write

$$\Delta g(\bar{c}) = -\left(c^{(2)}_{coex} - c^{(1)}_{coex}\right)\left(\mu - \mu_{coex}\right) \quad (16)$$

μ_{coex} being the chemical potential difference at the coexistence curve. Minimizing now $\Delta F(R)$ with respect to R yields that the maximum value occurs at

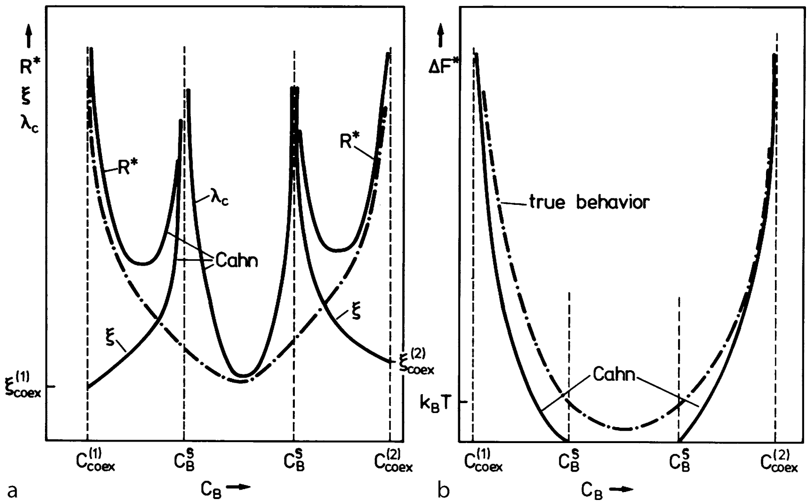
$$R^* = 2\gamma_{int} / \left[\left(c^{(2)}_{coex} - c^{(1)}_{coex}\right)\left(\mu - \mu_{coex}\right)\right] \quad (17)$$

and the free energy barrier against homogeneous nucleation becomes

$$\Delta F^*(R = R^*) = \frac{(16\pi/3)\gamma^3_{int}}{\left[\left(c^{(2)}_{coex} - c^{(1)}_{coex}\right)\left(\mu - \mu_{coex}\right)\right]^2} \quad (18)$$

According to this formula, ΔF^* decreases monotonically with increasing concentration $\bar{c}$, but one can trust this result near the coexistence curve only, of course. The nucleation rate (number of nuclei formed per unit volume and unit time) then is estimated from the Arrhenius formula, $J = \nu^* \exp(-\Delta F^*/k_B T)$, ν^* being the so-called *attempt frequency*.

A treatment of the nucleation barrier that is not restricted to the neighborhood of the coexistence curve is also based on the free energy functional, Eq. (5). In fact, using such an approach for an *order parameter* $\psi(z)$ designed such that for $z \to -\infty$ one has a phase characterized by $\psi(z \to -\infty) \to -\psi_{coex}$, while for $z \to +\infty$ one has a phase characterized by $\psi(z \to +\infty) = +\psi_{coex}$, Fig. 3a,



Demixing, Figure 2 (**a**) Characteristic lengths (a) and (b) nucleation barrier ΔF^* plotted vs. concentration c_B. *Full curves* show the predictions of the Cahn–Hillard mean-field theory of nucleation and spinodal decomposition for the critical wavelength λ_c and the correlation length ξ of concentration fluctuations in a metastable state, the radius R^* of a *critical droplet* (a) and the free energy barrier ΔF^* (**b**) *Dash-dotted curves* show, *on a different scale*, the conjectured smooth behavior of a system with short range interaction, for which the spinodal singularities at c^S_B are completely washed out

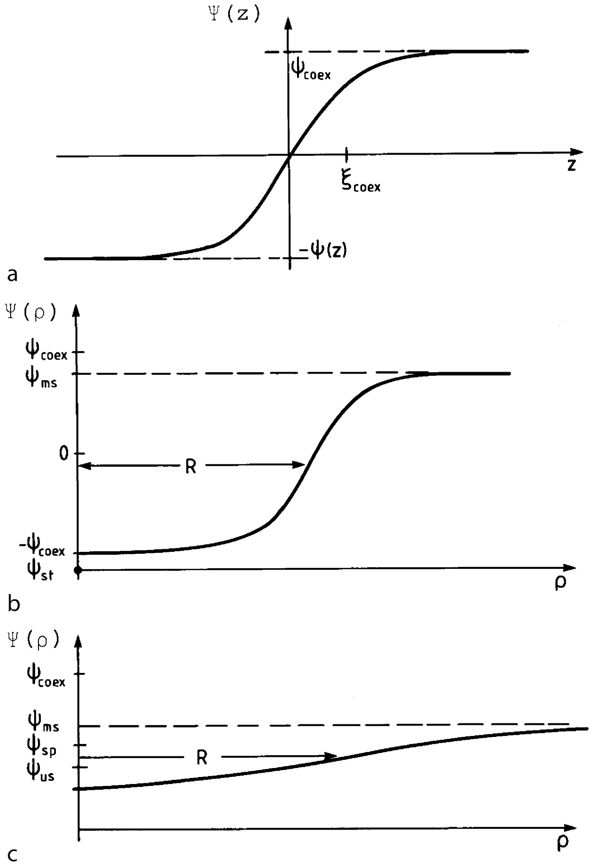
one can compute the interfacial profile $\psi(z)$ and associated interfacial tension by minimizing this free energy functional $\Delta F[\psi(z)]$ subject to the constraint that the specified boundary conditions are obeyed. Near the critical temperature T_c in Fig. 1 one obtains [4]

$$\psi(z) = \psi_{coes} \tanh\left[z/(2\xi_{coex})\right] ;$$
$$\xi_{coes} \propto r\left(1 - T/T_c\right)^{1/2} \qquad (19)$$

and $\gamma_{int} \propto r\left(1 - T/T_c\right)^{3/2}$. Since the range of the interaction (r) enters as a prefactor both in the correlation length ξ_{coex} at the coexistence curve, the *intrinsic width* $\ell_0 = 2\xi_{coex}$ of the interfacial profile, and the interfacial free energy, and hence ΔF^* scales as r^3 (Eq. (18)), we already see that r is a key parameter controlling the behavior of the system. In fact, for $r \to \infty$ it becomes too costly to form interfaces in the system, and so homogeneous nucleation is suppressed altogether, and then the spinodal curve and the singularities associated with it become well defined [3, 4].

This mean-field theory to calculate the interfacial profile and interfacial free energy can be extended to compute also for a critical droplet the order parameter profile (for a binary mixture near the critical point, $\psi_{coex} = c^{(2)}_{coex} - c_{crit}$, $-\psi_{coex} = c^{(1)}_{coex} - c_{crit}$, cf. Fig. 1). Qualitatively, the results are sketched in Figs. 3b and c: one simply imposes spherical symmetry to $\Delta F[\psi(\rho)]$ and minimizes this free energy functional subject to the constraint that $\psi(\rho \to \infty) \to \psi_{ms}$, the order parameter in the metastable phase surrounding the droplet. If ψ_{ms} is close to ψ_{coex}, the resulting profile $\psi(\rho)$ closely resembles the profile $\psi(z)$ of a flat interface; only the center of the interface now occurs at $\rho = R$, the droplet radius. In fact, this behavior is very well consistent with the separation of the excess free energy in bulk and interfacial terms, as written in Eq. (15). However, if ψ_{ms} is close to the spindodal, ψ_{sp}, Fig. 3c, the behavior is very different. There is no longer any clear-cut distinction between the droplet interior and its interface, and the amplitude of the whole order parameter variation across the droplet vanishes as $\psi_{ms} \to \psi_{sp}$. Physically, such a droplet profile can be interpreted as the spherical average of a ramified cluster, unlike the compact droplet assumed in Eq. (15) and found for ψ_{ms} near ψ_{coex} (Fig. 3b). Actually, the free energy cost to form such a droplet also is rather small, one finds $\Delta F^*(\psi_{ms} \to \psi_{sp}) \propto r^3(\psi_{sp} - \psi_{ms})^{3/2}$.

Now, although this mean field theory of nucleation can be executed throughout the full metastable region, from the coexistence curve all the way to the spinodal, it clearly makes sense only if the resulting free energy barrier against nucleation by far exceeds the thermal energy scale, $\Delta F^*(R = R^*) \gg k_BT$. If ΔF^* gets down to the order of k_BT, critical droplets could form everywhere in the system simultaneously, and the idea that far from the droplet one still has the homogeneous metastable phase fails. The condition that $\Delta F^* = 1$ yields then the ultimate limit of metastability, not $\Delta F^* = 0$ (the actual spinodal), and hence the condition $\Delta F^* = 1$, or equivalently $(\psi_{sp} - \psi_{ms}) \propto r^{-2}$, shows how close one can approach



Demixing, Figure 3 (**a**) Order parameter profile $\psi(z)$ across an interface between two coexisting bulk phases with order parameters $\pm\psi_{\text{coex}}$, the interface being oriented perpendicular to the z-direction and centered at $z = 0$ (**b**) Radial order parameter profile for a marginally stable droplet of radius R. In the center of the droplet the order parameter takes the value of the stable phase at coexistence, $-\psi_{\text{coex}}$, while for radial distances $\rho \to \infty$, $\psi(\rho) \to \psi_{\text{ms}}$, the order parameter of the considered metastable state, for ψ_{ms} close to ψ_{coex}. (**c**) Same as (**b**), but for ψ_{ms} close to the spinodal, ψ_{sp}. Then $\psi(\rho = 0)$ does not reach $-\psi_{\text{coex}}$, but rather stays close to the unstable extremum of the free energy $f'(\psi)$, ψ_{us}

the spinodal before the crossover from nucleation to spinodal decomposition sets in. Actually, the situation is even more unfavorable when one includes the dependence on temperature distance from the critical point into the consideration (cf. Eq. (17)), and then one concludes that for mean-field theory to be self-consistent one requires first that $r^3(1 - T/T_c)^{1/2} \gg 1$ and [3, 4]

$$1 \ll r^3\left(1 - T/T_c\right)^{1/2}\left[1 - \bar{c}/c_{\text{sp}}(T)\right]^{\frac{3}{2}} \tag{20}$$

Similarly, exponential growth of the structure factor in spinodal decomposition with time t is predicted to occur when [3]

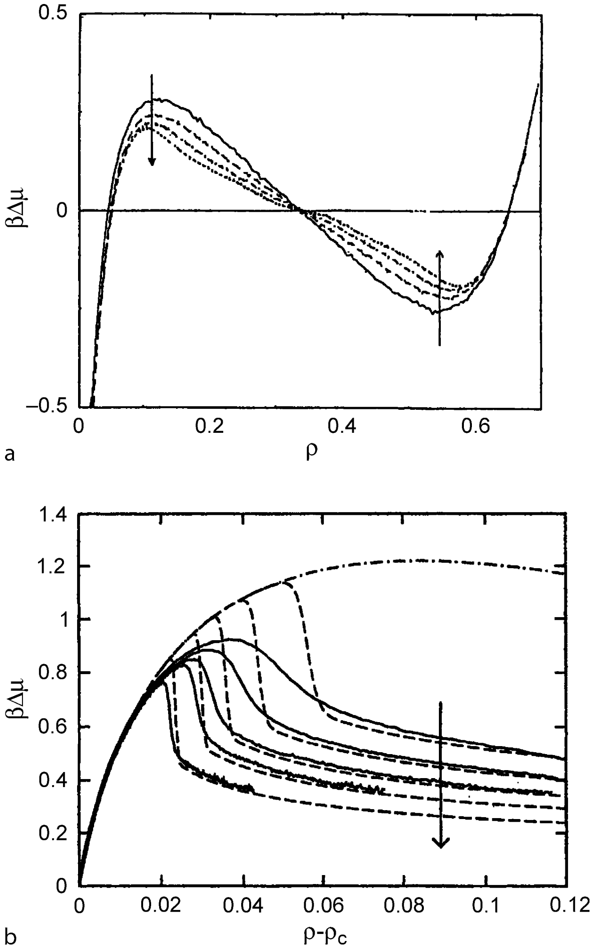
$$\exp(2A(k_m)t) \ll r^3\left(1 - T/T_c\right)^{1/2}\left[\bar{c}/c_{\text{sp}}(T) - 1\right]^{\frac{3}{2}} \tag{21}$$

These results explain why it is so difficult to verify experimentally the predictions of the linear theory of spinodal decomposition quantitatively.

Spinodals in Nanosystems

In the previous sections, a macroscopically large volume ($V \to \infty$) was tacitly assumed. Only then does the lever role hold, Eq. (1), which is based on ignoring interfacial contributions to the thermodynamic potential in the description of phase coexistence in thermal equilibrium.

If one considers a finite volume, say a box $L \times L \times L$, with periodic boundary conditions (or with *neutral* surfaces that do not prefer any of the coexisting phases), the situation is different: in a discussion of the thermodynamic equilibrium state of such a system, for conditions where for $L \to \infty$ one would have a two-phase coexistence, interfacial free energy contributions must not be neglected. And while for $L = \infty$ phase coexistence is described by a horizontal curve $\mu(c) = \mu_{\text{coex}}$, for $c^{(1)}_{\text{coex}} < c < c^{(2)}_{\text{coex}}$, for finite L one encounters a loop [5], with a maximum and a minimum (Fig. 4a). Actually, the example shown there does not refer to a fluid binary mixture, it rather refers to the demixing of a simple fluid into low-density vapor and high-density liquid, but we emphasize that the behavior of the fluid mixtures should be fully analogous. However, while in the regime of densities $\rho < \rho^{(1)}_{\text{coex}}$ (stable vapor) and $\rho > \rho^{(2)}_{\text{coex}}$ (stable liquid) the simulation data shown in this example rapidly converge with increasing L towards their limiting behavior, for $\rho^{(1)}_{\text{coex}} < \rho < \rho^{(2)}_{\text{coex}}$ the convergence is very slow: While for small L the loop is van der Waals-like, with increasing L the loop gets smaller, and the locations of the extrema $\rho^{(1)}_{\text{sp}}$, $\rho^{(2)}_{\text{sp}}$ slightly shift towards $\rho^{(1)}_{\text{sp}}$ and $\rho^{(2)}_{\text{sp}}$. Although, at first sight, these curves resemble van der Waals loops, their interpretation is completely different: the extrema are due to transitions from the homogeneous vapor and liquid phases (for $\rho < \rho^{(1)}_{\text{sp}}$ or $\rho > \rho^{(2)}_{\text{sp}}$, respectively) to a mixed state where vapor and liquid coexist (for $\rho^{(1)}_{\text{sp}} < \rho < \rho^{(2)}_{\text{sp}}$). As an example, Fig. 4b presents a more detailed study of these loops near $\rho_c \equiv \rho^{(1)}_{\text{coex}}$ at a lower temperature, where the behavior is more clearly seen. As L increases, a rather sharp transition from the supersaturated vapor (part of the curve where $\Delta\mu$ rises with increasing density ρ) to a less supersaturated vapor plus a liquid droplet occurs. This droplet evaporation/condensation transition becomes sharp only in the limit $L \to \infty$ where it disappears at the same time [5],



Demixing, Figure 4 (**a**) Normalized chemical potential difference $\beta\Delta\mu$ ($\beta = 1/(k_B T)$) of a simple Lennard-Jones fluid (particles interacting with a potential $u(r) = 4\varepsilon[(\sigma/r)^{12} - (\sigma/r)^6]$) plotted versus density ρ at a temperature $T = 0.85437$ (choosing units such that $\varepsilon = 1$). Here, μ_{coex} is the chemical potential of the fluid at which vapor–liquid coexistence occurs in the thermodynamic limit. Monte Carlo simulation *data* are shown, choosing cubic boxes of linear dimension $L \times L \times L$, with periodic boundary conditions in all three directions of space, and four sizes, $L = 6.74$, 9.0, 11.3 and 13.5, respectively (the arrows indicate increasing system size). (**b**) Same as (**a**), but for $T = 0.68$ and larger system sizes ($L = 11.3$, 13.5, 15.8, 18.3, and 22.5, from above to below, full curves). Dashed curves are corresponding predictions from an approximate analytical theory, describing the equilibrium of a liquid droplet with surrounding supersaturated vapor in a finite box, using Eq. (15). Dash-dotted curve represents the mean-field equation of state as given by the mean spherical approximation. From MacDowell et al. [5]

since then $\rho_{\text{sp}}^{(1)}$ coincides with $\rho_{\text{coex}}^{(1)}$. It is important to realize that these *loops* in Fig. 4 do not contain metastable and unstable parts, as are attributed to a van der Waals-like loop, but rather the whole loop, for the finite system, represents the true thermal equilibrium behavior. Thus, in a finite box for $\rho_{\text{coex}}^{(1)} < \rho < \rho_{\text{sp}}^{(1)}$ there is no possibility for the supersaturated vapor to decay, simply the total particle number contained in the box is too small to allow the nucleation of a stable droplet.

Of course, if the box is very small, e. g. $L \leqslant 3\xi_{\text{coex}}$ [4], then no phase separation within a box is possible at all, and then the state of the system is homogeneous irrespective of density. Thus, the mean field free energy density $f'(c)$ discussed above can be given a well-defined meaning when we re-interpret it as a coarse-grained free energy density $f_L(c)$ of a coarse-graining cell which has a linear dimension L of the order of ξ_{coex} or smaller. Note, however, that ξ_{coex} is typically only of the order of a Lennard-Jones diameter, except in the immediate vicinity of the critical point.

Coarsening: Dynamics of Phase Separation During the Late Stages

Irrespective of whether demixing has started by nucleation and growth or by spinodal decomposition, in the later stages of the process the state of the system is a heterogeneous arrangement of domains of the minority phase on the background of the majority phase. In cases where the volume fraction X of the minority phase is small enough, these domains are well separated from each other, while for large enough X the minority domains also form a percolating interconnected structure. It often is said that the morphology of well-separated droplets is evidence that phase separation has started by nucleation, but such an inference, in fact, is not conclusive: in reality there is no simple connection between the morphology of the late stages and the initial growth mechanism, and examples exist when an initially percolating rather ramified structure later breaks up into more compact separated droplets.

A comprehensive theory for the coarsening of such domains which are formed as a result of demixing is a formidable problem [2, 6, 7]. Here we only give a brief summary of some of the main mechanisms proposed in the literature.

The first mechanism proposed by Lifshitz and Slyozov (LS), also called the evaporation–condensation mechanism, is derived [6–8] for the situation where a *population* of droplets of the minority phase is in local equilibrium with the surrounding majority phase, which is slightly supersaturated because of the Gibbs–Thompson effect. Since in this droplet population more B-atoms *condense* on the larger B-rich droplets than *evaporate* into the supersaturated A-rich background, while for the smaller B-rich droplets the reverse is true, the diffusion of the B-atoms in the A-rich matrix maintain concentration gradients by which the smaller droplets shrink and finally dissolve in the matrix and the larger droplets grow. This mechanism

leads to a growth law $\ell(t) \propto t^{1/3}$ with time t after the quench, for $t \to \infty$, where $\ell(t)$ is the linear dimension of the growing droplets. This law holds in all dimensionalities $d \geqslant 2$. Although the original derivation [8] only holds for the limit of vanishing volume fraction of the B-rich phase, one now believes [6, 7] that the *LS* $t^{1/3}$ law holds for arbitrary volume fractions, but only in purely diffusive systems (i. e. solid rather than fluid binary mixtures, but in the latter it may also appear as a competing mechanism).

The droplet diffusion and coagulation mechanism [9] was the first proposal specifically addressing fluid mixtures, and is based on Stokes' law for the diffusion of droplets. That is, one assumes a diffusion constant $D(R)$ scaling with droplet radius R as $D(R) \propto \eta^{-1}R^{2-d}$, η being the shear viscosity of the fluid. The time τ for a droplet to travel a distance R then is estimated from the Einstein relation: $\tau D(R) = 2dR^2$, i. e. $\tau \propto \eta R^d$. At not too low volume fractions the average distance between droplets is of the order of R, and when two droplets collide they will coalesce. This leads to a volume change of the droplet of order $\Delta V \propto R^d$. So $\Delta V/\tau \propto \eta^{-1}$, and equating this to $\mathrm{d}V/\mathrm{d}t \propto R^{d-1}\,\mathrm{d}R/\mathrm{d}t$ yields $\mathrm{d}R/\mathrm{d}t \propto R^{1-d}/\eta$ or $R(t) \propto (t/\eta)^{1/d}$.

A faster mechanism of domain growth was proposed for the coarsening of interconnected domain structures [10], for $d = 3$, when the volume fraction of the minority phase is sufficiently large to maintain such a percolating structure. The key mechanism then is the deformation and break-up of tube-like regions in the domain structure. The characteristic velocity field v_ℓ around domains having linear dimensions ℓ is determined by a balance between the surface tension force density of order γ/ℓ, and the viscous stress of order $6\pi\eta v_\ell/\ell$. This leads to $v_\ell \propto \gamma/\eta$ and a growth law $\ell(t) \propto v_\ell t \propto (\gamma/\eta)t$, in $d = 3$ [10]. In $d = 2$, the analogue of this hydrodynamic mechanism is somewhat controversial, predictions range from $\ell(t) \propto t^{1/2}$ to $\ell(t) \propto t$, but it also has been suggested that different characteristic length scales may exhibit different growth exponents, and hence there would be no simple *dynamical scaling* [2, 6, 7] for domain growth in $d = 2$ at all. If dynamical scaling holds one expects that the equal-time structure factor $S(k,t)$ does not depend on both variables k and t in a completely general form, but essentially it depends on a single scaled variable $\zeta = k\ell(t)$ only

$$S(k,t) = [\ell(t)]^d \quad \tilde{S}(k\ell(t)) \,, \tag{22}$$

where $\tilde{S}(\zeta)$ is a *scaling function*. Prediction of $\tilde{S}(\zeta)$ is difficult even if the growth law $\ell(t) \propto t^a$ is known [2, 6, 7].

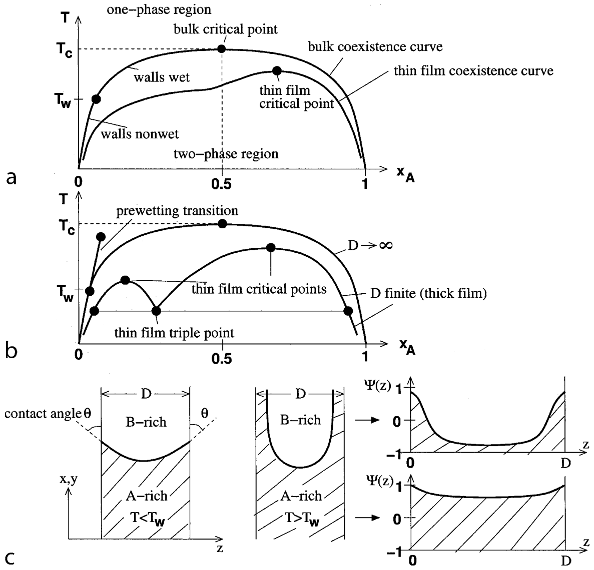
Finally, we note that the growth laws mentioned above hold only for low enough Reynolds numbers. On the scale of the domain size, the Reynolds number can be estimated as $\mathrm{Re}(\ell) = nv_\ell/\eta$, where n is the density, and hence $\mathrm{Re}(\ell)$ increases with time as the domain size grows. When $\ell(t)$ exceeds the so-called *inertial length* $\ell_{\mathrm{in}} \approx 10\eta^2/(n\gamma)$, one encounters both in $d = 2$ and $d = 3$ a regime where the surface energy density γ/ℓ is balanced with the kinetic energy density nv_ℓ^2. By setting $\ell = v_\ell t$ one obtains in this so-called *inertial regime* a growth law $\ell(t) \propto (\gamma/n)^{1/3}t^{2/3}$ [7].

From the above considerations it is clear that our discussion of spinodal decomposition in terms of a generalized nonlinear diffusion equation (Eq. (5)) was very incomplete, since there it was tacitly assumed that the concentration field $c(\boldsymbol{x},t)$ is the only relevant slow variable in the problems while in reality a second slow variable, the velocity field $v(\boldsymbol{x},t)$, needs to be included, even if the fluid on average is at rest. A particularly interesting complication arises for fluids exposed to shear flow, where the direction of $\boldsymbol{k}$ (relative to the flow direction) matters [11], while for fluids at rest $S(\boldsymbol{k},t)$ is isotropic. This problem is beyond our scope here, as are the subtleties which arise when the two constituents of a binary mixture have vastly different viscosity (*viscoelastic phase separation* [12]).

Binary Mixtures Confined Between Walls in Slit Pores: Equilibrium Behavior

In the context of microfluidics and nanofluidics, demixing of fluid binary mixtures confined in narrow pores is a particularly relevant issue. An important facet of this behavior is that the concentration of such confined mixtures is typically rather inhomogeneous in the z-direction perpendicular to the walls of a pore, and the equilibrium phase behavior due to the confinement which differs from that of the corresponding bulk mixture. The understanding of these phenomena is a prerequisite for a discussion of demixing kinetics in pores or narrow channels.

Figure 5 summarizes these effects in a qualitative way for a binary symmetric mixture [13]. Near the critical temperature T_c, the coexistence curve in the bulk is described by a power law for the concentrations x_A of A at the coexistence curve, $x_{\mathrm{A,coex}}^{(1,2)} - x_{\mathrm{A}}^{\mathrm{crit}} \hat{\to} \pm B(1 - T/T_c)^\beta$, where $x_{\mathrm{A}}^{\mathrm{crit}} = 1/2$ for a symmetric mixture, B is a system-dependent *critical amplitude* and the critical exponent $\beta \approx 0.325$, the universal value for the *universality class* of the $d = 3$ Ising model [2, 13]. At the surface of a semi-infinite mixture one may encounter a wetting transition [14]. This wetting transition implies a singular behavior of the surface excess free energy F_s, which is defined as (for a film between two walls at distance D) $F_{\mathrm{film}} = F_{\mathrm{bulk}} + (2/D)F_s$, $D \to \infty$, F_{bulk} being the bulk free energy of the system. Assuming, as done in figure 5, that the wetting transition occurs at the surface of B-rich mixtures (caused by the preferential attraction of A-particles to the walls), the transition is char-



Demixing, Figure 5 Schematic phase diagrams (**a**), (**b**) and corresponding state (**c**) of a symmetric A, B mixture in a thin film of thickness D, using temperature T and concentration x_A of A as variable. The film is symmetric, i. e. both walls attract the A-particles with the same strength. In the limit $D \to \infty$ a wetting transition occurs at a temperature T_W, while for finite D the transition of the walls from *nonwet* (or *partially wet*) to *wet* (or *completely wet*) is rounded into a smooth gradual change. The wetting transition is assumed to be of second order in (**a**), while (**b**) refers to a first-order wetting transition. In (**b**), a prewetting transition line exists in the one-phase region, with one end being a prewetting critical point at high temperatures. The other end of this line is at the wetting transition temperature T_W, at the coexistence curve that separates the two-phase region from the one-phase region. Note that the critical concentration of a symmetric binary mixture is $x_A^{crit} = 0.5$ in the bulk, but is shifted to a larger value x_A in the thin film. Further, the critical temperature of the thin film typically is lower than in the bulk, $T_C(D) < T_C(\infty) = T_C$. For the case of first-order wetting and large enough D, a thin-film analog of the prewetting transition exists, as evidenced by the thin-film critical point at the left side of the phase diagram. When the thin enrichment layer segregation meets the lateral segregation of the *thick* film, a thin film triple point occurs at a temperature close to T_W. In (**c**) we provide schematic pictures of the thin-film states in the case of lateral phase segregation

acterized by a divergence of the surface excess concentration of A, x_A^{surf}. This surface excess concentration can either be found from F_s via suitable derivatives, or, equivalently, by integrating the concentration profile, $x_A^{surf} = \int_0^{D/2} \left[x_A(z) - x_{A,coex}^{(1)}\right] dz$, $D \to \infty$, z being the distance from the left wall, which is oriented perpendicular to the z-axis at $z = 0$. If the wall is *nonwet* (also called *incompletely wet*), x_A^{surf} tends to a finite value, $x_{A,coex}^{surf}$, when $x_A \to x_{A,coex}^{(1)}$ from the one-phase region. For a *wet* wall, on the other hand, $x_{A,coex}^{surf} = \infty$ (corresponding to an infinitely thick A-rich wetting layer coating the wall, separated from the B-rich bulk by a flat interface).

This situation (*complete wetting*) implies a divergence of x_A^{surf} when $x_A \to x_{A,coex}^{(1)}$ at constant temperature. For short-range forces between the walls and the particles this divergence is only logarithmic, $x_A^{surf} \propto \left|\ln(x_{A,coex}^{(1)} - x_A)\right|$, while for attractive forces which decay with distance z like a power law (e. g. van der Waals forces) one also obtains a power law divergence of x_A^{surf} [14]. At the coexistence curve $x_{A,coex}^{(1)}$, the surface excess free energy thus is that of a B-rich phase $F_{s,coex}^{B\text{-rich}}$ if the wall is non-wet, while for a wet wall we have $F_s = F_{s,coex}^{A\text{-rich}} + \gamma$, γ being (as above) the interfacial tension between coexisting bulk A-rich and B-rich phases. These quantities also determine the contact angle θ under which an A–B interface in the non-wet region meets the wall, $\cos\theta = (F_{s,coex}^{B\text{-rich}} - F_{s,coex}^{A\text{-rich}})/\gamma$, if $F_{s,coex}^{B\text{-rich}} < F_{s,coex}^{A\text{-rich}} + \gamma$ (see Fig. 5).

If one changes the state of the system such that one increases the temperature but stays always at the coexistence curve $x_{A,coex}^{(1)}$, one may encounter a wetting transition at T_W where the state of the wall changes from non-wet ($T < T_W$) to wet ($T > T_W$). This transition may be of first order (Fig. 5b) or second order (Fig. 5a). In the latter case, x_A^{surf} diverges continuously when $T \to T_W$ from below, while otherwise there is a discontinuous jump from a finite value at T_W to infinity. In this latter case, there is also a prewetting transition occurring in the one-phase region, where the thickness of the A-rich surface layer jumps from a smaller value to a larger (but finite) value. This line of prewetting transitions ends in a prewetting critical point.

This brief review of wetting phenomena now is the basis of understanding the equilibrium behavior of a thin film [15]. If the wall would be *neutral* (i. e., same attractive forces to both types of particles A, B), the critical concentration would still be $x_A^{crit} = 1/2$, but the critical temperature $T_c(D)$ of the film would be somewhat depressed, relative to the bulk $\{T_c(D \to \infty) \equiv T_c\}$, $T_c - T_c(D) \propto D^{-1/\nu}$, where $\nu \approx 0.629$ is the critical exponent of the correlation length ξ of the concentration fluctuations, in the universality class of the $d = 3$ Ising model [15]. Note, however, that critical correlations at fixed finite D can attain arbitrarily long range only in the lateral direction parallel to the film, so the transition at $T_c(D)$ then belongs to the class of the $d = 2$ Ising model ($\beta = 1/8$, but as $D \to \infty$ there is a crossover to $d = 3$, of course, reflected in a singular dependence of the critical amplitude $B(D)$ in the power law describing the coexistence curve). This means that the shape of the coexistence curve of the thin film is ultimately much flatter than the coexistence curve of the bulk. This effect cannot be described by mean-field theories, of course: mean-field theories neglect statistical fluctuations and imply $\beta = 1/2$ in all dimensions. The states underneath the coexistence curve of the thin film always imply two-phase equilibria

characterized by *lateral* phase separation. The development of a *stratified* structure with surface enrichment layers at the walls (right upper part of Fig. 2c) develops in a smooth gradual manner when one reaches $T \approx T_c$ and does *not* imply a *phase transition* in the sense of thermodynamics.

When there is a preferential attraction of A particles by walls, as assumed here, the phase diagram of the thin film is no longer symmetric with respect to $x_A = 1/2$, although we did assume such a symmetry in the bulk. This shift of x_A^{crit}, for which scaling arguments predict $x_A^{crit}(D) - x_A^{crit} \propto D^{-\beta/\nu}$ [15], and the resulting change of the coexistence curve is the analog of *capillary condensation* of gases for binary mixtures.

The phases that coexist with each other in the region below the coexistence curve of the thin film are inhomogeneous in the direction perpendicular to the walls (Fig. 5c). In the A-rich phase, we typically expect only a slight enhancement of the order parameter $\psi(z)$, which here is defined in terms of the densities $n_A(z)$, $n_B(z)$ of A(B) particles as $\psi(z) = [n_A(z) - n_B(z)]/[n_A(z) + n_B(z)]$, near the walls. In the B-rich phase, however, we expect more or less pronounced enrichment layers. As $D \to \infty$, the thickness of these layers diverges for $T > T_w$ but stays finite for $T < T_w$: in a film of finite thickness, the width of A-rich surface layers also stays finite (e. g. for $T > T_w$ for short-range surface forces $x_A^{surf} \propto \ln D$). Thus, the wetting transition always is rounded off in a thin film, while the prewetting line (Fig. 5b) does have an analog in films of finite thickness D, for large enough D [15]. This transition causes the two-phase coexistence region at small x_A in between the thin-film triple point and the thin-film critical point at the B-rich side. This two-phase coexistence region corresponds to a coexistence between B-rich phases with A-rich surface layers which both have finite (but different) thickness. As $D \to \infty$, this thin-film critical point on the B-rich side moves into the prewetting critical point, while the thin-film triple point merges with the first-order wetting transition. On the other hand, when D becomes very small, this thin-film critical point and the thin-film triple point may merge and annihilate each other [15]. For still smaller D the thin-film phase diagram then has the shape as shown in figure 5a, although one has a first-order wetting scenario in the semi-infinite bulk (Fig. 5b).

Finally, we comment on the state of the thin film encountered below the coexistence curve of the bulk but above the coexistence curve of the thin film. When one crosses the bulk coexistence curve, one encounters a *rounded transition* towards a layered (*stratified*) structure with two A-rich layers at the walls and a B-rich layer in the middle. The temperature region over which this transition is smeared out also is of order $\Delta T \propto D^{-1/\nu}$ around T_c, and hence for large D this phase separation in the direction normal to the walls may easily be mistaken (in experiments or simulations) as a true (sharp) phase transition, but it is not: one is still in the one-phase region of the thin film although the structure is strongly inhomogeneous. Such A-rich layers at the walls have a thickness varying proportional to D when D is varied at fixed D, unlike true wetting layers at the surface of a B-rich phase which vary much more weakly than linear with D (logarithmic, in the case of short-range forces). Actually, if the thickness of the domain walls between the domains could be neglected, the thickness ℓ of these domains would simply be given by the lever rule, i. e. in this case by $\ell = (D/2)\big(x_{A,coex}^{(2)} - x_A\big)/\big(x_{A,coex}^{(2)} - x_{A,coex}^{(1)}\big)$. However, since the interfacial width close to T_c diverges in the bulk (see Eq. (16)), the interfacial width in the z-direction in the thin film near T_c also scales proportional to D, and so the thickness of the domain walls in the stratified structure is never negligible. Unfortunately, these layers in the stratified structure are often referred to in the literature as *wetting layers*, which is completely misleading.

When one considers slit pores with different types of walls, the situation can become much more complicated [15]. The extreme situation is often referred to as *competing walls*, i. e. one wall (e. g., the left one) attracts A particles, the other wall (the right one) B particles, with the same absolute strength. In this case near T_c a gradual transition occurs to a stratified structure with a single domain wall between the A-rich domain on the left and the B-rich domain on the right. At $T_c(D)$, then, an *interface localization* transition occurs [15], the domain wall gets bound to the left wall in one part of the system and to the right wall in another part (see [15] for a discussion of the corresponding phase diagrams).

Surface-Directed Spinodal Decomposition

We are now again concerned with the demixing kinetics following temperature quenches, but rather than in the bulk as in Fig. 1 we now assume a thin-film geometry, with a phase diagram in equilibrium as shown in Fig. 5. Again one wishes to derive a phenomenological description, similar as for spinodal decomposition in the bulk (Eqs. (2)–(12)). Using a local order parameter $\psi(\rho, z)$, defined in analogy to $\psi(z)$ of the above section, but allowing now an inhomogeneity in the lateral directions (ρ), we amend the free energy functional $\Delta F[\psi(\rho, z, t)]$ (cf. Eq. (5)) by surface terms. Normalizing ψ by the order parameter ψ_{coex} describing the bulk coexistence curve and measuring distances $\vec{\rho}, z, D$ in units of the corresponding correlation length in the bulk, ξ_{coex}, the free energy functional

becomes ($\phi \equiv \psi/\psi_{\rm coex}$)

$$\Delta F[\phi] = F_{\rm bulk}[\phi] + F_{\rm s,1}[\phi] + F_{\rm s,2}[\phi] \tag{23}$$

where one often assumes a Ginzburg–Landau ϕ^4 form for the bulk [16]:

$$F_{\rm bulk}[\phi(\rho,z)] = \int d\rho \int_0^D dz[-\frac{\phi^2}{2} + \frac{\phi^2}{4} + \frac{1}{4}(\nabla\phi)^2 + V(z)\phi] \tag{24}$$

where $V(z)$ describes a long-range surface potential, e. g. $V(z) = -V_0\big[(z+1)^{-3} + (D+1-z)^{-3}\big]$, where the divergence at $z = 0$, $z = D$ was cut off by adding ± 1 at the locations of both walls [13, 16], to avoid problems with the numerical solutions of the resulting equations [16]. The surface terms $F_{\rm s,1}[\phi]$, $F_{\rm s,2}[\phi]$ are extended over the surfaces 1, 2 only:

$$F_{\rm s,1}[\phi] = \int_1 d\rho \left\{-\frac{g}{2}\big[\phi(\rho,0)\big]^2 - h_1\phi(\rho,0) - g'\phi(\rho,0)\frac{\partial\phi}{\partial z}\Big|_{z=0}\right\} \tag{25}$$

and

$$F_{\rm s,2}[\phi] = \int_2 d\rho \left\{-\frac{g}{2}\big[\phi(\rho,D)\big]^2 - h_D\phi(\rho,D) + g'\phi(\rho,D)\frac{\partial\phi}{\partial z}\Big|_{z=D}\right\} \tag{26}$$

The terms $F_{\rm s,1}, F_{\rm s,2}$ represent the *bare* surface excess free energy contributions due to local effects at and near the walls: additional short-range forces are included in the terms $-h_1\phi(\rho,0)$, $-h_D\phi(\rho,D)$; the other terms may represent physical effects such as the fact that a particle close to a wall has less neighbors to interact with (*missing neighbor effect*). Anyway, in the following the constants g, g', and $h_1 = h_D$ are treated as phenomenological parameters. Depending on the parameters g/g' and h_1/g', one may encounter first- or second-order wetting transitions in the limit $D \to \infty$ [15, 16] when $V_0 = 0$, and for finite D phase diagrams as shown in Fig. 5 result.

The extension to dynamics is again based on equations similar to Eqs. (2)–(4); however, in addition to an equation similar to Eq. (7) one now has to satisfy two boundary conditions resulting from the surfaces. Since the local order parameter at the surface is not a conserved quantity, Eq. (25) leads to [16]

$$\tau_0\frac{\partial}{\partial t}\phi(\rho,z=0,t) = -\delta F/\delta\phi(\rho,z=0,t) = h_1 + g\phi(\rho,0,t) + g'\partial\phi/\partial z|_{z=0} \tag{27}$$

and a similar equation for $\phi(\rho,D,t)$ results from Eq. (26). Another boundary condition expresses the physical requirement that the z-component of the flux at the surfaces must vanish,

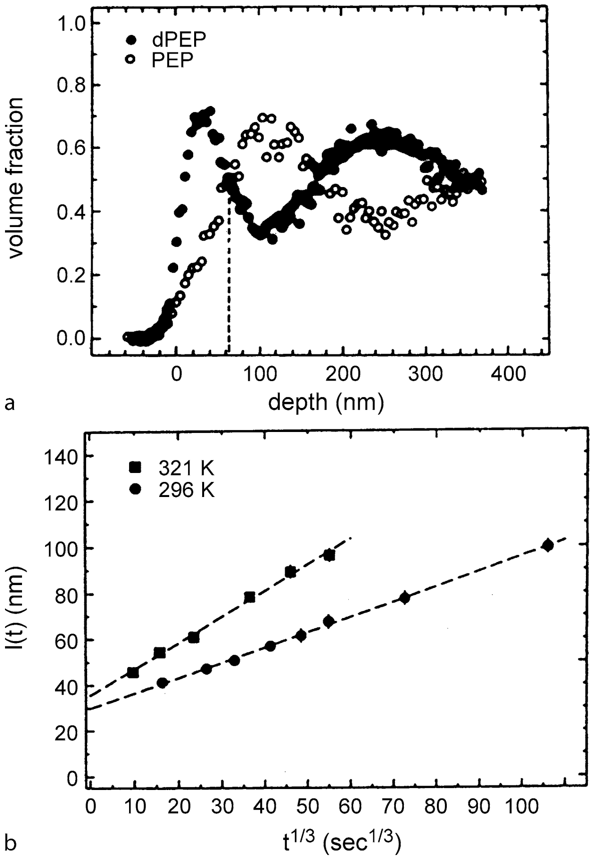
$$J_z(\rho,0,t) = -\left\{\frac{\partial}{\partial z}\left[-\phi+\phi^3-\frac{1}{2}\nabla^2\phi+V(z)\right]+\theta_z\right\}_{z=0} = 0 \tag{28}$$

$\theta(\boldsymbol{r},t)$ being a random force which also enters the analog of Eq. (7) [16].

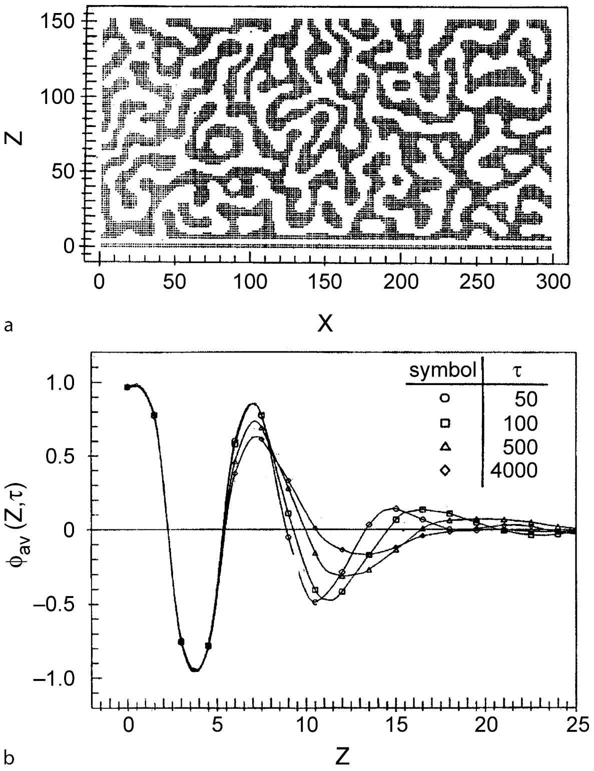
During the early stages, the fast relaxation of the nonconserved order parameter at the surfaces provides a boundary condition for the phase of the concentration waves which grow in the thin film. While in the bulk the random orientations and phases of these growing waves do not yield a time evolution of the average order parameter, these surface-directed concentration waves add up to an average oscillatory concentration profile near the surfaces of a thin film [16]. However, for a quantitative description extensive numerical calculations solving Eqs. (2)–(7), (27), and (28) are required [16].

Key Research Findings

Kinetics of demixing of fluid and solid mixtures in the bulk has been intensively studied for decades [2, 17]. A general conclusion of these studies is that the linearized Cahn theory of spinodal decomposition is not quantitatively valid (with the exception of symmetrical mixtures of polymers with high molecular weight [18]), but – within a factor of two or so – predicts the correct order of magnitude of the characteristic wavenumber $k_{\rm m}$ at which the peak of the equal-time structure factor first develops. No evidence of any singular behavior associated with the spinodal has been found, as expected in view of the theoretical arguments summarized above. The fact that for polymers with very large chain length N the initial exponential growth of $S(k,t)$, cf. Eq. (13), can be observed, and that the growth rate $A(k)$ agrees with Eq. (11), can be explained in terms of the self-consistency criterion for the linear theory, Eq. (21), since one can show [2, 19] that for polymers in $d = 3$ one needs to replace the factor r^3 in Eq. (28) by $\sqrt{N}$, and hence symmetrical ($N_{\rm A} = N_{\rm B} = N$) polymer mixtures



Demixing, Figure 6 (**a**) Volume fraction of deuterated poly(ethylene propylene), dPEP (full dots), and protonated PEP (open circles) versus depth, for a degree of polymerization $N \approx 2300$ for both constituents, after a 4 h quench to $T = 294$ K ($T_c = 365$ K). Profiles are obtained with time-of-flight forward recoil spectroscopy. The dashed line indicates the surface domain thickness $\ell(t)$. (**b**) Plot showing the growth of the surface domain thickness $\ell(t) \propto t^{1/3}$. From Krausch et al. [20]



Demixing, Figure 7 (**a**) Snapshot picture of a two-dimensional system with a wall at $z = 0$ undergoing spinodal decomposition, starting at time $t = 0$ from a random configuration, with average order parameter $\phi = 0$. Using the model of Eqs. (7), (23)–(28) for $V_0 = 0$, $h_1 = 4$, $g = -4$, $g' = 4$, a discrete implementation using a lattice of size 150 × 300 was used. The cells with order parameter ϕ near $\phi = +1$ are shown in black, cells with order parameter $\phi = -1$ are left white. The snapshot refers to a scaled time $\tau = 500$. Note that at the wall an enrichment layer, followed by depletion layer, has formed. From Puri and Binder [21]. (**b**) Laterally averaged profiles $\phi_{av}(z, \tau)$ as a function of the scaled distance z from the surface, for four scaled times as indicated, obtained from the same calculation as (**a**). From Puri and Binder [21]

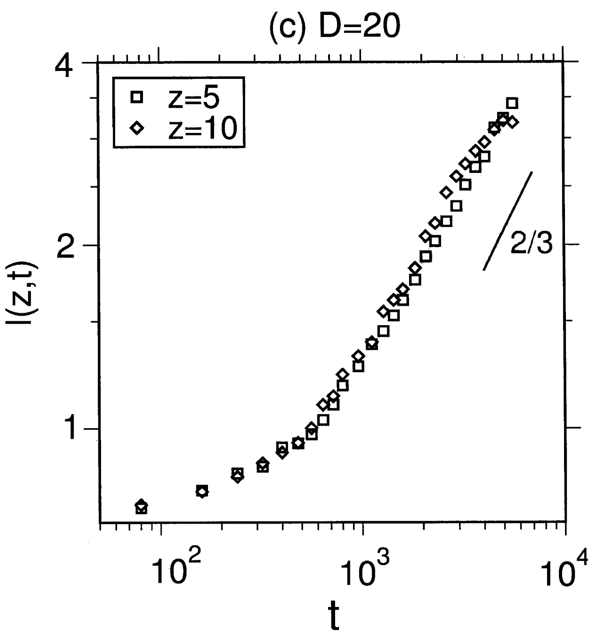
satisfy the theory during their initial stages, if N is large enough.

With respect to late stages of phase separation in the bulk, rather convincing and broad evidence for scaling in the late stages, Eq. (20), has been obtained [2, 6, 7, 17]. For off-critical quenches in binary fluid mixtures, one normally finds a growth law $\ell(t) \propto t^{1/3}$ in the last stages, compatible with the droplet diffusion–coalescence mechanism [2, 9]. For critical quenches, a slow crossover to the law [10] $\ell(t) \propto t$ has been seen, while experimental evidence for the growth law of the inertial regime [7], $\ell(t) \propto t^{2/3}$, is still lacking.

All the above statements refer to relatively simple, approximately symmetric, mixtures. For very asymmetric cases, in particular when one fluid is close to its glass transition while the other component of the mixture is much more mobile, no simple scaling behavior occurs [12] and the morphology of the domain pattern may change its character during the coarsening. The details of this behavior still are only poorly understood.

For systems quenched only slightly inside of their coexistence curve also nucleation behavior has been studied. Quantitative tests of homogeneous nucleation theory (as outlined in Eqs. (15)–(17)) turned out to be difficult, and different conclusions emerged for different systems: sometimes the *classical formula*, Eq. (18), fails dramatically, sometimes it gives reasonable estimates.

In the last two decades a lot of effort has been directed towards phase separation of fluid mixtures confined in thin films [16, 19]. Qualitative evidence for surface-directed spinodal decomposition has been found both experimentally [19, 20], see e. g. Fig. 6, and from numerical simula-



Demixing, Figure 8 Log–log plot of the length scale $\ell(z,t)$ of a thin film of a binary Lennard-Jones mixture between two flat planar walls $D=20$ Lennard-Jones parameters apart plotted versus time, for two different values of z. Lennard-Jones parameters were chosen $\sigma_{AA}=\sigma_{AB}=\sigma_{BB}=\sigma=1$, $\varepsilon_{AA}=\varepsilon_{BB}=\varepsilon=1$, $\varepsilon_{AB}=\varepsilon/2$, and masses of the particles are chosen to be equal, $m_A=m_B=1$. Time is measured in units of $t_0=(m\sigma^2/48\varepsilon)^{1/2}$. The density was chosen $n=1$, and a quench was performed (using $n_A=n_B=n/2$) from $T=5$ to $T=1.1$, far below $T_c(=1.638)$. At both walls, a potential $u_W(z)=(2\pi n\sigma^3/3)\varepsilon_W[(2/15)(\sigma/z')^9-\delta_\alpha(\sigma/z')^3]$ acts, where $z'=z+\sigma/2$ or $z'=D+\sigma/2-z$, respectively, $\delta_A=1$, $\delta_B=0$, $\varepsilon_W=0.005$ (yielding an incompletely wet wall). From Das et al. [13]

tion of Eqs. (5), (23)–(21), see e. g. Fig. 7 [21]. Note that this theory does ignore the coupling to the velocity field, and hence it yields in the late stages the LS growth law [8] $\ell(t)\propto t^{1/3}$. While some experiments observe the same growth law (Fig. 6b), other experiments observe faster growth, however. A full account of hydrodynamics can be obtained by molecular dynamics simulation of demixing of binary fluid mixtures, however. Figure 8 shows that in such a model fluid binary mixture indeed [13] a faster growth law than the LS growth is obtained, $\ell(t)\propto t^{2/3}$. While this law is reminiscent of domain growth in the inertial regime, the accessible length scales are too small by far to reach this regime, and hence a theoretical explanation for this finding is still lacking.

Thus while for demixing in the bulk, at least for *simple* symmetric mixtures, the theoretical results are to some extent supported by experiments and simulations, demixing kinetics in pores is still much less understood in detail.

Future Directions for Research

Particularly interesting future research should include systematic studies of phase separation in thin slit pores under flow, varying the slit widths and boundary conditions at the walls.

Depth of Field

Definition

The depth of field defines the distance to the focal plane an object can have to still appear sharp. For example in ►PIV/PIT measurements particles which are not within the depth of field appear blurred and with a bigger diameter. The depth of field depends on the wavelength of the illuminating light, the optics and the surrounding medium (e. g. air).

Detection Groove

Definition

The detection groove is a feature etched into a microchannel perpendicular to the fluid flow. The groove is very small, but much deeper than the channel itself, accumulating and mixing the fluid that passes through the channel. This feature can be used to improve the detection sensitivity for shear driven chromatography.

Developing Flows

Definition

When a fluid runs through a channel and its velocity and/or the temperature profile changes axially, the flow is said to be a developing flow.

Overview

In any type of flow (laminar or turbulent), the particles of a nonrarefied fluid immediately adjacent to the walls of a microchannel are always at zero velocity and in thermal equilibrium with the walls. Consider a fluid with a uniform velocity and temperature profile, entering a channel with walls maintained at a different value of temperature (lower or higher than the inlet fluid temperature). Upon entering the channel, therefore, the fluid particles that come into contact with the walls are slowed down and the temperature of the fluid at the walls becomes coincident with the wall temperature. For this reason, velocity and/or temperature gradients appear in the fluid near the walls, and the velocity and temperature profiles tend to change axially along the channel. The flow in this region is said to be a *developing flow*, and the part of the microchannel in which the velocity and/or the temperature field is not completely developed is named the *entrance region*.

In this region, a dynamic and a thermal boundary layer are thus formed, in which large velocity and temperature gradients exist. In the first part of the dynamic boundary layer the flow is laminar, but after a certain distance from the leading edge a transition to turbulent conditions can take place in the flow, with only a laminar sublayer remaining very close to the walls. The dynamic and thermal boundary layers increase in thickness in the entrance region until a fully developed condition is reached across the channel (see ► entrance region).

The development of the thermal and dynamic boundary layers can be either coupled or uncoupled. When the thermal and dynamic boundary layers develop together, the flow is said to be a *simultaneously developing flow*. When only the dynamic boundary layer develops, with the fluid in thermal equilibrium with the walls, the flow is said to be a *hydrodynamically developing flow*. When the flow is hydrodynamically fully developed but the thermal boundary layer develops, the flow is said to be a *hydrodynamically fully developed* and *thermally developing flow*: this situation can be obtained in a microchannel with adiabatic walls in the region near the entrance (*adiabatic preparation*) and where heating at the walls starts beyond the hydrodynamic entrance region.

The development of the velocity and temperature fields has a marked effect on the friction factor and the heat transfer coefficient near the channel entrance region. Correlations for the calculation of the friction factor and of the convective heat transfer coefficients in the entrance region of a microchannel are given in ► entrance region.

In general, the values of the friction factor and of the convective heat transfer increase near the beginning of the entrance region. For the convective heat transfer coefficient, from a physical point of view, this fact can be explained by observing that at the beginning of the thermal entrance region, a finite heat flux exists but only a near-zero temperature difference between the fluid and the wall, and the convective heat transfer coefficient would tend theoretically to infinity. However, because of axial heat conduction through the wall toward the entrance, the wall temperature actually rises above the temperature of the adjacent fluid and the heat transfer coefficient, though large, is finite. As the temperature profile develops, the local heat transfer coefficient decreases until, at a distance from the entrance-defined thermal entrance length (see ► entrance region), the change in the local coefficient becomes negligible and it reaches its fully developed value (see ► heat transfer in microchannels).

It should be added here that rounded or square-edged entrances can influence the values assumed by the convective heat transfer coefficient and, especially, the values assumed by the friction factor in the entrance region [1, 2]. Since the data cover only a few simple entrance geometries, the designer must exercise judgment in the application of the correlations proposed for calculating the friction factor and the convective heat transfer coefficient in the entrance region.

Since it is customary to use the simplified technique of assuming average, constant values for the friction factor and convective heat transfer coefficient along the entire microchannel, equal to their fully developed values, it is important to highlight the fact that this assumption holds only for microchannels for which the total channel length is larger (by three to four times at least) than the dynamic and thermal entrance lengths. These lengths can be calculated by using the correlations quoted in ► entrance region.

In microchannels, care must be used in order to analyze the dynamic and thermal behavior of developing flows under the following conditions:

- *Compressible flows*: in this case the velocity profile has a continuous variation in shape. This fact influences the convective heat transfer coefficient, since no fully developed temperature profile can occur if the flow is developing (see ► heat transfer in microchannels).
- *Electroosmotic flows* in microchannels subjected to an axial variation of the *zeta potential* (see ► electroosmotic flows and ► zeta potential).
- *Nonnegligible wall–fluid conjugate heat transfer*: when the conduction heat transfer at the walls of a microchannel is comparable to the wall–fluid convection heat transfer (see ► heat transfer in microchannels), thermally fully developed conditions cannot be reached along the microchannel.
- *Rarefied flows*: in the slip flow regime, rarefaction increases the hydrodynamic and thermal entrance lengths owing to slip at the walls (see ► pressure-driven single phase gas flows).

Future Directions for Research

Further investigations are required in order to highlight the roles of wall–fluid conjugate heat transfer, temperature-dependent fluid properties (i. e. viscosity), rarefaction, compressibility, and axial variation of the zeta potential in electroosmotic flows in developing flows for the most common microchannel cross-sectional geometries.

Definition

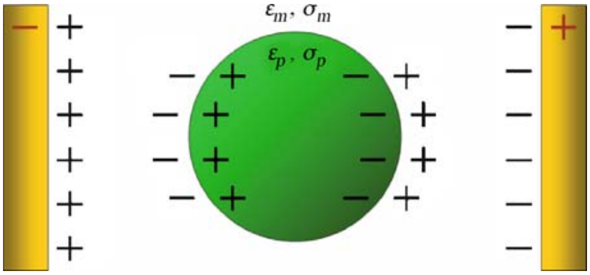
Dielectrophoresis is defined as the motion of an electrically polarisable particle in a non-uniform electric field.



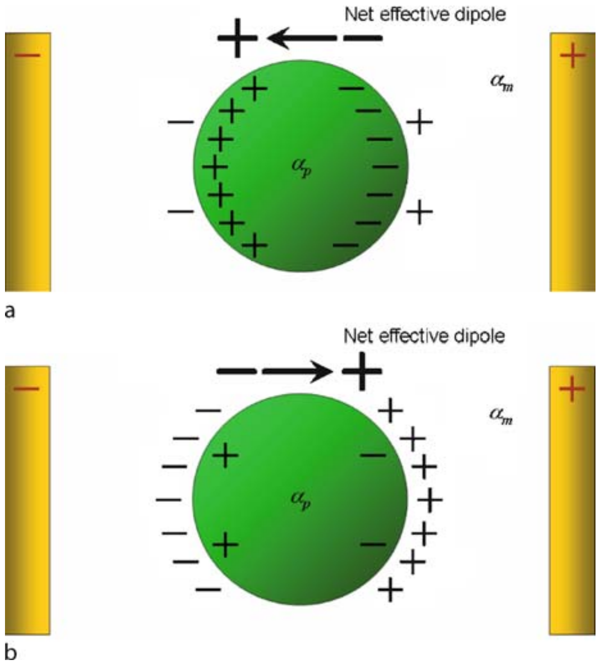
Dielectrophoresis, Figure 1 Schematic diagram of how a dielectric particle suspended in a dielectric fluid polarises in a uniform applied electric field ***E***

Chemical and Physical Principles

The key to understanding dielectrophoresis is the charge distribution at the interface between two materials of different conductivity and/or permittivity. The two materials might be for example a particle (e. g. latex bead or cell) and an electrolyte (such as potassium chloride). When an electric field is applied, charge moves and accumulates at the interface between the particle and the electrolyte as shown in Fig. 1. The amount of charge at the interface depends on the field strength and the electrical properties (conductivity and permittivity) of the particle and the electrolyte. However, a slight asymmetry in the charge density on the particle can occur as shown in Fig. 2. This produces an *induced* dipole across the particle. (Note that if the field is removed the dipole disappears). The magnitude of the dipole moment depends on the amount of charge moved and the size of the particle. For a spherical particle in an electrolyte subject to a uniform applied electric field, three cases can be considered:

1. If the polarisability of the particle is much greater than the electrolyte, more charge accumulates inside the interface than outside (Fig. 2a). Here the dipole is aligned with the applied field. This could be a conducting particle in an insulating medium or a particle with a high dielectric constant (permittivity) in an insulating medium with low dielectric constant.
2. When the particle polarisability is much less than the electrolyte, the net dipole points in the opposite direction (Fig. 2b). This case is an insulating sphere suspended in a liquid with a high dielectric constant or a high conductivity.
3. The third case is where the polarisability of the particle and electrolyte are the same and there is no net dipole (not shown).

These figures show the charge distribution at one instant in time. If we reverse the direction of the applied field and wait long enough, the opposite charge distribution is established, with the dipole in the same relative direction



Dielectrophoresis, Figure 2 Schematic diagram of how different dielectric particles polarise if they have a much higher (**a**) or much lower (**b**) polarisability than the suspending fluid medium. If the polarisability is higher, more charges are produced on the inside of the particle/fluid interface and there is a net dipole across the particle that is parallel to the applied field. If the polarisability is lower, more charges are produced on the outside of the interface and the net dipole points in the opposite direction, against the field

with respect to the applied field. Following application of the field, charges do not move instantaneously; they take a few microseconds to reach equilibrium. At low frequencies, the movement of free charge keeps pace with the changing field. However, as the field frequency increases there comes a point where the charges no longer have sufficient time to respond. At high frequencies, free charge movement is no longer the dominant mechanism responsible for charging the interface, instead the polarisation of the bound charges (permittivity) dominates. The difference between these two states is termed a dielectric dispersion.

Extend this picture to consider a particle subjected to a **non-uniform** electric field. Figure 3a shows a particle with polarisability greater than the suspending medium where the electric field lines bend towards the particle, meeting the surface at right angles as if it were a metal sphere (note the field inside the particle is nearly zero). The converse (Fig. 3b) is where the particle polarisability is less than the electrolyte. The field lines now bend around the particle as if it were an insulator. The field inside is similar to that outside. When the polarisability of the particle and electrolyte are the same it is as if the particle does not exist and the field lines are parallel and continuous everywhere.

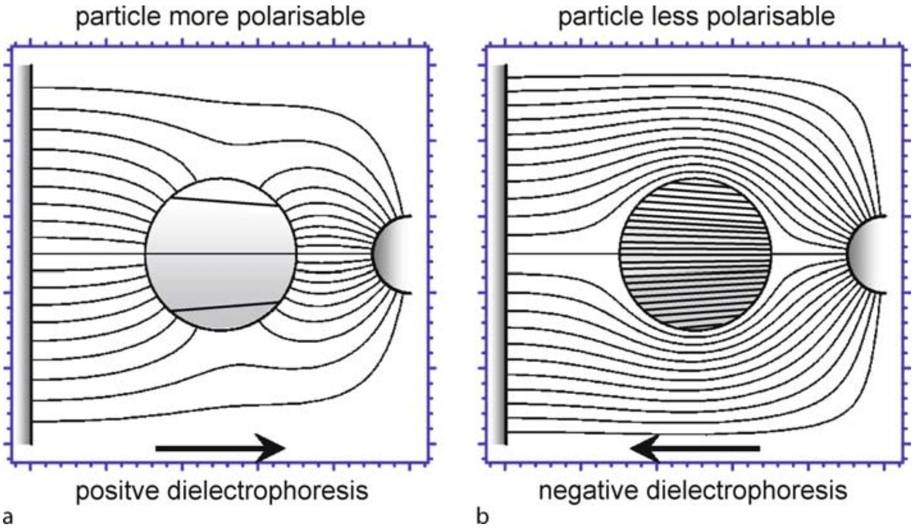
The figures also show that the field strength on one side of the particle is greater than the other. This leads to an imbalance of forces on the induced dipole, giving rise to particle movement. This effect is called *dielectrophoresis*, a term first coined by Pohl [1], [2]. When the polarisability of the particle is greater than its surrounding medium, the direction of the dipole is with the field and the particle experiences a force called *positive* DEP: the particle moves towards the high field region, Fig. 3a. The opposite situation gives rise to *negative* DEP, Fig. 3b; and the particle moves away from regions of high electric fields. The induced dipole is also a function of frequency. Therefore, the direction in which the particle moves is not only a function of the properties of the particle and the suspending medium, but also the frequency of the applied field. It is because of this that AC electrokinetics is such a useful tool for the manipulation and separation of particles.

Frequency Dependence of the Force

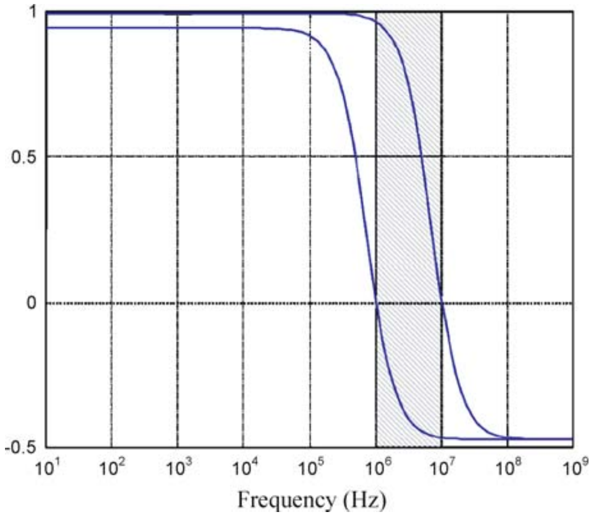
An example of the DEP force experienced by two different (solid homogeneous) polystyrene particles with different conductivities suspended in an electrolyte is plotted in Fig. 4. The force is constant at low frequencies for both particles, since the free charge has ample time to respond to the field. At high frequencies, the force is again constant but opposite in sign, since the dielectric constant of the fluid is much higher than that of particle, (80 for water, compared with 2.5 for polystyrene). At the intermediate frequency range there is a transition in the force spectrum so that the particle's behaviour switches from positive DEP to negative DEP. At one particular frequency, the polarisability of the particle is identical to the suspending medium, there is no induced dipole and the force is zero. This frequency is the cross-over frequency and can be used to characterise particles. As shown in the figure, for different particles there is a frequency band over which one particle experiences positive DEP and the other negative as shown by the shaded region in the figure so that binary separation is possible.

This illustrates two of the main features of dielectrophoresis for particle manipulation and separation:

- in a non-uniform field, the intrinsic electrical properties can give rise to a force which varies with the applied frequency of the (non-uniform) AC field.
- two different particles can exhibit quite different force-frequency spectra. The force could not only be different in magnitude but also in direction, so that the particles move in opposite directions in the same field with the



Dielectrophoresis, Figure 3 Electric field lines for a particle in a non-uniform field. (**a**) particle more polarisable than the suspending medium and (**b**) less polarisable than the suspending medium. The arrows show the direction of the force and movement in each case



Dielectrophoresis, Figure 4 Plot of the Clausius Mossotti factor against frequency for two different solid particles. In the shaded area one particle experiences positive dielectrophoresis and the other negative dielectrophoresis, enabling separation in this frequency window

same frequency and thus dynamic separation of particles is possible.

Theory

From classical electrostatics the effective dipole moment $\boldsymbol{p}$ of homogenous dielectric sphere (volume v) in an electric field $\boldsymbol{E}$ is given by:

$$\boldsymbol{p} = v\tilde{\alpha}\boldsymbol{E} \tag{1}$$

where complex effective polarisability $\tilde{\alpha}$ is:

$$\tilde{\alpha} = 3\varepsilon_{\mathrm{m}} \left(\frac{\tilde{\varepsilon}_{\mathrm{p}} - \tilde{\varepsilon}_{\mathrm{m}}}{\tilde{\varepsilon}_{\mathrm{p}} + 2\tilde{\varepsilon}_{\mathrm{m}}} \right) = 3\varepsilon_{\mathrm{m}} \tilde{f}_{\mathrm{CM}} , \tag{2}$$

In this equation the factor, $\tilde{f}_{\mathrm{CM}}$ is called the Clausius–Mossotti factor and describes the frequency dependence of the polarisability. Combining Eqs. (1) and (2) leads to the expression for the dipole in terms of the complex permittivity of the particle and the suspending medium (subscript p and m respectively):

$$\boldsymbol{p} = 4\pi\varepsilon_{\mathrm{m}} \left(\frac{\tilde{\varepsilon}_{\mathrm{p}} - \tilde{\varepsilon}_{\mathrm{m}}}{\tilde{\varepsilon}_{\mathrm{p}} + 2\tilde{\varepsilon}_{\mathrm{m}}} \right) a^3 \boldsymbol{E} \tag{3}$$

where a is the particle radius, and a general complex permittivity is defined as: $\tilde{\varepsilon} = \varepsilon - j\sigma/\omega$, with permittivity ε, conductivity σ, angular frequency $\omega = 2\pi f$, and $j^2 = -1$ The magnitude of the polarisability, and therefore the effective dipole moment of the particle, is frequency dependent, described by the Clausius–Mossotti factor:

$$\tilde{f}_{\mathrm{CM}}(\tilde{\varepsilon}_{\mathrm{p}}, \tilde{\varepsilon}_{\mathrm{m}}) = \frac{\tilde{\varepsilon}_{\mathrm{p}} - \tilde{\varepsilon}_{\mathrm{m}}}{\tilde{\varepsilon}_{\mathrm{p}} + 2\tilde{\varepsilon}_{\mathrm{m}}} \tag{4}$$

This expression characterises the relaxation in the polarisability of the particle with a relaxation time of

$$\tau_{\mathrm{MW}} = \frac{\varepsilon_{\mathrm{p}} + 2\varepsilon_{\mathrm{m}}}{\sigma_{\mathrm{p}} + 2\sigma_{\mathrm{m}}} \tag{5}$$

The angular frequency $\omega_{MW} = 2\pi f_{MW} = 1/\tau_{MW}$ is the Maxwell–Wagner relaxation frequency since the dispersion in the dipole moment is caused by interfacial polarisation. The real part of the Clausius–Mossotti factor reaches a low frequency limiting value of $(\sigma_p - \sigma_m)/(\sigma_p + 2\sigma_m)$, i. e. it depends solely on the conductivity of the particle and suspending medium. Conversely the high frequency limiting value is $(\varepsilon_p - \varepsilon_m)/(\varepsilon_p + 2\varepsilon_m)$, dominated by the permittivity of the particle and suspending medium. Note that for a solid particle there is one dispersion in the dipole because there is one interface between particle and medium. In general there is one dispersion for each interface.

Derivation of the DEP Force

Consider an electric field with spatially varying field magnitude but no phase variation. Define an arbitrary, harmonic potential as $\phi(\boldsymbol{x}, t) = \mathrm{Re}\left[\tilde{\phi}(\boldsymbol{x})\,\mathrm{e}^{j\omega t}\right]$ where $\boldsymbol{x}$ is the position, the tilde indicates the complex phasor $\tilde{\phi} = \phi_R + j\phi_I$ and Re[...] indicates the real part of. The electric field is then given by $\boldsymbol{E}(\boldsymbol{x}, t) = \mathrm{Re}\left[\tilde{\boldsymbol{E}}(\boldsymbol{x})\,\mathrm{e}^{j\omega t}\right]$ where the vector $\tilde{\boldsymbol{E}} = -\nabla\tilde{\phi} = -(\nabla\phi_R + j\nabla\phi_I)$ is the corresponding phasor. The dipole moment of the particle is therefore $\boldsymbol{p} = v\tilde{\alpha}\boldsymbol{E}\,\mathrm{e}^{j\omega t}$ and the time-averaged force on the particle is (from Eq. (2))

$$\langle \boldsymbol{F}_{\mathrm{DEP}} \rangle = \frac{1}{2}\mathrm{Re}\left[(\boldsymbol{p}\cdot\nabla)\,\boldsymbol{E}^*\right] \tag{6}$$

where * indicates a complex conjugate. Since the phasors are real, the time-averaged force is

$$\langle \boldsymbol{F}_{\mathrm{DEP}} \rangle = \frac{1}{2}v\mathrm{Re}\left[\tilde{\alpha}\right](\boldsymbol{E}\cdot\nabla)\,\boldsymbol{E} = \frac{1}{4}v\mathrm{Re}\left[\tilde{\alpha}\right]\nabla(\boldsymbol{E}\cdot\boldsymbol{E}) \tag{7}$$

Using vector identities, the DEP force can be written as

$$\langle \boldsymbol{F}_{\mathrm{DEP}} \rangle = \frac{1}{4}v\mathrm{Re}\left[\tilde{\alpha}\right]\nabla\,|\boldsymbol{E}|^2 \tag{8}$$

or using *root-mean-square* (*rms*) values the DEP becomes

$$\langle \boldsymbol{F}_{\mathrm{DEP}} \rangle = \frac{1}{2}v\mathrm{Re}\left[\tilde{\alpha}\right]\nabla\,|\boldsymbol{E}_{\mathrm{rms}}|^2 \tag{9}$$

Substituting for the volume of the particle and the dipole moment, we obtain the widely used general expression for the DEP force on a spherical particle:

$$\langle \boldsymbol{F}_{DEP} \rangle = \pi\varepsilon_m a^3 \mathrm{Re}\left[\frac{\tilde{\varepsilon}_p - \tilde{\varepsilon}_m}{\tilde{\varepsilon}_p + 2\tilde{\varepsilon}_m}\right]\nabla\,|\mathbf{E}|^2 \tag{10}$$

Similar expressions can be obtained for particles of non-spherical shape, such as rods and ellipsoids [3].

This equation shows that the dielectrophoretic force depends on:

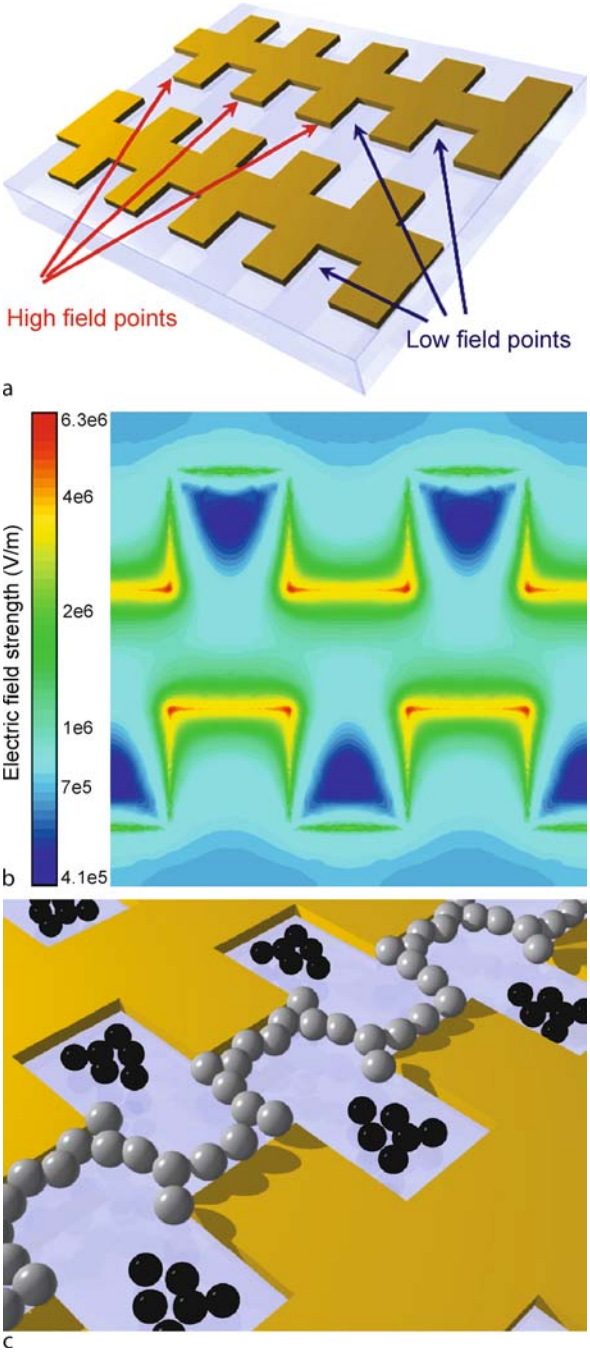
- the particle radius a (more correctly volume)
- the frequency of the applied field, through the real part of Clausius–Mossotti factor
- the energy density of the electric field and degree of non-uniformity of the electric field.

D

Key Research Findings

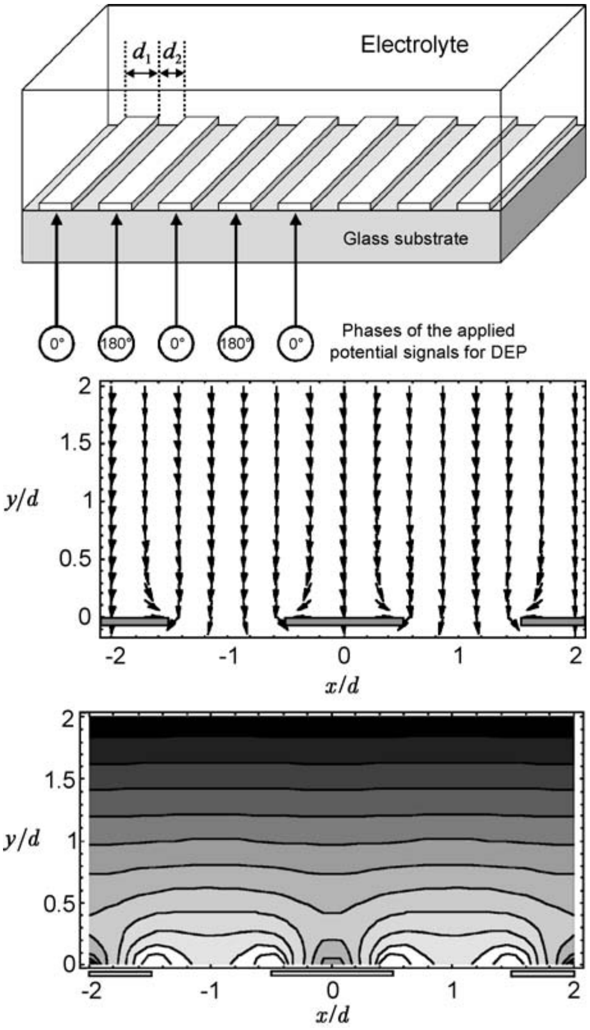
Dielectrophoresis has many applications such as trapping single particles, manipulating and separating large numbers of cells, creating ordered arrays of particles etc. However, all of these technological uses rely on being able to generate well defined electric field gradients. This is generally performed using microelectrodes fabricated onto insulating substrates (e. g. glass) as part of a microfluidic or Lab on a Chip system. Modern techniques allow fabrication of micro-electrodes with precise sizes and dimensions, enabling accurate control of the electric field geometry and therefore particle position. The DEP force is generated with AC fields, avoiding problems associated with electrolysis which occur with DC fields and electrophoresis. Dielectrophoretic manipulation of particles can be performed with almost any shape of electrode that produces a non-uniform electric field. An example of a microelectrode array is shown in Fig. 5a. This is a castellated microelectrode, made from metal typically 100 nm thick, and was first introduced by Pethig and coworkers [4]. The electric field map shown in Fig. 5b indicates where the regions of high and low electric field occur and therefore where particles move under either positive or negative DEP-shown schematically in Fig. 5c.

The DEP force is a short range force, this is because the electric field gradient decays rapidly from an electrode edge. Contrast this with electrophoresis where the force on the particle is constant wherever the electric field is present. The short range behaviour of DEP can be illustrated using the following example. A simple interdigitated electrode structure is shown in Fig. 6a, showing a semi-infinite array of electrode fingers. The electrodes are typically 10 to 50 μm wide (with similar gaps) and are connected alternately to a low voltage source of variable frequency. The space above the electrodes is filled with conducting electrolyte. When the voltage is applied the electrodes generate a field gradient, with force vectors shown in Fig. 6b. These vectors are drawn for a particle experiencing positive DEP; and point in the opposite direction for particles experiencing negative DEP. Far from the electrodes, the vectors point directly down towards the surface. Approaching the surface, the vectors point towards the electrode edges, where the field is highest. Although



Dielectrophoresis, Figure 5 (**a**) Schematic diagram of the "castellated"electrode design, which consists of square features on parallel interdigitated electrodes; (**b**) Plot of the numerically calculated electric field magnitude for the castellated electrode design a horizontal plane 100 nm above the upper surface of the electrodes; (**c**) Schematic diagram showing where particles move on the microelectrodes under positive or negative DEP

the vectors show the direction of the force, the magnitude of the force is quite different, as shown in Fig. 6c.

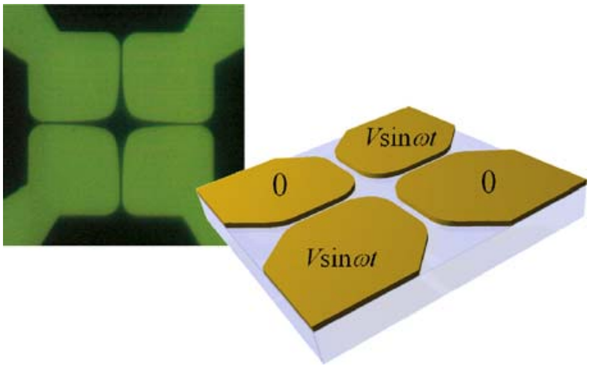


Dielectrophoresis, Figure 6 (**a**) Schematic diagram of the interdigitated electrode array in a microfluidic system; (**b**) Plot of the direction of the dielectrophoretic force for the interdigitated electrode array; (**c**) Plot of the magnitude of the dielectrophoretic force (Log_{10}) for the interdigitated electrode array

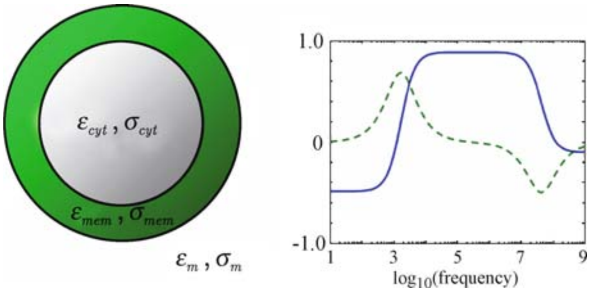
Here the force is maximum at the electrode surface (as expected), but it very quickly decays exponentially into the space above the electrodes. Therefore, particles at some distance from the electrodes experience very little force. For an electrode with width and gap d, and applied voltage V, (with y the vertical direction), the DEP force is proportional to the field gradient according to

$$\nabla|\boldsymbol{E}|^2 \approx \frac{V^2}{d^3} \exp\left(-\frac{\pi y}{d}\right) \tag{11}$$

This expression shows that the characteristic decay length of the force is $y = d/\pi$, and at this height the magnitude



Dielectrophoresis, Figure 7 Schematic drawing of a quadrupole electrode set



Dielectrophoresis, Figure 8 Schematic diagram of a cell represented by the shell model, together with a plot of the real and imaginary part of the Clausius–Mossotti factor for a single shelled object

of the field gradient will be 37% of its maximum. For an electrode with width and gap of 20 μm, this height is only 6.4 μm. Also we see that the force scales with the square of the voltage and the inverse third power of electrode gap. Changing the electrode gap by a factor of two can therefore change the force by a factor of 8. For further details of scaling in these systems see [5].

DEP characterisation of particles can be performed with a number of different electrode designs. One common design consists of four separate electrodes pointing towards a central region, called a quadrupole electrode (see Fig. 7) [6]. These electrodes generate an electric field gradient with a minimum in the centre and maximum at the edge. They are used for trapping single particles and also for electrorotation studies. A pair of quadrupole electrode arrays facing each other (on the top and bottom of a microfluidic channel) can form a *closed* electric field cage used for trapping single particles, for further details see [7].

Biological Particles

The theoretical analysis presented above assumes a solid homogeneous spherical dielectric particle; e. g. a polystyrene bead. Biological cells are neither perfect spheres nor completely homogenous dielectrics. However, their DEP properties can be predicted by treating the cell as a series of shells, with the first shell representing the cell membrane, as shown in Fig. 8. The cell membrane is extremely thin, and has very low conductivity and high capacitance. Because there are now two interfaces (membrane to outside and membrane to inside), the Clausisus–Mossotti factor has two dispersions. At low frequencies the cell is less polarisable than the medium and undergoes negative DEP. There is a region at intermediate frequencies where positive DEP is observed, at high frequencies negative DEP dominates because of the lower polarisability of the cell cytoplasm compared with the suspending medium. Different cells exhibit different DEP force-frequency profiles and can therefore be separated, see [8] for a review.

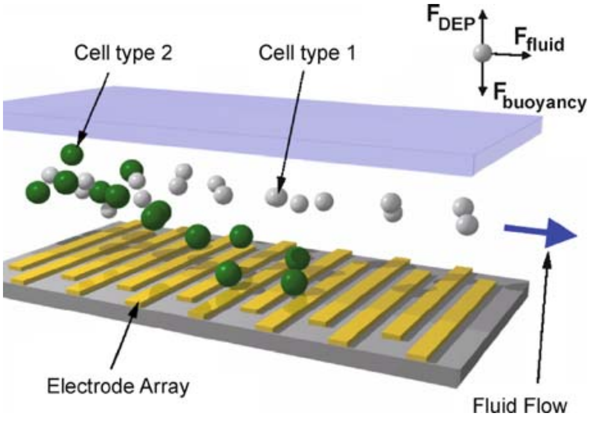
The position of the lower of the two cross over frequencies is dominated by the properties of the cell membrane (and also cell size) and measurement of this parameter is often used to characterise the dielectrophoretic properties of cells. The membrane capacitance of a cell can be determined by measuring the dielectrophoretic cross over frequency as a function of suspending medium conductivity [9]. The cross over frequency is as a function of membrane capacitance and membrane conductance according to:

$$f_{\text{Cross}} = \frac{\sqrt{2}}{8\pi r C_{\text{Mem}}} \sqrt{(4\sigma_m - rG_{\text{Mem}})^2 - 9r^2 G_{\text{Mem}}^2} \quad (12)$$

where G_{Mem} is the specific conductance of the membrane, C_{Mem} the specific membrane capacitance, σ_m the conductivity of the suspending medium and r the cell radius. Assuming that the particle has a very low membrane conductivity (i. e. $G_{\text{Mem}} = 0$), the specific membrane capacitance is given by the following simplified expression:

$$C_{\text{Mem}} = \frac{\sigma_m}{\pi \sqrt{2} f_{\text{Cross}} r} \quad (13)$$

Therefore measurement of both the cross over frequency and cell radius can be used to calculate an average membrane capacitance. Values of cell membrane capacitances per unit area range from 0.7 μF/cm^2 to over 2 μF/cm^2 indicating that the DEP cross over frequencies can differ substantially – one of the reasons why DEP has been used to fractionate different cell types. Measurement of the cell capacitance is also used to predict the DEP response of different cell populations and aid in the design and operation of DEP-based cell separation devices [10].



Dielectrophoresis, Figure 9 Diagram showing the working principle of a DEP-based flow-through microdevice which can be used to separate or fractionate cells and other particles

Examples of Applications

Cell Analysis and Separation Technologies

Because different cells exhibit different responses, one of the attractions of DEP is that it is could be used not only to manipulate cells, but also to trap and separate cells. There are many papers in this field, references [8], [9], [10], [11] provide excellent reviews. In general different types of cells may exhibit different dielectric properties, which, when particle size is also considered gives rise to differences in DEP force. These differences are exploited to effect cell separation. One of the simplest practical dielectrophoretic separators is based on flow separation. A mixture of cells moves through a microfluidic chamber with an electrode array fabricated on the bottom of the chamber – see Fig. 9. The cell or particle mixture is pumped across the electrode using a syringe pump. Correct choice of voltage and frequency on the electrodes leads to binary separation one population experiences positive dielectrophoresis and is attracted to the electrodes, whilst the other particles are repelled by negative dielectrophoresis. When all the cells are trapped, the electric field is switched off and the trapped cells released for collection down stream. The same electrode structure can also be used to fractionate particles along the device. In this case, the frequency of the electric field is chosen to attract all the particles to the electrodes, but the trajectory of each particle type will differ (depending on size and polarisability). The end result is a distribution of particles along the electrode array.

Cell-based DEP separation devices that utilise positive DEP forces suffer from one major drawback, which is that the cells must be suspended in a low-conductivity buffer. Although the buffer has to be iso-osmotic to prevent cell damage, this process is undesirable from the point of view of a Lab on a Chip system and furthermore causes considerable stress on the cells. One technique, developed by Gascoyne et al. [8], that uses negative DEP is a method called DEP-Field Flow Fractionation (FFF). In this technique, the particles are suspended in a medium above an interdigitated microelectrode array (e. g. Fig. 9). A voltage is applied to the electrodes at a frequency such that all the particles experience negative DEP. The DEP force induces levitation of the particles above the electrodes, and each particle reaches an equilibrium position where the upward DEP force is balanced by a downward (negative) buoyancy force. A fluid is now pumped through the device, and owing to the parabolic flow profile of the fluid, particles at different equilibrium heights are eluted at different times. The particles whose equilibrium height corresponds to the centre of the channel are carried through by the fastest flowing stream line and are the first to exit the system and so on.

These few examples serve to illustrate the wide range of methods that can be used to separate particles according to their polarisability. Many methods have not been discussed; the literature on DEP technologies is growing steadily and the reader is urged to refer to this for further examples.

Nano-Particle Manipulation and Characterisation

During the last 15 years, many developments in both the understanding and technology has lead to DEP being used to manipulate nano-scale objects, including macromolecules (particularly DNA), viruses, latex particles and carbon nanotubes. During manipulation of nano-particles, Brownian motion can dominate the behaviour of the particles. As shown by Eq. (10), the DEP force scales with particle volume. Therefore, in order for the DEP force to be sufficiently large to overcome the randomising effects of Brownian motion, the magnitude of the field gradient must be increased proportionally. Equation (11) shows that the factor $\nabla|\boldsymbol{E}|^2$ (which controls the DEP force) scales with the square of the voltage, and the inverse cube of the electrode gap. Therefore, the simplest way to increase the force is to reduce the electrode dimensions, which can be done fairly easily with modern microfabrication methods. One major obstacle to the manipulation of very small particles is that the large electric fields that are required also induce other effects in the liquid, notably AC electroosmosis and electrothermally driven fluid flow. For further details see [12].

Dielectrophoretic force

Definition

Dielectrophoresis is the translational motion of an electrically neutral particle by induced polarization in a nonuniform electric field. The magnitude and direction of the induced dielectrophoretic force is dependant on the characteristics of the applied electric field as well as the dielectric properties of the surrounding medium and of the particle itself.

Overview

Herbert Pohl was the first to study particle electrokinetics in the 1950's, particularly the manipulation of uncharged particles with nonuniform electric fields. He coined the term *dielectrophoresis*, details of his investigations can be found in his classic text [1]. The advancement of microfabrication techniques and the demand of Lab-on-a-Chip technologies have led to the development of dielectrophoresis techniques for particulate, biological and pharmaceutical applications. Dielectrophoresis was initially used to manipulate particles and cells in the micrometer range (1 μm to 1 mm). Since the early 1990's, nanotechnology has incorporated dielectrophoresis for the manipulation of viruses, DNA, protein molecules and other nanoparticles (diameters of 1 nm to 1 μm). This article provides a brief background necessary for the development of dielectrophoresis followed by the theory of the basic dielectrophoretic manipulation techniques of translation, rotation (electrorotation) and orientation (electroorientation). Simulation and design considerations will be discussed for the micrometer length scale; this article will not specifically address all dielectrophoresis complexities at the nanometer scale. For a more extensive explanation of dielectrophoretic manipulation of particles it is suggested that the reader consults texts by T.B. Jones [2], Morgan and Green [3], and M.P. Hughes [4], the latter of which addresses these techniques for nanometer-sized particles.

It is important to note the differences between electrophoresis and dielectrophoresis. Both technologies manipulate particles with their interaction to an applied electric field. In electrophoresis, a force is created on a charged particle by its attraction to a potential with the opposite polarity. The speed at which a particle moves through a stagnant fluid under applied electrophoresis forces is proportional to its size and electrical charge. The applied electric field for electrophoresis is typically a direct-current (DC) signal. Dielectrophoresis utilizes a nonuniform electric field to induce a dipole or higher moments in a neutral particle. The magnitude and orientation of the induced dipole is a function of the dielectric properties of the particle and the surrounding medium. These induced moments in a nonuniform electric field can create a translational

and/or rotational force on a particle. The applied electric field for dielectrophoresis can be either direct-current or alternating-current (AC), but it is typically the latter of the two.

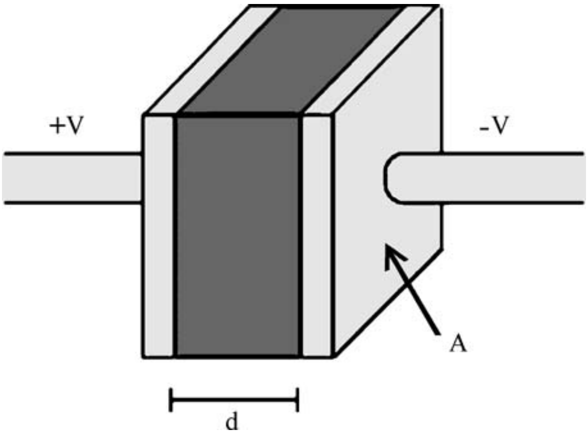
For most dielectrophoresis cases, the applied electric field can be created with a common frequency generator with frequencies typically greater than 100 kHz and magnitudes below 20 V peak-to-peak. Electrode geometries with features below 1mm can be created using simple microfabrication techniques. Electrodes are typically fabricated on the surface of silicon wafers or glass substrates, including microscope slides. For most biological applications it is recommended that the species of interest be visually observed by optical means, which leaves glass or other transparent materials as favorable substrates. In the case where the electrodes themselves hinder visual observation they are patterned with indium tin oxide (ITO), a transparent conducting material. Microfluidic channels and other fabricated features can easily be incorporated into the system. Due to its simple fabrication and its susceptibility to visual observation and analysis, dielectrophoresis is a favorable technique for biological experimentation.

There are several disadvantages when working with dielectrophoresis. This technique does not work at larger scales (>1 mm) based on the shear magnitude generated voltage necessary to apply an electric field to manipulate larger particles. This would require voltages greater than hundreds of volts (which is difficult to generate at high AC frequencies) and generate undesirable effects such as electrochemical reactions and Joule heating. By working at the micrometer length scale the required voltage decreases and some of these negative effects are minimized, however they may slightly influence the system and cannot be ignored. There are other forces that will work against the dielectrophoretic force including gravity, hydrodynamic drag and electrothermal forces. Additionally, the electric field itself can affect the physiology of a biological cell by inducing cell heating and influencing transmembrane voltage. These effects will be discussed later in this article.

Basic Methodology

Electrostatics

Capacitance is a measure of the electric charge stored for an applied electric potential. The simplest case for a capacitor consists of a dielectric material between two parallel, conductive plates (Fig. 1). When a potential is applied across the plates (+V and −V) a charge will accumulate on the plates due to the effects of the electric field and applied charge. On either side of the sandwiched material are accumulations of opposite charges, which induces a dipole and polarize the capacitor. It takes a finite amount of time for the dipole to accumulate and, when the potential is removed, it takes a finite amount of time for the induced dipole to dissipate. Capacitance of a material is typically expressed as



Dielectrophoretic Motion of Particles and Cells, Figure 1 A parallel plate capacitor

$$C = \frac{\varepsilon_0 \varepsilon_r A}{d} \quad (1)$$

where d is the distance between the plates, A is the cross-sectional area of the material, ε_0 is the permittivity of free space (8.854×10^{-12} F/m) and ε_r is the material's relative permittivity (a dimensionless quantity). When a capacitor is used in an AC circuit it will restrict the flow of current through the dielectric material for an applied electric potential. This out-of-phase impedance component can be incorporated into Eq. (1) to describe the dielectric properties of a material in terms of its conductivity and permittivity:

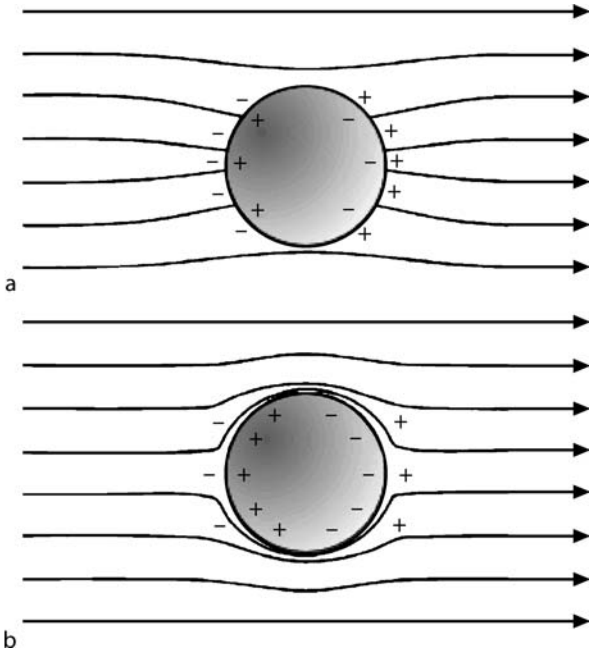
$$C = \frac{\varepsilon^* A}{d} \quad (2)$$

where ε^*, called the complex permittivity, replaces the $\varepsilon_0\varepsilon_r$ term in (1) and is expressed by

$$\varepsilon^* = \varepsilon_0 \varepsilon_r - j\frac{\sigma}{\omega} \quad (3)$$

where j is $\sqrt{-1}$, $\omega = 2\pi f$ and f is the applied frequency in Hertz. It is important to note that this term is frequency dependent. At very high frequencies the imaginary term is minimized and the complex permittivity is dominated by the material's permittivity. However, for very low frequencies the conductivity term dominates.

The dipole across the parallel plate capacitor is induced and does not hold a permanent charge. This induced dipole will align itself along the electric field lines. The ability of a material to polarize is dependent on its dielectric properties (conductivity and permittivity) and the applied electric potential magnitude and frequency. Additionally, there are other polarization effects that should be noted. The Debye relaxation is associated with the inability for a dipole to reorient with the applied electric field. This orientation lag of the induced dipole occurs due to the fact that it takes a finite time to form and unform, known as the relaxation time. For high applied AC frequencies the dipole will not have enough time to form, resulting in the inability to transfer charge. The Debye relaxation occurs within the dielectric material while a second relaxation, called the Maxwell–Wagner relaxation, occurs at the interface between two separate materials. Consider a parallel plate capacitor with two different materials in series between the plates with separate conductivities and permittivities. At the interface between these materials Maxwell–Wagner polarization occurs, which is a function of their dielectric properties. Both of these materials transfer charge differently, creating an accumulation of charge and inducing a dipole at their interface.



Dielectrophoretic Motion of Particles and Cells, Figure 2 A uniform electric field interacting with (**a**) a particle more polarizable than the medium and (**b**) a particle less polarizable than the medium

Dielectrophoresis

These previously mentioned principles will now be applied to a homogeneous dielectric sphere suspended in a conductive medium and exposed to an electric field. The magnitude of a dipole moment ($\boldsymbol{m}$) of a spherical particle is

$$\boldsymbol{m} = 4\pi r^3 \varepsilon_0 K(\omega) \boldsymbol{E} \tag{4}$$

where r is the radius of the particle and $K(\omega)$ is the Clausius–Mossotti factor defined by

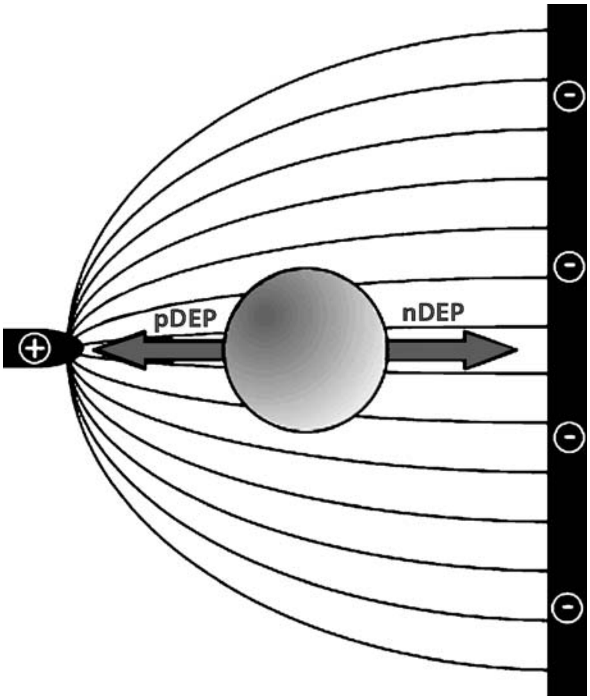
$$K(\omega) = \frac{\varepsilon_{\mathrm{p}}^* - \varepsilon_{\mathrm{m}}^*}{\varepsilon_{\mathrm{p}}^* + 2\varepsilon_{\mathrm{m}}^*} \tag{5}$$

where the subscripts p and m refer to the particle and medium, respectively. The dipole is a function of the complex permittivities of the particle and medium which determine its magnitude and charge orientation. Consider a suspended particle in a uniform electric field (Fig. 2). For a particle which is more polarizable than the surrounding medium, there will be a greater accumulation of charge on the medium side of its interface and result in Fig. 2a. If the surrounding medium is more polarizable than the particle then the greater accumulation of charge will occur within the particle and result in Fig. 2b. Note the distorted electric fields in each figure, the induced dipole itself will affect the surrounding electric field accordingly. In a uniform electric field, though, the induced charges on both sides of the particle are equal, creating no net force on the particle. However, if it were placed in a nonuniform electric field, dielectrophoretic forces would be present.

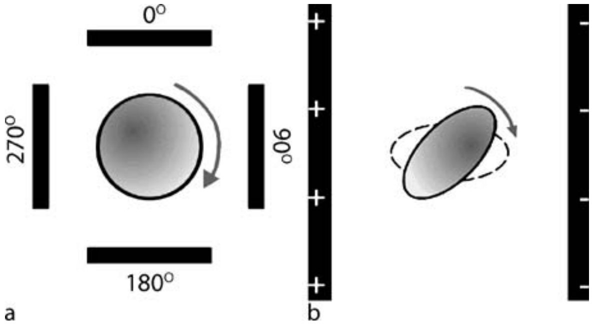
Let's now consider a polarizable particle placed in a nonuniform electric field (Fig. 3). The nonuniform electric field is created by the electrode geometry shown. The general expression for the dielectrophoretic force of a homogenous sphere is expressed as

$$F_{\mathrm{DEP}} = 2\pi \varepsilon_0 \varepsilon_{\mathrm{m}} r^3 \mathrm{Re}\left[K(\omega)\right] \nabla E^2 \tag{6}$$

where $\mathrm{Re}\left[K(\omega)\right]$ is the real part of the Clausius–Mossotti factor and ∇E^2 is the gradient of the magnitude of the square of the electric field. This equation assumes that the there is no applied phase gradients to the electric field. The Clausius–Mossotti factor is a function of frequency and, depending on the dielectric properties of the medium and particle, this factor can be either positive or negative. If $\mathrm{Re}\left[K(\omega)\right]$ is negative, then the particle experiences negative dielectrophoresis (nDEP) and is repelled from gradients in the nonuniform electric field (Fig. 3). For positive $\mathrm{Re}\left[K(\omega)\right]$, the particle is attracted to high electric field gradients with positive dielectrophoresis (pDEP). The frequencies at which the particle changes from pDEP to



Dielectrophoretic Motion of Particles and Cells, Figure 3 A polarizable particle in a nonuniform electric field



Dielectrophoretic Motion of Particles and Cells, Figure 4 Illustrations of (**a**) electrorotation and (**b**) electro-orientation

nDEP, or vice versa, is called its *crossover frequency*. By looking at (5), the maximum range of values for the Clausius–Mossotti factor is between +1 ($\varepsilon_p^* \gg \varepsilon_m^*$) and −0.5 ($\varepsilon_p^* \ll \varepsilon_m^*$). This demonstrates that the maximum induced pDEP force can be twice as strong as the nDEP force. The conductivity of the experimental medium and the applied frequency can be manipulated to induce either pDEP or nDEP forces on a particle. Effective manipulation of cells using dielectrophoretic forces requires novel electrode geometry design and applied signaling. A number of these techniques have been established including electrorotation and electro-orientation (Fig. 4).

Electrorotation

In brief, electrorotation involves an induced torque on a particle that is subjected to a rotating electric field (Fig. 4a). The electric field induces a dipole in the particle and, as the field rotates, the dipole attempts to rotate with the electric field. As the dipole lags behind the rotating field it attempts to reorient itself and a torque is induced on the particle. This dipole orientation lag is due to its relaxation time. The general equation for the electrorotational torque induced on a homogenous spherical particle is

$$\Gamma = -4\pi\varepsilon_0\varepsilon_m r^3 \mathrm{Im}\,[K(\omega)]\,E^2 \qquad (7)$$

The direction and rate of rotation relative to the electric field is dependent on the imaginary component of the Clausius–Mossotti factor ($\mathrm{Im}\,[K(\omega)]$). When this component is positive the direction of rotation is opposite of the direction of the rotating field and vice versa for a negative value of $\mathrm{Im}\,[K(\omega)]$. By properly applying a nonuniform electric field and controlling the real and imaginary parts of the Clausius–Mossotti factor, a particle can be simultaneously manipulated by dielectrophoresis and electrorotation.

Electro-Orientation

Electro-orientation involves the alignment of a nonspherical particle in a uniform electric field (Fig. 4b). When an ellipsoidal particle polarizes, the dipole moment will align the particle parallel with the electric field. Typically this alignment occurs with the nonspherical particle's longest axis, as this is the location of the longest dipole moment. However, one or more of their axes may become dispersed, resulting in its orientation with its longest nondispersed dipole parallel to the field lines. Its orientation is a function of the dielectric properties of the medium and the particle as well as the frequency of the applied electric field. A plot of a particle's preferred orientation with varied medium conductivities and applied frequencies is known as its *orientation spectrum*. The orientation spectrum includes the particle's turnover frequencies, or the conditions at which the particle reorients itself to the electric field. A particle's dielectric properties can be derived from these graphs, examples of which can be found in literature [5]. Similarly, electrorotation can be used to determine unknown dielectric properties of cells.

Modeling Particles and Cells

Obviously, biological cells and other particulates are not all completely spherical nor are they homogeneous. Typically cells are modeled as multi-shelled particles with each

shell having its own respective conductivity and permittivity. If the dielectric properties of each layer and the interior of the particle are known then it can be modeled with an effective conductivity and permittivity. This simplified model, however, is valid for only pointlike particles whose axes are small relative to electrode geometry features. It is also possible to adapt dielectrophoretic effects for nonspherical cells by modeling the particles as ellipsoids. For each of these situations the Clausius–Mossotti factor is extended to include these geometrical and layered effects by applying polarization factors. These modifications are beyond the scope of this article and are described in detail elsewhere [2–4]. Additionally, a comprehensive approach to apply dielectrophoresis, electrorotation and other dielectrophoretic techniques to ellipsoidal particles is detailed by J. Gimsa [6].

Particle Chains

When two polarized particles come into close proximity with each other they will undergo an attractive force due to their dipole interactions. This is referred to as dipole-dipole interactions, mutual dielectrophoresis or more commonly known as pearl chaining because this phenomenon creates strings of particles. Recall that a particle's induced dipole aligns itself to the electric field and that like particles will always have the same dipole orientation. These particles will have an attractive force since their opposite charges are aligned facing each other. Additionally, these particle chain formations can also be attributed to the distorted electric field caused by the particle's induced dipole (recall the modified, otherwise-uniform electric field lines in Fig. 2). These field disturbances can cause a localized dielectrophoretic force, increasing the strength of these particle-particle interactions. Pearl chains are typically observed near electrode edges where the strength of the electric field is the greatest. The measurement of chain length in experiments has been used to characterize the Clausius–Mossotti factor as well as create micro- and nanostructures.

Multipoles

The dielectrophoresis theory is based on the approximation that a sole dipole is induced in a particle. For most applications this assumption accurately depicts the behavior of a spherical particle; however, higher order poles (called multipoles) can be induced. A finite-sized particle in a uniform electric field will have higher multipole moments than a pure dipole moment. This is due to the mathematical nature of the multipole expansion which assumes pointlike particles. As soon as a particle is no longer pointlike, the higher multipoles start to contribute. This occurs when the electrode geometry is on the same length scale as the particle or when a particle is in an electric field null. Multipoles have multiple charge centers contained within the particle which interact with the electric field differently than the assumed dipole. Multipoles have been extensively investigated [7] and have been incorporated into various dielectrophoresis models.

D

Modeling Electric Fields

In order to determine the magnitude of the applied dielectrophoretic force it is necessary to quantify the gradient of the electric field squared (∇E^2). The nonuniformity of the generated electric field is the foundation for the dielectrophoretic manipulation of particles. A 3D electric field profile is typically created using a geometrical arrangement of surface electrodes. Mathematical models exist that have derived the electric field gradients of common electrode geometries. However, it is necessary to model the electric field of novel electrode geometries. By utilizing finite element computer programs such as ANSYS or COMSOL, a user can simulate the electric field for a defined electrode geometry. This data can be analyzed further by a postprocessing program that computes the gradient of the nonuniform field. For example, MATLAB has been used to determine these gradients from electric field input data [8].

Considerations

Outside of multipole theory, there are other electrokinetic effects that need to be considered when using dielectrophoresis to manipulate cells. Joule heating occurs when a current passes through a liquid medium, heating the solution due to the rapid movement of electrons. The thermal gradient across the solution causes convective circulation. Additionally, the dielectric properties of the medium are a function of temperature. These medium conductivity gradients are manipulated by the electric field to induce unwanted fluid flow. These induced temperature changes can affect cell physiology and, at temperatures above physiological conditions, can cause cell death. These temperature variations are more noticeable at larger length scales as the change in temperature (ΔT) is proportional to the applied voltage (V) by

$$\Delta T \approx \sigma V^2 L^3 \tag{8}$$

where L is the length scale of the system. These effects are obviously minimized at smaller length scales. Scaling effects that are commonly associated with dielectrophoretic techniques, including electrothermal heating, are discussed in detail elsewhere [9].

The electric field itself can directly interact and affect the cell. It can impose a transmembrane voltage across the cell, which can effect ion movement and damage voltage-sensitive proteins. There have been numerous investigations to correlate cell viability and their exposure to electric fields. Typically these experimentations involve monitoring the cell growth rate after exposure to the electric field and compare these results to a control. These negative physiological effects can be avoided, but dielectrophoretic techniques should still be used with caution.

The particles of interest can also interact with the surrounding medium due to hydrodynamic drag. This drag force is directly related to the particle shape and the fluid flow profile, which is determined by the incorporated channel geometry and pumping methods. Brownian motion refers to the random chaotic movement of particles and it plays a significant role in dielectrophoresis applications for nanometer-sized particles. Since most biological cells are micrometers in length, Brownian motion effects can be neglected. However, to manipulate proteins, viruses, or other molecules it is necessary to account for Brownian effects.

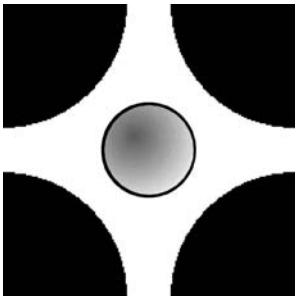
Key Research Findings

The major application of dielectrophoresis in micro- and nanofluidic systems continues to be the manipulation of particles and cells. Popular applications include particle trapping, dielectrophoretic microsystems, traveling wave dielectrophoresis and determination of cell dielectric properties. The specific dielectrophoretic techniques used in existing applications are too numerous to cover in this article. This article does provide a brief overview of some of the established manipulation techniques.

Particle Trapping

One of the more popular dielectrophoretic manipulation techniques involves the trapping of individual or groups of particles. Dielectrophoresis can be thought of as *electrical tweezers* that will grab onto and position particles. Trapping can be accomplished by means of novel electrode geometries that utilize pDEP or nDEP forces to selectively capture a particle or cell. For example, four electrodes can be positioned in a quadrupole arrangement and, when the proper electric field is applied to the electrode, a particle or particles are trapped in the electric field null in the center of the electrodes with nDEP forces (Fig. 5). Additionally, two sets of quadrupole electrodes can be placed and aligned on the top and bottom microchannel surfaces to create an octopole trap and capture a particle in suspension. One novel geometry that can capture particles with either pDEP or nDEP forces is with interdigitated electrodes. Planar electrode fingers, whose width and gap separation is a few times larger than the diameter of the particles of interest, have alternating applied AC signals (either 180° out of phase or alternating signal/ground). This geometry creates a strong pDEP force at the edges of the electrodes and a field null above the center of each electrode strip. Besides trapping, this geometry has been used to separate particles of different dielectric characteristics as they would be experiencing opposite dielectrophoretic forces (nDEP or pDEP). There are numerous other trap geometries that exist for both pDEP and nDEP.

There are a number or parameters that need to be addressed when attempting to trap a particle with dielectrophoresis. First, and most obvious, the dielectrophoretic force needs to be calculated for the respective electrode geometry. Electric field gradients are modeled and the resulting dielectrophoretic force is calculated with computer software. Forces generated by induced multipoles need to be considered and implemented into the dielectrophoresis calculations. The additional forces that need to be considered include the hydrodynamic drag force, the hydrodynamic lift force and sedimentation force. With all of these forces it is assumed that the fluid is under low Reynolds number flow due to dimensions typical with these microsystems and particles of interest. Hydrodynamic drag is directly proportional with the radius of the particle and the applied fluid velocity which is determined by the flow profile. For a particle near a planar surface a shear flow approximation can be used; the resultant force is similar to Stoke's drag. If the particle is held in suspension, as in nDEP octopole traps, the fluid flow can be modeled with a parabolic profile known as Poiseuille flow. The flow profile, though, is ultimately determined by the microchannel geometry and additional parameters will need to be addressed for a complete hydrodynamic drag assessment. There is hydrodynamic lifting force associated with a particle near the surface of a substrate and



Dielectrophoretic Motion of Particles and Cells, Figure 5 A particle trapped by a negative dielectrophoresis quadrupole trap

under applied fluid flow. This is expressed with

$$F_{\text{lift}} = 9.22\left(36\,Q^2/w^2h^4\right)\rho r^4 \tag{9}$$

where Q is the volumetric flow rate, w and h are the microchannel dimensions, ρ is the density of the fluid and r is the radius of the particle [10]. As shown in (9), the lifting force significantly increases for larger particles and higher flow rates. Last, the sedimentation force is caused by gravity (g) and, for a spherical particle, is given by

$$F_{\text{sed}} = -\frac{4}{3}\pi r^3\left(\rho_{\text{p}} - \rho_{\text{m}}\right)g \tag{10}$$

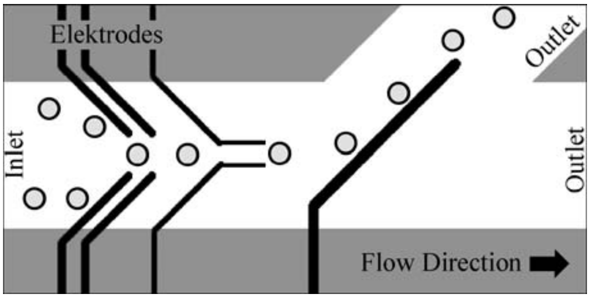
A more in-depth explanation of dielectrophoretic trapping, including these additional modeling parameters, are shown elsewhere [8].

Electrode-Based Microsystems

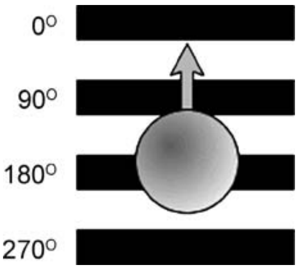
Microsystems have incorporated dielectrophoretic forces into microchannels to manipulate particles and cells with various electrode geometries. Electrodes can be used to align target cells or separate particulate cells from the rest of the sample, an example of which is illustrated in Fig. 6. These systems use a 3D arrangement of electrodes, with mirrored electrode geometries aligned and separated by a thin film with microfluidic structures. Thus the electrodes in Fig. 6 are on the top and bottom surfaces of the microchannel and do not significantly impede or manipulate the flow field. This system is optimized for a particular set of cells such that the applied signals generate the strongest dielectrophoretic forces; this system will operate with the maximum possible applied flow rate for more effective processing. The system, though, will be selective to a set of cells with the same or similar dielectric properties. This process is obviously advantageous for an application that selectively separates cells based on their dielectric properties. Additionally, these systems can simultaneously separate and trap targeted cells for selective biological investigations. These dielectrophoresis techniques can be coupled with a variety of existing biological tools for innovative applications including fluorescence evaluation of cells in small populations, cell sorting, long-term investigations of single cells, cellular kinetics and other similar Lab-on-a-Chip analyses.

Traveling Wave Dielectrophoresis

Traveling wave dielectrophoresis is simply a linear application of electrorotation. An AC electric wave is produced by applying an electric field that travels linearly along a series of electrodes. An example of a traveling wave dielectrophoresis system with a 90° phase shift between electrodes is shown in Fig. 7. The expression for the traveling wave dielectrophoresis force for a homogeneous spherical particle is given by



Dielectrophoretic Motion of Particles and Cells, Figure 6 An illustration of a dielectrophoretic microsystem that can selectively sort particles (top view). Recall that the electrodes are on the top and bottom surfaces of the microchannel and to not mechanically manipulate the particles



Dielectrophoretic Motion of Particles and Cells, Figure 7 Traveling wave dielectrophoresis

$$F_{\text{tw}} = \frac{-4\pi^2\varepsilon_0\varepsilon_{\text{m}}r^3\text{Im}\left[K(\omega)\right]E^2}{\lambda} \tag{11}$$

where λ is the wavelength of the applied signal. This is very similar to the electro-rotation force (7) including the incorporation of the imaginary part of the Clausius–Mossotti factor; the direction of the particle with respect to the traveling wave is dependent on this factor. The particle will translate in the same direction as the traveling wave if the dipole lags within one-half of a cycle of the electric field. For a lag greater than this the particle will travel in the opposite direction. Traveling wave dielectrophoresis can do more than just induce controlled translational motion, including separating particles of different dielectric properties. A geometry using a spiral electrode arrangement can concentrate particles towards its center while repelling unlike particles.

Dielectric Properties

Dielectric extraction for biological particles is complicated due to their unknown electrical properties and nonuniform geometries. However, dielectrophoretic techniques have been used to determine the dielectric properties of particles and cells. For non-spherical particles an orientation spectra can be obtained from electro-orientation experimentation and utilized to determine dielectric properties. Additionally, a particle's crossover frequency can be obtained through a visual observation when, at a given frequency, the cell of interest translates from an area of high electric field gradients to a field null (or vice versa). This can be observed for electrodes of various dimensions; for example, in an interdigitated electrode geometry as a dielectrophoretically-induced particle undergoes a change from pDEP to nDEP, it will translate from the electrode edge to above the center of the electrode strip. With careful experimentation and observation, the dielectric properties of unknown layers of multi-shelled particles can be determined. Dielectric properties have also been extracted from experiments measuring the translational speed of a particle under a dielectrophoretic force as well as counting and comparing dielectrophoresis-captured population spectra. Also, electrorotation and traveling wave dielectrophoresis experiments have been used to determine dielectric properties. There are a variety of ways to extract dielectric characteristics of particles and cells and, once determined, optimal dielectrophoresis systems can be designed.

Future Directions for Research

Dielectrophoretic techniques have continued to evolve from primitive, macroscale experimentation of Pohl to nanometer-sized particulate manipulation. This evolution is brought in part by the decreasing length scale of microfabrication techniques. As the feature size of fabricated electrodes become smaller and smaller, nanometer dielectrophoresis experimentations and phenomena will continue to unfold. The use of dielectrophoresis as a tool for micro- and nano-assembly has only recently emerged and these applications will continue to be developed. As a nonmechanical and minimally invasive process, dielectrophoresis presents itself for continued investigation as a constructive tool, including integration with sub-cellular biological entities.

As the number of applications of dielectrophoresis continues to increase, an accurate, comprehensive model becomes a necessary tool for optimal design. Although models exist describing individual dielectrophoretic manipulation techniques (especially for dielectrophoretic trap geometries), few exist for dynamic systems incorporating multiple dielectrophoresis applications with hydrodynamic, electrohydrodynamic and electrothermal phenomena. Additionally, these models need to incorporate non-spherical and non-rigid particle variables as well as fluid behaviors as you reach the nanometer length scale (such as Brownian motion) without ignoring important dielectric parameters such as particle–particle interactions and multipole theory.

Definition

Diffusiophoresis is defined as the migration of a colloidal particle in a solution in response to the macroscopic concentration gradient of a molecular solute that interacts with the surface of the particle; the solute can be either ionic or nonionic. Diffusiophoresis, which is due to the formation of a diffuse and mobile layer of neutral molecules or ions at the surface of the particle in an imposed solute concentration field, is different from *osmophoresis*, in which the particle is a vesicle composed of a body of fluid surrounded by a semipermeable membrane and the driving force for the migration is the osmotic pressure gradient along the particle surface caused by the solute concentration gradient prescribed in the ambient solution. In contrast to the diffusiophoresis of colloidal particles in prescribed solute concentration gradients, *diffusioosmosis* refers to the flow of a fluid solution in a micropore involving tangential concentration gradients of a solute that interacts with the pore wall.

Chemical and Physical Principles

A colloidal particle can be driven to move in a solution by the application of a nonuniform solute concentration field. The particle migrates toward or away from regions of higher solute concentration, depending on long-range interactions between the solute molecules and the particle. In a solution of uncharged solute, the solute molecules interact with the particle through the van der Waals and/or dipole forces, and thus, diffusiophoresis proceeds in the direction of increasing solute concentration. For a charged particle in an electrolyte solution, the particle-solute interaction is electrostatic in nature and its range is the Debye screening length κ^{-1}. In principle, diffusiophoresis of a charged particle in an electrolyte solution can be considered as a combination of two effects:

- chemiphoresis due to the nonuniform adsorption of counter-ions and depletion of co-ions over the surface of the particle, which is analogous to diffusiophoresis in nonionic media, and
- electrophoresis due to the macroscopic electric field generated by the concentration gradient of the electrolyte whose anion and cation have unequal diffusion coefficients.

A charged particle with a zeta potential of order kT/e ($\sim$25 mV; e is the elementary electric charge, k is Boltzmann's constant, and T is the absolute temperature) in electrolyte gradients of order 100 kmol/m^4(1 M/cm) will move by diffusiophoresis at speeds of several micrometers per second. The typical diffusiophoretic velocity of a particle in a solution of uncharged solute is of the same order of magnitude.

Key Research Findings

Diffusiophoresis of a Particle with a Very Thin Diffuse Layer

In an unbounded solution with a linear solute concentration distribution n^∞ or a constant macroscopic concentration gradient ∇n^∞, the diffusiophoretic velocity of a par-

ticle is [1–3]

$$\mathbf{U}^{(0)} = \frac{kT}{\eta} LK \nabla n^{\infty} \quad (1)$$

for the case of a nonionic solute, and

$$\mathbf{U}^{(0)} = \frac{\varepsilon\zeta}{\eta}\left(\alpha + \bar{\zeta}^{-1}\ln\cosh\bar{\zeta}\right)\frac{kT}{Ze}\nabla\ln n^{\infty} \quad (2)$$

for the case of a symmetric electrolyte solute with valence Z (which is positive). Here, L is a characteristic length for the particle-solute interaction (of order 1–10 nm), K is the Gibbs adsorption length characterizing the strength of the adsorption of the molecular solute [K and L are defined later by Eqs. (8) and (9)], η is the fluid viscosity, the dimensionless parameters

$$\alpha = \frac{D_2 - D_1}{D_2 + D_1}, \quad (3)$$

$$\bar{\zeta} = \frac{Ze\zeta}{4kT}, \quad (4)$$

D_1 and D_2 are the diffusion coefficients of the anion and cation, respectively, ζ is the zeta potential of the particle surface, and ε is the fluid permittivity. For the special case of $D_2 = D_1$ or $\alpha = 0$, Eq. (2) predicts that the particle movement (due to chemiphoresis only) is in the direction of increasing solute concentration, same as that predicted by Eq. (1) for a nonionic solution, regardless of the sign of ζ and the particle velocity is a monotonic increasing function of the magnitude of ζ.

Equations (1) and (2) indicate that the diffusiophoretic velocities of a particle are independent of the particle size and shape (and there is no rotational motion of the particle). However, their validity is based on the assumptions that the local radii of curvature of the particle are much larger than the thickness of the particle-solute interaction layer (diffuse layer) at the particle surface and that the effect of polarization (relaxation effect) of the diffuse solute species in the interfacial layer due to nonuniform "osmotic" flow is negligible. Important advances have been made in the past in the evaluation of the diffusiophoretic velocities of colloidal particles relaxing these assumptions and will be discussed below.

Diffusiophoresis of a Particle with a Thin but Polarized Diffuse Layer

For the case of diffusiophoretic motion of a colloidal sphere of radius a with a thin but polarized particle-solute interaction layer in a gradient of nonelectrolyte solute, the formula for the particle velocity was analytically derived by Anderson and Prieve [1],

$$\mathbf{U} = \frac{kT}{\eta} LK \left(1 + \frac{\beta}{a}\right)^{-1} \nabla n^{\infty}. \quad (5)$$

In the above equation, β is a relaxation coefficient defined by

$$\beta = (1 + \nu \mathrm{Pe}) K, \quad (6)$$

where

$$\mathrm{Pe} = \frac{kT}{\eta D} LK n^{\infty}, \quad (7)$$

$$K = \int_0^{\infty} \left[\exp(-\Phi(y)/kT) - 1\right] \mathrm{d}y, \quad (8)$$

$$L = K^{-1} \int_0^{\infty} y \left[\exp(-\Phi(y)/kT) - 1\right] \mathrm{d}y, \quad (9)$$

and

$$\nu = \left(LK^2\right)^{-1} \int_0^{\infty} \left\{ \int_0^{\infty} \left[\exp(-\Phi(y)/kT) - 1\right] \mathrm{d}y \right\}^2 \mathrm{d}y. \quad (10)$$

In Eqs. (7)–(10), Φ represents the potential energy resulting from the interaction between a single solute molecule and the particle surface (Φ is positive if the interaction force is repulsive and negative if it is attractive), D is the solute diffusion coefficient, and y is the normal distance measured from the particle surface into the fluid phase. The dimensionless parameter ν depends primarily on the shape of the function Φ rather than on its magnitude, and a typical value for it is 1/2. The adsorption length K equals the ratio of the Gibbs excess concentration of the solute in the adsorption layer to the solute concentration in the bulk solution at equilibrium, and it can be measured independently. There does not seem to be any means of quantitatively determining the length L, other than to say that it is positive and comparable to the size of the solute molecule. The relaxation coefficient β represents the ratio of apparent surface-to-bulk diffusion coefficients.

To obtain Eqs. (5)–(10), it was assumed that the concentration of solute within the adsorption boundary layer is related to the solute-surface interaction energy by a Boltzmann distribution. The essence of the thin-layer polarization approach is that a thin diffuse layer can still transport a significant amount of solute molecules so as to affect the solute transport outside the diffuse layer. For a strongly adsorbing solute (e. g., a surfactant), the dimensionless relaxation parameter β/a (or K/a) can be much

greater than unity. If all the adsorbed solute were "stuck" to the surface of the particle (the diffuseness of the adsorption layer disappears), then $L = 0$ and there would be no diffusiophoretic migration of the particle. In the limit of $\beta/a \to 0$ (very weak adsorption), the polarization of the diffuse solute in the interfacial layer vanishes and Eq. (5) reduces to Eq. (1).

Taking the double-layer distortion from equilibrium as a perturbation, Prieve and Roman [2] obtained a numerical calculation for the diffusiophoretic velocity of a dielectric sphere of radius a in concentration gradients of 1 : 1 electrolytes (KCl or NaCl) which was applicable to arbitrary values of ζ and κa, where κ^{-1} is the Debye screening length equal to $(2Z^2e^2n^\infty/\varepsilon kT)^{1/2}$. On the other hand, Keh and Chen [3] obtained an analytical expression for the diffusiophoretic velocity of a dielectric sphere surrounded by a thin but polarized electric double layer in the solution of a symmetric electrolyte,

$$\mathbf{U} = \frac{\varepsilon\zeta}{3\eta}\left\{c_1' - c_2' + \alpha(2 + c_1 + c_2) + \left[2 + c_1' + c_2' + \alpha(c_1 - c_2)\right]\bar{\zeta}^{-1}\ln\cosh\bar{\zeta}\right\}\frac{kT}{Ze}\nabla\ln n^\infty\,, \quad (11)$$

where

$$c_1 = \frac{1}{2a^2\Delta_1}\left(a^2 - 2a\beta_{11} + 3a\beta_{12} + a\beta_{22} + 2\beta_{12}\beta_{21} - 2\beta_{11}\beta_{22}\right)\,, \quad (12a)$$

$$c_2 = \frac{1}{2a^2\Delta_1}\left(a^2 - 2a\beta_{22} + 3a\beta_{21} + a\beta_{11} + 2\beta_{12}\beta_{21} - 2\beta_{11}\beta_{22}\right)\,, \quad (12b)$$

$$c_1' = c_1 - 3\frac{\beta_{12}}{a\Delta_1}\,, \quad (12c)$$

$$c_2' = c_2 - 3\frac{\beta_{21}}{a\Delta_1}\,, \quad (12d)$$

$$\Delta_1 = \frac{1}{a^2}\left(a^2 + a\beta_{11} + a\beta_{22} - \beta_{12}\beta_{21} + \beta_{11}\beta_{22}\right)\,, \quad (13)$$

and the relaxation coefficients

$$\beta_{11} = \frac{1}{\kappa}\left[4\left(1 + \frac{3f_1}{Z^2}\right)\exp\left(\bar{\zeta}\right)\sinh\bar{\zeta} - \frac{12f_1}{Z^2}\left(\bar{\zeta} + \ln\cosh\bar{\zeta}\right)\right]\,, \quad (14a)$$

$$\beta_{12} = -\frac{1}{\kappa}\left(\frac{12f_1}{Z^2}\right)\ln\cosh\bar{\zeta}\,, \quad (14b)$$

$$\beta_{21} = -\frac{1}{\kappa}\left(\frac{12f_2}{Z^2}\right)\ln\cosh\bar{\zeta}\,, \quad (14c)$$

$$\beta_{22} = \frac{1}{\kappa}\left[-4\left(1 + \frac{3f_2}{Z^2}\right)\exp\left(-\bar{\zeta}\right)\sinh\bar{\zeta} + \frac{12f_2}{Z^2}\left(\bar{\zeta} - \ln\cosh\bar{\zeta}\right)\right]\,. \quad (14d)$$

In the above equations, $f_m = 2\varepsilon k^2T^2/3\eta e^2D_m$ and $\bar{\zeta}$ was defined by Eq. (4).

To obtain Eqs. (11)–(14), it was assumed that the concentration of each ionic species within the electric double layer is related to the electric potential energy by a Boltzmann distribution. A comparison of Eq. (11) with the numerical results obtained by Prieve and Roman [2] shows that the thin-layer polarization model is quite good over a wide range of zeta potentials when $\kappa a > 20$. If $|\zeta|$ is small and κa is large, the interaction between the diffuse counter-ions and the particle surface is weak and the polarization of the double layer is also weak. In the limit of

$$(\kappa a)^{-1}\exp\left(2\left|\bar{\zeta}\right|\right) \to 0\,, \quad (15)$$

the effect of double-layer polarization disappears, $\beta_{11} = \beta_{12} = \beta_{21} = \beta_{22} = 0$, $c_1 = c_2 = c_1' = c_2' = 1/2$, and Eq. (11) reduces to the Eq. (2). Numerical calculations of Eq. (11) show that, even when κa is as large as 300, the effect of ionic transport inside the diffuse layer cannot be ignored if $|\zeta|$ equals several kT/e. In the other limit of very large relaxation coefficients, Eq. (12) becomes $c_1 = c_2 = c_1' = c_2' = -1$. Even for the case of $D_2 = D_1$, the particle velocity given by Eq. (11) for a finite value of κa may not be a monotonic function of the magnitude of $\bar{\zeta}$ and its direction can reverse (toward lower electrolyte concentration) when $|\bar{\zeta}|$ becomes large.

It could be found from Eqs. (5) and (11) that the effect of polarization of the diffuse layer is to decrease the particle velocity. The reason for this outcome is that the transport of the solute within the particle-solute interaction layer reduces the local solute concentration gradient along the particle surface. Although Eq. (11) is derived for the solution of a symmetric electrolyte, it can also be applied to the solution containing an arbitrary electrolyte using the reasoning that only the most highly charged counter-ions play a dominant role in the ionic fluxes along the particle surface.

On the other hand, the extension of Eqs. (5) and (11) to the diffusiophoretic velocity of spheroidal [4] and cylindrical [3, 5] particles with thin but polarized particle-solute

interaction layers was also derived. A remarkable feature was found that the diffusiophoretic velocity of a long circular cylinder in a transversely applied solute gradient is exactly the same as that of a sphere with an equal radius, given by Eqs. (5) and (11).

Diffusiophoresis of a Charged Particle with Arbitrary Double-Layer Thickness

Recently, analytical formulas in closed forms for the diffusiophoretic mobility of a charged sphere [6] and circular cylinder [7] of radius a in symmetric electrolytes at low surface charge density σ (valid for ζ up to 50 mV) and arbitrary κa have been obtained. The diffusiophoretic velocity of the charged particle can be expressed as an expansion in powers of ζ,

$$\mathbf{U} = \frac{\varepsilon}{\eta}\left[\frac{kT}{Ze}\alpha\Theta_1(\kappa a)\zeta + \frac{1}{8}\Theta_2(\kappa a)\zeta^2 + O\left(\zeta^3\right)\right]\nabla \ln n^{\infty} . \quad (16)$$

In this equation, Θ_1 and Θ_2 are functions defined by

$$\Theta_1(x) = 1 - e^x\left[5E_7(x) - 2E_5(x)\right] , \quad (17a)$$

$$\begin{aligned}\Theta_2(x) = 1 &+ \tfrac{1}{3}e^{2x}\left[10E_6(2x) + 7E_8(2x)\right] \\ &- 40e^{2x}E_7(x)\left[E_3(x) - E_5(x)\right] \\ &+ \tfrac{4}{3}e^x\left[3E_3(x) + 9E_4(x) - 7E_5(x) - 15E_6(x)\right] ,\end{aligned} \quad (17b)$$

$$E_n(x) = \int_1^{\infty} t^{-n}e^{-xt}\,\mathrm{d}t \quad (18)$$

for a spherical particle, and

$$\Theta_1(x) = 1 + B_{(0,3,1,0)}(x) - 4B_{(0,5,1,0)}(x) , \quad (19a)$$

$$\begin{aligned}\Theta_2(x) = 2 &- 4B_{(0,3,1,0)}(x) + 2B_{(0,3,2,0)}(x) \\ &+ 4\frac{K_1(x)}{K_0(x)}\left[B_{(1,2,1,0)}(x) - 2B_{(1,4,1,0)}(x)\right] \\ &- x^2\left[B_{(1,-1,2,0)}(x) - B_{(1,1,2,0)}(x) + 2B_{(1,1,2,1)}(x)\right] ,\end{aligned} \quad (19b)$$

$$B_{(m,n,i,j)}(x) = \int_1^{\infty} t^{-n}(\ln t)^j\left[\frac{K_m(xt)}{K_0(x)}\right]^i \mathrm{d}t \quad (20)$$

for a long circular cylindrical particle in a transversely imposed electrolyte concentration gradient, where K_m is the modified Bessel functions of order m of the second kind. The values of the functions $\Theta_1(x)$ and $\Theta_2(x)$ calculated numerically using Eqs. (17) and (19) are given in Tables 1 and 2, respectively. The effect of the polarization (or relaxation) of the diffuse ions in the electric double layer surrounding the particle is not included in Eq. (16) up to the order ζ^2. Note that the results of $\Theta_1(\kappa a)$ given by Eqs. (17a) and (19a) are the same as those derived by Henry for the electrophoretic mobilities of a dielectric sphere (6) and circular cylinder in the direction normal to its axis [7], respectively. All results of the above investigations show that the diffusiophoretic mobility of a particle in general decreases with an increase in $(\kappa a)^{-1}$. Also, the particle can reverse the direction of its migration when the value of $|\zeta|$, $(\kappa a)^{-1}$, or the valence of the electrolyte increases.

Particle-Interaction and Boundary Effects on Diffusiophoresis

In practical applications of diffusiophoresis, colloidal particles are not isolated and the surrounding fluid is externally bounded by solid walls. Thus, it is important to determine if the presence of neighboring particles and/or boundaries significantly affects the movement of a particle. In the limiting case that Eqs. (1) and (2) are applicable, the normalized velocity field of the immense fluid that is dragged by a single particle during diffusiophoresis is the same as for electrophoresis of the particle; thus, the particle-interaction and boundary effects on electrophoresis under the situation of infinitesimally thin double layer (satisfying Eq. (15)), which have been studied extensively

in the past, can be taken to interpret those in diffusiophoresis [8–10]. An important result of these investigations is that the particle-interaction and boundary effects on electrophoresis/diffusiophoresis are much weaker than on sedimentation, because the disturbance to the fluid velocity field caused by a phoretic particle decays faster than that caused by a Stokeslet.

When the polarization effect of solute species in the diffuse layer surrounding the particle is considered, the particle-interaction and boundary effects on diffusiophoresis can be quite different from those on electrophoresis, due to the fact that the particle size and some other unique factors are involved in each transport mechanism. Through the use of a boundary collocation method, the quasi-steady axisymmetric diffusiophoresis of a chain of colloidal spheres with thin but polarized diffuse layers was examined and numerical results of the diffusiophoretic velocity of the particles were presented for various cases. The diffusiophoretic velocities of two spherical particles with thin polarized diffuse layers but with arbitrary surface properties, arbitrary sizes, and arbitrary orientation with respect to the imposed solute concentration gradient correct to $O(r_{12}^{-7})$ were obtained by using a method of reflections, where r_{12} is the particles' center-to-center spacing. Based on the concept of statistical mechanics, the reflection results of interaction effects between pairs of spheres were also used to calculate approximately the average diffusiophoretic velocity of particles with thin but polarized diffuse layers in a statistically homogeneous suspension subjected to a uniform solute concentration gradient to the first order of the volume fraction of the particles. Using a unit cell model, the steady-state diffusiophoresis of a swarm of identical colloidal spheres with thin but polarized diffuse layers or with an arbitrary value of κa suspended uniformly in a solution with a constant imposed solute concentration gradient has been analyzed with various boundary conditions at the virtual surface of the cell [8]. The particle velocity as functions of the volume fraction of the particles was obtained in closed-form expressions, and comparisons of the results among the cell models and between the statistical model for dilute suspensions and the cell models have also been provided.

On the other hand, through the use of the boundary collocation technique, the diffusiophoretic motion of a colloidal sphere with a thin but polarized diffuse layer in the direction perpendicular to a plane wall was examined [9]. The wall effect on diffusiophoresis was found to be a complicated function of the properties of the particle and ions. Recently, the motions parallel to two plane walls at an arbitrary position between them and along the axis of a circular cylindrical pore were also investigated by using the boundary collocation method [10]. Numerical results of the wall corrections to Eqs. (5) and (11) for the particle velocity were presented for various values of the relative separation distances and other relevant parameters.

Examples of Application

Analogous to electrophoresis, diffusiophoresis is of practical importance in some applications to particle characterization and separation. In the metal and rubber technologies concerning surface treatment, diffusiophoresis is a transport mechanism in certain latex-particle coating processes. On the other hand, diffusiophoresis may be responsible for the repulsion of small particles by living cells, because each cell generates around itself a concentration field with gradient diminishing away from the cell as a result of material exchange with the surrounding continuous medium; the range of such repulsive forces may reach several tens of micrometers. Diffusiophoresis also plays an important role in other biological systems, such as the transport of proteins (hemoglobin, insulin, etc.) in solute concentration gradients.

Electrowetting on dielectric (EWOD)

Definition

Digital microfluidics is based upon the micromanipulation of discontinuous fluid droplets within a reconfigurable network. Complex instructions can be programmed by combining the basic operations of droplet formation, translocation, splitting, and merging.

Overview

Digital microfluidics is a relatively new term in Lab-on-a-Chip technology and its definition is not very clear. In the literature, digital microfluidics is a name given to a second-generation Lab-on-a-Chip architecture based upon micromanipulation of discontinuous fluid droplets. The basic operations required in digital microfluidics include droplet formation, droplet translocation, droplet splitting, and merging [1]. Although some continuous-flow microfluidic devices can also generate and manipulate discrete droplets [2], this is not commonly referred to as digital microfluidics. This could be due to the permanently etched microchannels involved, which limit the control reconfigurability and design scalability. Digital microfluidic networks are usually controlled by electrowetting on dielectric (EWOD), where droplets are driven by changing the substrate hydrophobicity using electric fields. A recently published magnetic droplet formation device may also fall into this category [3]. In such a device, a water droplet with magnetic particles added is driven by a changeable magnetic field controlled by a multilayer set of coils on a printed circuit board.

Basic Methodology

Theory

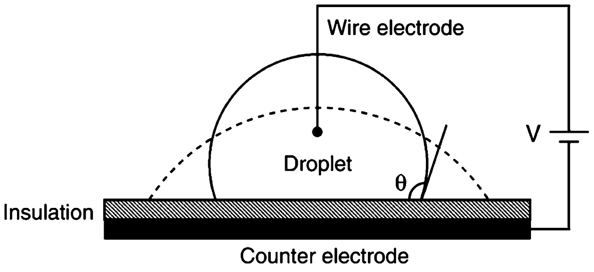
Figure 1 illustrates the electrowetting effect, where a polarizable, conductive liquid droplet is initially at rest on a hydrophobic surface [4]. When an electrical potential is applied between the droplet and an insulated counter-electrode underneath the droplet, a reduction in the contact angle of the droplet will occur and result in improved wetting. This improved wetting is a consequence of the lowering of the effective solid–liquid interfacial energy through the electrostatic energy stored in the capacitor formed by the droplet–insulator–electrode system. The dependence of the effective solid–liquid interfacial tension γ_{SL} on the applied voltage V is given by Lippmann's equation,

$$\gamma_{SL} = \gamma_{SL}^0 - \frac{\varepsilon V^2}{2d} \qquad (1)$$

where γ_{SL}^0 is the interfacial tension at zero applied potential, and ε and d are the dielectric constant and thickness of the insulating film. The effect of the Debye layer in the liquid can be neglected since its capacitance is connected in series with the solid insulator, which typically has a much smaller capacitance. Consequently, the electrowetting effect is relatively independent of the concentration or type of ions in the solution. Furthermore, the use of a solid insulator rather than a spontaneous space-charge layer to serve as the capacitor dielectric permits larger surface energies to be achieved at lower electric fields, while greater control over the surface chemistry is possible [12].

Experimental

Our experimental setup is illustrated in Fig. 2. The electrowetting system comprised a photolithographically patterned control electrode array (made from chromium or indium tin oxide, ITO) on a glass substrate, and a continuous ground plane (ITO on glass) parallel to it. Both electrode surfaces were covered by a film of hydrophobic insulation (e. g. a Teflon AF 1600 film, with a contact angle of 104° with water) that was insufficient to electrically insulate the ground electrode from the droplet. The control electrodes were patterned on a glass substrate using standard microfabrication techniques, and the top plate consisted of a glass substrate coated with a conducting layer



Digital Microfluidics, Figure 1 A droplet of conducting liquid forms a contact angle θ with a solid hydrophobic insulator (solid curve). Applying a voltage V between the droplet and a counterelectrode underneath the insulator reduces the solid–liquid interfacial energy, leading to a reduced θ and improved wetting of the solid by the droplet (dashed curve) [4]

of optically transparent ITO to form the ground electrode. By clamping the two plates with a spacer between them, the electrode array and the ground plane were separated and a droplet was sandwiched between the two plates. Surrounding the droplet was a filler fluid (immiscible with the droplet, e. g. 1 cSt silicone oil) to prevent evaporation and facilitate transport. The electrode array was computer-controlled and was capable of independently switching each output between ground and the voltage output of a dc power supply [4, 5].

Key Research Findings

Basic Operations

Droplet Translocation

Translocation is achieved by sequentially energizing electrodes beneath the leading meniscus of a droplet. Pollack et al. [4] showed that the movement of a droplet was initiated at around 48 V, and thereafter the droplet was repeatedly transported. In the study of Cho et al. [6], movement of a droplet was achieved at a much lower applied poten-

tial, about 18 V. A combination of thin Teflon and oxide layers enabled this low-voltage operation.

Droplet Splitting and Merging

Sequentially captured images of the complete splitting process are shown in Figs. 3a–d. A neck shape is initially formed (Fig. 3c), and the droplet is then cut into two droplets (Fig. 3d). After the electric potential is turned off, the separated droplets relax into circular shapes. Droplet merging is essential for mixing in many microfluidic devices and is achieved by moving two droplets toward each other. This is the reverse process of splitting and is shown in Figs. 3e and 3f [4]. However, it has been reported that a design that can split droplets into two may not necessarily be able to merge two droplets back into one. This phenomenon is more likely to occur with a smaller channel gap and larger droplets, where the effect of contact angle hysteresis becomes more apparent [6].

Droplet Formation

To generate droplets from an on-chip reservoir, liquid needs first to be pulled out of the reservoir and separated from it. This process is strongly related to the droplet-splitting process, and a smaller channel gap (H in Fig. 2) makes droplet formation easier. The sequence of droplet formation is depicted in Fig. 3 (parts 1–4) [7], where gray squares represent energized electrodes and white squares represent electrodes that are not energized. Note that two side electrodes have been introduced beside the main fluid path. While this is not a prerequisite for droplet formation, side electrodes help to form a better-defined droplet and provide control of the location of the splitting. Without the side electrodes, it is reported that the liquid may continue to follow the leading meniscus to some extent, forming a long liquid column. The location of the splitting depends on the initial shape of the meniscus in the reservoir, on the surface condition, and on how the control electrodes are activated [4, 6].

Droplet Mixing

Droplet mixing is achieved by translocation of a droplet between several electrodes. For example, when three electrodes were used, the coalesced droplet had four possible configurations, as shown in Fig. 4a. Time-lapse images of three of the four configurations during three-electrode mixing at 8 Hz are shown in Fig. 4b. Flow reversibility is also demonstrated here. In the later frames, it can be observed that the interface between the fluorescent and nonfluorescent areas behaves as if it is more diffuse, even though flow reversibility can still be observed. A further increase in the number of electrodes can increase the number of possible mixing configurations. Since diffusion-based mixing depends on the total interfacial area generated within the coalesced droplet, increasing the number of possible configurations improves mixing by extending the interface. Moreover, increasing the frequency of oscillation will change this interface more quickly, since the switching time between different configurations is reduced. To achieve even faster mixing times, a greater number of electrodes can be used with operation at higher frequencies, at the cost of using a larger mixing area [8].

Applications

EWOD/Absorbance Detector for Glucose Detection

Figure 5 illustrates how optical absorbance measurements were made in a plane perpendicular to an EWOD device [13]. The setup consisted of a green LED (545 nm, RadioShack) and a photodiode (TSL257, Texas Advanced Optoelectronic Solutions), which functioned as a light-to-voltage converter. The voltage output of the photodiode $V(t)$ was directly proportional to the light intensity incident on it. A colorimetric enzyme-kinetic method was used for the determination of glucose concentration on the basis of Trinder's reaction. First, glucose was enzymatically oxidized to gluconic acid and hydrogen peroxide in the presence of a glucose oxidase. The hydrogen peroxide formed was reacted with 4-aminoantipyrine and *N*-ethyl-*N*-sulfopropyl-*m*-toluidine in the presence of a peroxidase to give violet-colored quinoneimine, which has an absorbance peak at 545 nm. Detection of glucose in a concentration range of 25 – 300 mg/dl was achieved [5].

EWOD/PCR

Figure 6 depicts an EWOD-based PCR biochip device, with operation details as follows. First, droplets containing a PCR reagent/primer and a cDNA sample were created from separate reservoirs. Then, both droplets were moved away from their respective reservoirs to reach the mixing region by means of basic droplet translocation operations. The droplets were merged and mixed using a 2×2 electrode array. By switching the voltages applied to the electrodes in specific cycles, the merged droplet could be completely mixed. When the mixed droplet reached the periphery of the PCR chamber, a surface tension gradient was induced by the hydrophobic/hydrophilic interface. Without power being applied, the mixed droplet was then moved to the micro-PCR chamber. Finally, the mixed droplet was completely transported inside the micro-PCR chamber.

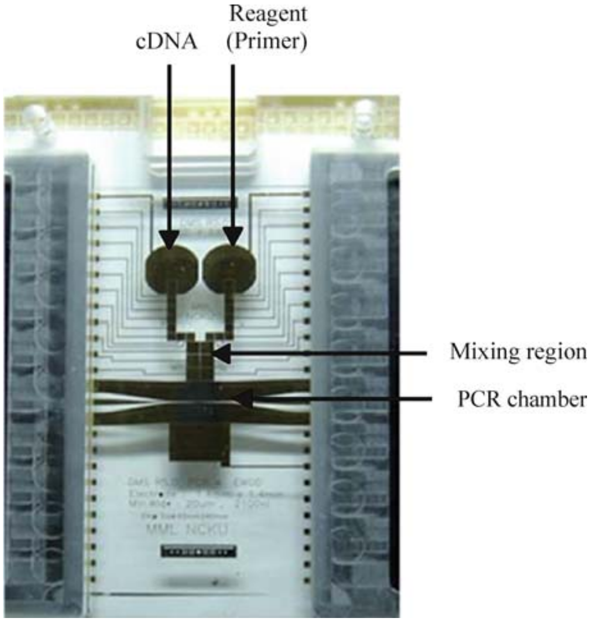
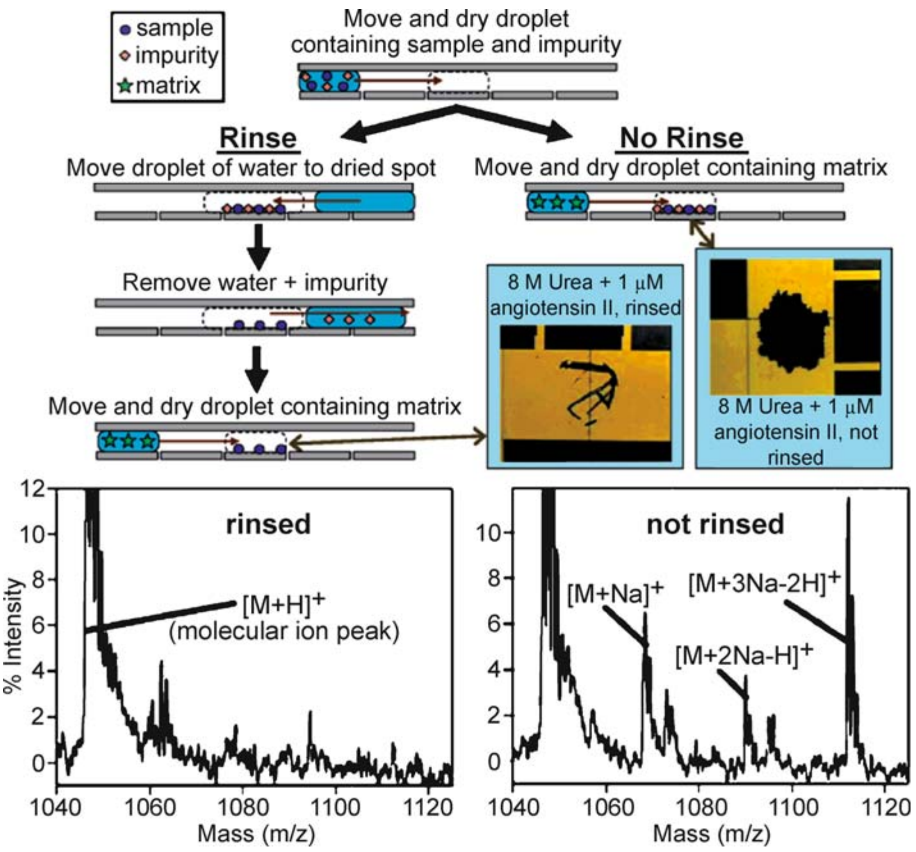
Digital Microfluidics, Figure 5 (**a**) Optical detection implemented by sandwiching an EWOD device between a green light-emitting diode and a photodiode. (**b**) A glucose assay was initiated by mixing a sample and reagent together. The change in absorbance was detected by the photodiode



Digital Microfluidics, Figure 6 A digital EWOD/PCR biochip with integrated on-chip heater and temperature sensor. See text for details

Two microheaters and a temperature microsensor were integrated into the on-chip PCR chamber. A novel design of the hydrophobic (Teflon) and hydrophilic (SiO_2) layers was used to cover the microheaters. The different contact angles caused by the hydrophobic/hydrophilic structure generated a surface tension gradient that pulled mixed droplets into the PCR chamber with no power application. The whole pulling process took about 0.13 s. The PCR procedure was performed for 25 thermal cycles. The final PCR products were analyzed by using a gel electrophoresis technique in 1.5% agarose gel stained with ethidium bromide (Sigma Chemical, USA), and visualized



Digital Microfluidics, Figure 7 (**a**) EWOD-driven sample purification and micrographs of dried spots. Insets: the rinsed sample (left) appears to be primarily composed of DHB crystals, while the nonrinsed sample (right) is dominated by urea. MALDI-MS spectra of (**b**) rinsed and (**c**) control spots

with ultraviolet light. The total time for the on-chip PCR test was 55 min and the total sample volume consumed was 15 μL. In comparison with the total time of 110 min and total sample volume of 50 μL for a traditional PCR machine, the reductions of total time and sample consumption are 50% and 70%, respectively [9].

EWOD/MALDI-MS

Figure 7 illustrates an in-line sample purification method for MALDI-MS which relies on an EWOD-based technique. In this study, air was used as the filler medium instead of silicone oil because the oil hindered the droplet-drying process. A droplet containing peptides and impurities was moved by EWOD to a specific location on the array and then dried to form a spot. Subsequently, an EWOD-driven droplet of deionized water was moved onto the spot; after visual confirmation that the impurities had dissolved, the droplet was moved away from the spot. After this rinsing step, a droplet containing a MALDI matrix was moved by EWOD to the same spot and dried; finally, the spot was analyzed by MALDI-MS. Control experiments were performed without the water rinse. The purification method was originally evaluated using the same volume, 0.5 μL, for the sample and rinsing droplets. However, because the dried spot was protein-fouled and changed the surface properties, the size of the rinsing droplet was increased so as to touch the adjacent clean electrodes for droplet translocation. Rinsing droplets 1 μL in size were easily moved over spots formed from 0.5 μL sample droplets.

In MALDI-MS, impurities at low to intermediate concentrations form adducts with analyte molecules that can obscure the relevant data and reduce the overall signal intensity. Figures 7b and c contain representative EWOD-MALDI-MS spectra for rinsed and nonrinsed samples of angiotensin II prepared with 20 mM sodium phosphate. In the spectrum of the nonrinsed sample (Fig. 7b), peaks at $M + 23$, $M + 45$, and $M + 67$ corresponded to the monosodium, disodium, and trisodium adducts of the parent molecule. These adduct peaks are barely visible in the spectrum of the rinsed sample. The intensities of the molecular-ion peaks in the rinsed spectra were about twice as great as those observed in the control spectra [10].

Future Directions for Research

Since they feature permanently etched microchannels, continuous-flow microfluidic devices suffer from inherent difficulty in integrating and scaling them because the parameters that govern the flow field (e. g., pressure, fluid resistance, and electric field) vary along the flow path, making the fluid flow at any one location dependent on the properties of the entire system [11]. In other words, major redesign is often required just to integrate and scale up several functionalities. In contrast, increasing the complexity of digital microfluidic devices can be achieved through combining and reusing a finite set of basic instructions. Digital microfluidics seems to be an easier approach to achieving a high degree of functional integration and control to further advance microfluidic technology.

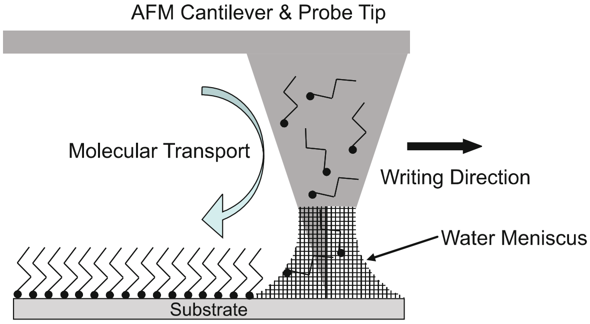
DPN

Definition

Dip Pen Nanolithography (DPN) is a direct-write scanning-probe-based lithography method in which an atomic force microscope (AFM) tip or array of tips is used to deliver chemical reagents directly to specific regions of a substrate surface.

Overview

Dip Pen Nanolithography (DPN) is a direct-write scanning-probe-based lithography method in which an AFM tip is used to deliver chemical reagents directly to specific regions of a substrate surface as shown schematically in Fig. 1. It was originally developed and reported by Mirkin and coworkers in 1999 [1]. The early development of the technique involved use of the AFM tip to deliver alkanethiols to gold surfaces, allowing the formation of patterned self-assembled monolayers (SAMs). The patterns produced in this early work demonstrated the capability of the method to generate material patterns with high resolution and excellent spatial registration. Interestingly, it was also shown that the SAM monolayer patterns formed from the alkanethiol materials were of high quality, i. e. of high density. In fact, the early work with 1-octadecanethiol (ODT) and 16-mercaptohexadecanoic acid (MHA) showed that SAM patterns formed from these reagents on gold surfaces were crysystalline. This high quality nature of the SAM patterns allowed these features to be used as masking layers to resist etch processes such that metal and semiconductor nanostructures could be generated from the DPN pattern [2]. Such techniques have



Dip-Pen Nanolithography, Figure 1 Schematic of the basic dip-pen nanolithography (DPN) process. In the example shown, molecules deposited onto the AFM probe tip are transferred to the substrate through the water meniscus formed at the probe tip-substrate contact point

subsequently been extended to produce a variety of high-resolution metal and semiconductor structures with controlled surface chemistry.

More recently, DPN techniques have been extended and developed to pattern a variety of ink-substrate combinations. DPN has been shown to be compatible with a wide array of ink types including small organic molecules, organic and biological polymers, colloidal particles, metal ions, and sols. DPN has also been demonstrated to work on a wide variety of substrates ranging from metals to insulators, but gold surfaces, silicon, and silicon oxide surfaces remain the most commonly used. DPN is perhaps the only lithography technique that offers a combination of extremely high resolution, precise registration, and the ability to directly print materials without need for other lithographic processing. Due to this combination of characteristics, DPN has become a particularly attractive tool for research related to the patterning of biological and soft organic surfaces. The main advantages for DPN in these applications are that biological and other sensitive molecules can be deposited in either ambient or inert environments without the need to expose them to either harsh radiation (e. g. UV or e-beam), the use of harsh solvents and chemicals required in most other lithography techniques is avoided, and cross-contamination of the surface is avoided since the materials are deposited only where they are wanted on the surface and no bulk chemical treatments of the surface are utilized.

Basic Methodology

In general, DPN is conceptually a very simple process. The major steps involved in the process are:

- the AFM tip is "inked" with the molecule of interest that is to be deposited,
- the AFM tip is aligned to a region where material is to be deposited,
- the tip is brought into contact with the surface and either allowed to dwell in a particular spot (i. e. to create a well defined dot) or scanned over the surface in some pattern-wise manner (to create features composed of lines), and
- the tip is disengaged from the surface to stop transfer of material from the tip to the substrate.

This procedure brings to light one of the limitations of conventional DPN using standard passive AFM probes, namely that material is being transferred from the tip to the substrate any time the tip is in contact with the substrate. Thus the tip must be engaged and disengaged from the surface to start and stop the writing process. Those who work with AFM systems know that this process of tip engagement is relatively slow which prevents the modulation of writing in conventional DPN at very high rates. As will be discussed later, a number of strategies that utilize active AFM cantilever probes have been developed to overcome this limitation and allow for faster modulation of writing in DPN.

Inking of the AFM tip with the molecules of interest can be accomplished using a variety of methods including:

- solution deposition,
- vapor deposition,
- solid precursor deposition directly onto the tip (generally followed by heating and melting of the material on the tip to allow the material to flow and better coat the tip), and
- direct wicking of the pure compound onto the tip.

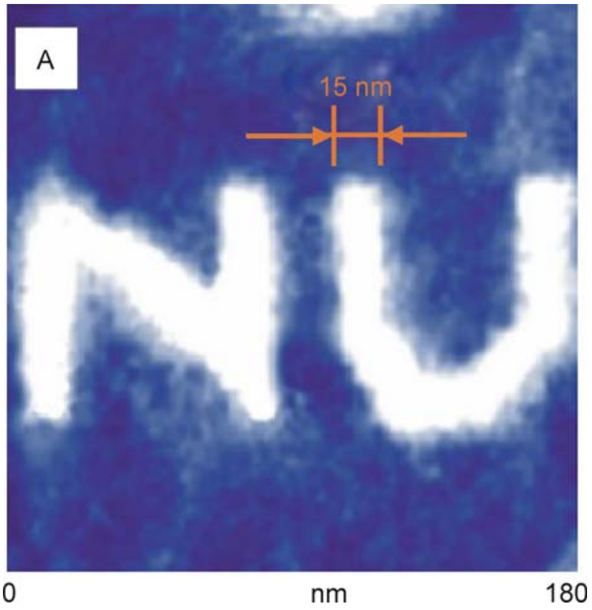
The choice of method used to ink the tip depends on a variety of factors including the physiochemical properties of the molecule that is being coated, the amount of material that is desired on the tip, and the type of tip being used. In solution deposition, the molecule of interest is dissolved into an appropriate solvent at relatively low concentrations, the tip is placed in contact with the solution, molecules are allowed to adsorb to tip from solution, the tip is removed from contact with the solution and allowed to dry (which can result in further deposition of dissolved molecules depending on the method of drying the tip), and this process can be repeated if desired to attempt to build up a significant coating on the tip. The problem in general with this method is that it results in substantial coverage of all parts of the cantilever exposed to the solution, which can be problematic if the top of the AFM cantilever is coated to the extent that the coating interferes with laser reflection from the probe tip when and if the tip is used in a conventional AFM configuration. In vapor deposition, a quantity of the molecule of interest is heated to generate a significant vapor pressure and vapor stream of the

molecule and the tip to be coated is placed cold in contact with the vapor stream and material is allowed to condense on the surfaces of the AFM probe tip. Direct wicking involves placing the AFM probe tip in contact with a small quantity of the molecule of interest which may then require heating to melt the compound and provide sufficient molecular mobility to coat the tip.

Alignment of the tip to the substrate is accomplished using the various normal imaging modes available using an atomic force microscope. At this point, the problem mentioned earlier with DPN in which material is generally transferred from the tip to the surface any time the tip is in contact with the substrate can become problematic. When the coated tip is used to image the surface for the purposes of aligning the tip to the substrate, the accidental transfer of material and contamination of the surface can result. Since conventional DPN requires the tip to be in contact with the surface to transfer material, oscillatory modes of imaging (i. e. so-called "tapping-mode" imaging) can help to reduce accidental contamination of the surface under certain conditions. In other cases, control of the ambient environment around the tip can be used to dramatically affect the rate of deposition of material from the tip and can thus be used as a means to minimize contamination of the surface during imaging and alignment. For example, it has been shown in some cases that writing in a humid environment is needed for particular inks to be effectively deposited, in which cases it is believed that material transfer through a water meniscus formed at the tip-substrate interface is the important mode of material transfer. In such cases, imaging of the surface with the probe tip in a dry environment does not result in substantial material transfer and can be used to aid in tip alignment to features on the substrate surface.

Once the tip is aligned to a location on the surface where writing is to be performed, the tip is brought into contact with the surface and allowed to dwell in one spot (i. e. to deposit a spot) or is scanned over the surface to make extended features. The rate at which material is transferred to the surface and the shape and size of the deposited material region is affected by a number of factors including:

- the type of molecule being deposited and its physiochemical properties,
- the ambient environment in which the writing is being performed,
- the type of surface on which writing is being performed and the existence of any previous patterns on that surface, and
- the length of time the tip is allowed to dwell in one spot or equivalently the rate at which the tip is scanned over the surface and the total time it is scanned over the same spot [3, 4].



Dip-Pen Nanolithography, Figure 2 Example of high resolution pattern of mercaptohexadecanoic acid on atomically-flat gold surface formed using DPN (courtesy Mirkin group, Northwestern University)

The behavior observed in the transfer of material from the tip to the substrate surface is quite rich and the details of these phenomena are beyond the scope of the simple discussion presented here. Overall, transfer of material from the tip is accomplished via some combination of two basic mechanisms:

- thermal diffusion of molecules along the tip surface toward the point of tip-surface contact and ultimately onto the substrate and
- dissolution of the molecules into a solvent meniscus (commonly water under normal humid ambient conditions as mentioned earlier) and deposition of the molecules from the solvent onto the surface.

This first mode has been shown to be the principle mechanism involved in the transfer of hydrophobic, non-water soluble inks while the latter mechanism can be important in more hydrophilic, water soluble ink systems. Although both mechanisms have been shown to be active depending on the ink system used, in the case where a solvent meniscus is present the rates of material transfer are generally significantly enhanced.

Due to the difficulty in modulating writing using standard DPN due to the slow nature of engaging and disengaging a tip or tip array from the surface, a variety of strategies have been developed that allow for such modulation without requiring the crude removal of the cantilever or cantilever array from the surface. Such modulation strategies are of course also critical for applications where cantilever

arrays are used and it is desired that individual cantilevers in the array write independently of one another. One class of modulation techniques focuses on providing ways to locally mechanically actuate a cantilever tip and deflect it over a distance sufficient to remove it from contact with the surface and thus prevent material transfer without requiring gross removal of the AFM scanner head from proximity with the surface (i. e. like the process normally used in disengaging an AFM tip from the surface). Cantilevers and cantilever arrays have been designed that use a variety of local actuation methods including thermal deflection of the cantilever tip [5] and electrostatic deflection of the cantilever tip [6]. For example, in one example of the thermal deflection method, cantilevers were built in which the main cantilever arm consisted of a silicon nitride membrane coated with a gold layer (see Fig. 2). The gold was patterned into narrow lines at the base end of the cantilever to form a resistive heater element which could be heated by flowing a current through the gold lines. The difference in the thermal expansion coefficients of the gold metal and silicon nitride layers results in thermal stress build-up and bending of the cantilever when the temperature of the cantilever is raised. This provides a simple method for modulating contact of the cantilever with the surface by simply modulating current flow to the AFM cantilever probe. In fact, this basic design was used to fabricate a simple 10 element linear cantilever array and to demonstrate that each cantilever could be actuated independently to write different patterns as the array was scanned over a surface. A second method that has been employed to achieve active control of writing from the tip without requiring removal of the tip from the surface has been to use the DPN tip in an electrochemical mode whereby the tip not only delivers material to the surface, but in addition when current is also allowed to flow from the tip it causes an electrochemical reaction in the deposited molecules that forms the final desired product. In this case, the tip is not mechanically actuated to modulate the deposition process but is instead controlled by controlling current flow to the tip to modulate a chemical reaction involved in the deposition process. Thus, although precursor molecules may be deposited any time the tip is in contact with the surface, the desired material is only deposited when the electrochemical reaction is allowed to occur and thus the is modulating a bias between the tip and substrate to control current flow. Specifically, it has been demonstrated that such a combined DPN-electrochemical deposition technique can be used to deposit metal patterns using metal salt precursors [7]. Finally, a very interesting technique that utilizes heating of the cantilever probe tip to control when material is transferred from tip to the substrate has also been recently developed [8]. In this technique, which has been termed so-called "thermal dip-pen nanolithography" or tDPN, AFM cantilevers that contain an electrical resistance heater in the end of the cantilever platform above the base of the probe tip are used. The probe tip is inked with a molecule that is a solid and does not deposit at substantial rates at room temperature from the tip to the substrate. When current is allowed to flow to the heater on the cantilever, the probe tip temperature can be raised above the melting temperature of the ink and it can be transferred to the substrate at a significantly higher rate than in the case when the cantilever is operated at lower temperatures. Therefore, ink deposition can be controlled by modulating heating of the tip using control of current flow through the cantilever.

Key Research Findings

Dip Pen Nanolithography techniques provide the unique ability to directly deposit patterned material structures on surfaces with extremely high resolution, precise registration, and without the need for the multiple subsequent lithographic processing steps that are common to most lithographic processes. A wide variety of molecules and materials have been deposited using such techniques ranging from insulators to conductors and from inorganic materials to biological molecules. Therefore, DPN techniques are finding use in a wide variety of research fields ranging from microelectronics to genomics.

Future Directions for Research

As mentioned earlier, while DPN techniques present novel opportunities for the direct patterned deposition of materials at feature sizes that would either be difficult or significantly more expensive using other standard micro- and nanofabrication techniques, DPN is still limited to small scale research applications at this point. This limitation is due in large part to the fact that useful feature writing using passive cantilever probes is either

- not possible at speeds which are practical for many potential larger scale applications, or
- passive probe arrays do not offer the possibility to write the arbitrarily complex and heterogeneous layers of material that would be needed in such applications.

Therefore, as mentioned earlier, one active direction for future research is still in the development of methods for actively and independently controlling writing from large arrays of cantilever probes. In addition, as the name dip-pen nanolithography implies, standard probe tips must be re-inked at some point to continue to write features at a controlled rate and size. The development of more sophisticated approaches and tools for continuous delivery of ink to the cantilever probe tip to allow for uninter-

rupted continuous writing is still an active area of research. Finally, since DPN is a basic research tool and method, significant research will continue in terms of finding new applications for the technique.

Dirac Delta Function

Synonyms

Delta function; Unit impulse function

Definition

The Dirac delta function $\delta(x)$ is a function that has the value of unity at $x = 0$ while vanishes elsewhere. The integral of the Dirac delta from any negative limit to any positive limit is 1. The discrete analog of the Dirac delta function is the Kronecker delta.

Numerical discretization

Definition

Discretization refers the process of transforming continuous differential equations into discrete difference equations, suitable for numerical computing. The difference equations are usually algebraic equations expressed in terms of the problem unknowns.

The discretization also refers to the process of decomposing a computational domain into smaller sub-domains, frequently called cell or element, within which simple approximate functions can be used to define physical unknown variables. The discretized domain is frequently called a computational grid or mesh.

Disjoining Pressure

VICTOR M. STAROV
Department of Chemical Engineering, Loughborough University, Loughborough, Leicestershire, UK
V.M.Starov@lboro.ac.uk

Synonyms

Surface forces; Colloidal forces; DLVO theory

Definition

Pressure in thin liquid films (thickness usually less than 10^{-7} m) is different from the pressure in the bulk liquid. This difference is caused by the action of additional forces, which are referred to as surface or colloidal forces. This force over the area of the film is the disjoining pressure. The additional pressure can be either disjoining or conjoining. However, the term disjoining is used in the literature because of historical reasons.

Chemical and Physical Principles

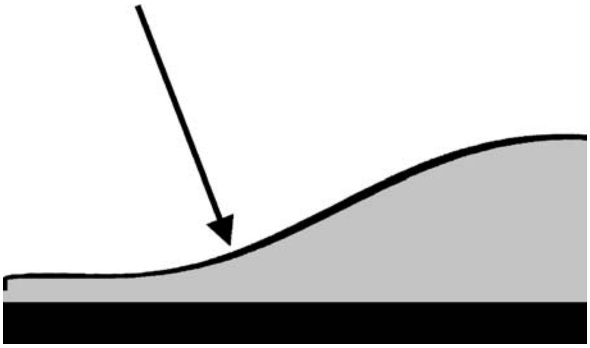
For partial or complete wetting at non-equilibrium adsorption of vapor and flow from a droplet or a meniscus on the solid substrate occurs. As a result at equilibrium the solid surface is covered with a thin liquid layer of equilibrium thickness h_e. The presence of this layer changes the interfacial tension of the bare solid surface, γ_{sv}, to γ_{svh_e}, which is the surface tension of the solid substrate covered with a thin liquid layer of the equilibrium thickness h_e. Formation of this thin layer is caused by surface forces.

A sharp transition from the liquid droplet/meniscus to the liquid film is impossible (arrow in Fig. 1), otherwise the capillary pressure will be infinite. Hence, there is a smooth transition from the flat equilibrium liquid film on the solid surfaces to the spherical droplet, as shown in Fig. 1.

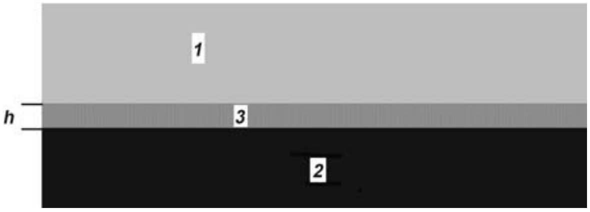
The presence of the transition zone shows that pure capillary forces cannot keep the liquid in this zone at equilibrium: to the right of the arrow in Fig. 1 the liquid profile is concave (hence, the capillary pressure under the liquid surface is higher than in the ambient air); to the left of the arrow in Fig. 1 the liquid profile is convex (hence, the capillary pressure under the liquid surface is lower than in the ambient air).

The surface phenomena are determined by the forces acting in thin liquid films or layers in the vicinity of the apparent three-phase contact line [1].

Surface forces are well known and are important in colloid science. They determine the stability and behaviour of colloidal suspensions and emulsions [2]. In the case of emulsions/suspensions their properties and behaviour (stability, instability, rheology, interactions, and so on) are governed by surface forces acting between colloidal particles or droplets [2]. The corresponding theory is widely referred to as DLVO theory [1] according to the names of four scientists who substantially contributed to the area: Derjaguin, Landau, Vervey and Overbeek.



Disjoining Pressure, Figure 1 Transition zone from a flat equilibrium liquid film on a solid surface to a liquid droplet. The arrow shows the point where to the right the liquid profile is concave and to the left the profile is convex

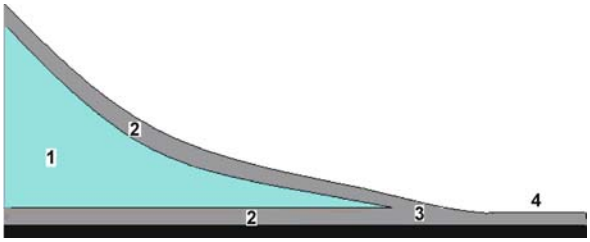


Disjoining Pressure, Figure 2 Interaction between two thick plates 1 and 2, possibly made of different materials, with a thin layer, 3, in between

The range of action of surface forces is usually of the order of 0.1 μm [1]. Note that in the vicinity of the three-phase contact line (Fig. 1), the liquid profile tends to zero thickness. The latter means that close to the three-phase contact line surface forces come into play and their influence cannot be ignored.

A manifestation of surface forces (either between particles, bubbles, emulsion droplets or in the vicinity of the three-phase contact line (Fig. 1)) is the disjoining pressure.

Let us consider the interaction of two thick plain parallel surfaces divided by a thin layer of liquid of thickness h (aqueous electrolyte solution, for example) in Fig. 2. The surfaces are not necessarily the same, as shown by two examples: (i) 1 is air, 3 is a liquid film, 2 is solid support; (ii) 1 and 2 are air or a liquid, 3 is a liquid film (of a different liquid). Example (i) is as a liquid film on a solid support and models a liquid layer in the vicinity of the



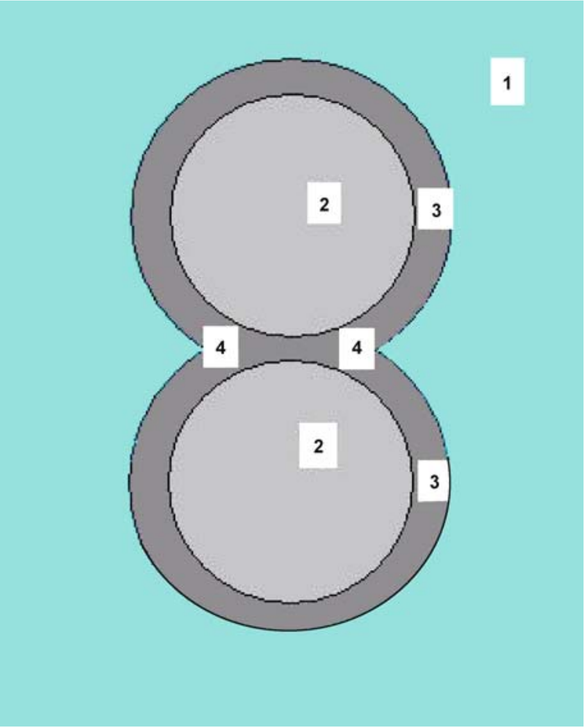
Disjoining Pressure, Figure 3 The liquid profile in the vicinity of the apparent three-phase contact line. 1, Bulk liquid, where boundary layers do not overlap; 2, boundary layer in the vicinity of liquid–air and liquid–solid interfaces; 3, a region where boundary layers overlap; 4, flat thin equilibrium film. The latter two are the regions where disjoining pressure acts

three-phase contact line; (ii) is a free liquid film and models the film between emulsion droplets/bubbles. There is a range of experimental methods to measure the interaction forces between these two surfaces as a function of the thickness h [1, 3, 4].

If h is bigger than 0.1 μm (Fig. 2), then the interaction force is equal to zero. However, if $h < 0.1$ μm, then an interaction force appears. This force can depend on the thickness h in a particular way. The interaction forces divided by the surface area of the plate has a dimension of pressure and is referred to as the disjoining pressure [1]. Note that the term *disjoining pressure* is misleading, because the force can be either disjoining (repulsion between surfaces) or conjoining (attraction between surfaces). However, disjoining is used because of historical reasons.

Let us consider a liquid–air interface as an example (Fig. 3). It is obvious that the physical properties of the very first layer on the interface are substantially different from the properties of the liquid in the bulk far from the interface. It is understandable that the physical properties do not change in an abrupt manner from the very first layer on the interface to the subsequent layers but the change proceeds in a continuous way. The latter results in the formation of a special layer, which we refer to as a boundary layer, where all properties differ from corresponding bulk properties.

Such boundary layers exist in proximity to any interface: solid–liquid, liquid–liquid, liquid–air. In the vicinity of the apparent three-phase contact line (Fig. 3) those boundary layers overlap. The overlapping of boundary layers is the physical phenomenon which results in the existence of surface forces. Let the thickness of the boundary layers be δ. In the vicinity of the three-phase contact line the thickness of a droplet/meniscus, h, is small enough, that is, $h \sim \delta$, and, hence, boundary layers overlap (Fig. 3), which results in the creation of disjoining pressure. A similar situation occurs at a contact of two particles in a liquid (Fig. 4). The above mentioned characteristic scale of boundary layer thickness, $\delta \sim 10^{-5}$ cm, determines the characteristic thickness where the disjoining pressure acts.



Disjoining Pressure, Figure 4 Colloidal interaction between two solid particles 2 in a liquid 1. 3, Boundary layers far from the contact; 4, overlapped boundary layers in the zone of contact, where the disjoining pressure acts

Components of the Disjoining Pressure

Molecular or Dispersion Component (van der Waals component)

Calculation of the molecular contribution to the disjoining pressure Π_m has been approached in two ways: from the approximation of interactions as pairwise additive, and from a field theory of many-body interactions in condensed matter. The simpler and historically earlier approach is a theory based on summing up of individual London–van der Waals interactions between molecules pair-by-pair undertaken by Hamaker [1].

The modern theory of Π_m was developed [1] based on a fluctuating electromagnetic field. The molecular component of the disjoining pressure, Π_m, for a film of uniform thickness h between two semi-infinite phases (1 and 2) in

vacuum (for simplicity) is [1] given by

$$\Pi_{\mathrm{m}} = \frac{kT}{\pi c^3} \sum_{N=0}^{\infty} \int_1^{\infty} p^2 \xi_N^3 \left\{ \left[\frac{(s_1+p)(s_2+p)}{(s_1-p)(s_2-p)} \exp\left(\frac{2p\xi_N h}{c}\right) - 1 \right]^{-1} + \left[\frac{(s_1+p\varepsilon_1)(s_2+p\varepsilon_2)}{(s_3-p\varepsilon_3)(s_2-p\varepsilon_2)} \exp\left(\frac{2p\xi_N h}{c}\right) - 1 \right]^{-1} \right\} \mathrm{d}p\,, \tag{1}$$

where c is the speed of light, $s_1 \equiv (\varepsilon_1 - 1 + p^2)^{1/2}$, $s_2 \equiv (\varepsilon_2 - 1 + p^2)^{1/2}$, subscripts 1 and 2 mark corresponding semi infinite phases, p is a dummy variable, $\xi_N = 2\pi kTN/\hbar$, $\hbar$ is the Plank constant, and the dielectric constants ε_1, ε_2 are functions of imaginary frequency $\omega \equiv \mathrm{i}\xi$ given by

$$\varepsilon(\mathrm{i}\xi) = 1 + \frac{2}{\pi} \int_0^{\infty} \frac{\omega \varepsilon''(\omega)}{\omega^2 + \xi^2} \mathrm{d}\omega\,, \tag{2}$$

where $\varepsilon''(\omega)$ is the imaginary component of the dielectric constant. In the limiting case of film thickness h small in comparison with the characteristic wavelength λ of the adsorption spectra of the bodies, the molecular component of disjoining pressure is inversely proportional to the cube of film thickness [1]:

$$\Pi_{\mathrm{m}} = \frac{\hbar}{8\pi^2 h^3} \int_0^{\infty} \frac{[\varepsilon_1(\mathrm{i}\xi) - 1][\varepsilon_2(\mathrm{i}\xi) - 1]}{[\varepsilon_1(\mathrm{i}\xi) + 1][\varepsilon_2(\mathrm{i}\xi) + 1]} \mathrm{d}\xi = \frac{A_{\mathrm{H}}}{h^3}\,, \tag{3}$$

where A_{H} is the Hamaker constant. Note that for historical reasons, instead of A in Eq. (3) $\Pi_{\mathrm{m}} = A/6\pi h^3$ is frequently used and the value A is also referred to as the Hamaker constant, i. e. $A_{\mathrm{H}} = A/6\pi$. In the limiting case of h large in comparison to λ, the disjoining pressure turns out to be inversely proportional to the fourth power of film thickness [1]:

$$\Pi_{\mathrm{m}} = \frac{\hbar c}{32\pi^2 h^4} \int_0^{\infty} \int_1^{\infty} \frac{x^3}{p^2} \left\{ \left[\frac{(s_{10}+p)(s_{20}+p)}{(s_{10}-p)(s_{20}-p)} e^x - 1 \right]^{-1} + \left[\frac{(s_{10}+p\varepsilon_{10})(s_{20}+p\varepsilon_{20})}{(s_{10}-p\varepsilon_{10})(s_{20}-p\varepsilon_{20})} e^x - 1 \right]^{-1} \right\} \mathrm{d}p\,\mathrm{d}x = \frac{B}{h^4} \tag{4}$$

where $s_{10} \equiv (\varepsilon_{10} - 1 + p^2)^{1/2}$, $s_{20} \equiv (\varepsilon_{20} - 1 + p^2)^{1/2}$ and ε_{10}, ε_{20} are the electrostatic values of the dielectric constants, i. e. the values of the dielectric constant at $\xi = 0$, $x = 2p\xi h/c$.

There are corresponding expressions for the molecular component of the disjoining pressure of films of non-polar liquids. Those expressions are presented in [1]. The functional dependency

$$\Pi_{\mathrm{m}}(h) = \begin{cases} \dfrac{A_{\mathrm{H}}}{h^3}\,, & h < \lambda \\ \dfrac{B}{h^4}\,, & h > \lambda \end{cases} \tag{5}$$

is approximately valid and frequently used.

A technique for calculating these properties to an adequate approximation from dielectric data has been suggested [1]. Precise measurements of Π_{m} in thin films of non-polar liquids are in good agreement with the theoretical predictions [1]. However, the latter theory does not apply to films so thin as to have dielectric properties that vary with thickness.

The Hamaker constant can be either positive (repulsion) or negative (attraction). Note that the precise value of the Hamaker constant according to direct summation can be wrong. This is a reason why a number of approximations have been developed to calculate the Hamaker constant using the exact theory [1].

The characteristic value of the Hamaker constant is $A_{\mathrm{H}} \sim 10^{-21}$ J (oil films on glass, quartz or mica surfaces).

Electrostatic Component of the Disjoining Pressure

Let us consider two charged surfaces (not necessarily of the same nature) in an aqueous electrolyte solution (Figs. 5a and b). The surfaces are assumed to be similarly or oppositely charged, i. e. there are electrical double layers near each of them. The sign of the charge of the diffusive part of each of electrical double layer is opposite to the sign of the charge of the corresponding surface. If the width of clearance between surfaces is $h \gg R_{\mathrm{d}}$, the electrical double layers of the surfaces do not overlap (Fig. 5a) and there is no electrostatic interaction of the surfaces. However, if the thickness of the clearance h is comparable with the thickness of the electrical double layer R_{d}, then electrical double layers overlap resulting in an interaction between the surfaces. If the surfaces are equally charged their diffusive layers are equally charged as well, i. e. the repulsion appears as a results of their overlapping (the electrostatic component of the disjoining pressure is positive in this case).

If surfaces are oppositely charged, then as a result of the overlapping of opposite charges an attraction appears, and the electrostatic component of the disjoining pressure is negative in this case.

There are a number of approximate expressions for the electrostatic component of the disjoining pressure [1]. For example, in the case of low potentials ζ of both surfaces the following relation is valid [1]:

$$\Pi_e(h) = \frac{\varepsilon\kappa^2}{8\pi}\,\frac{2\zeta_1\zeta_2\cosh\kappa h - \left(\zeta_1^2+\zeta_2^2\right)}{\sinh^2\kappa h}\,, \tag{6}$$

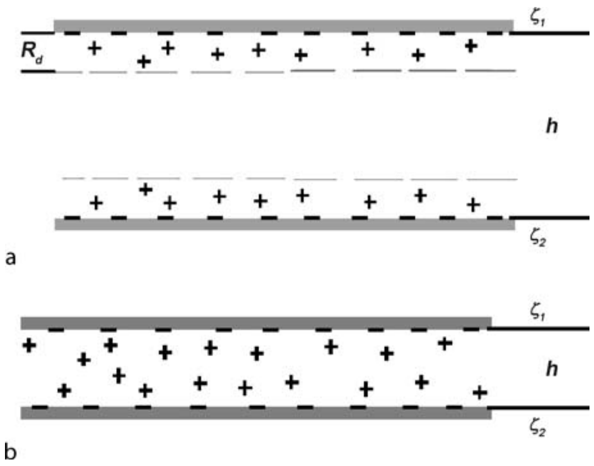
where ε is the dielectric constant of water and $1/\kappa = R_d$. The potential ζ is considered as low if the corresponding dimensionless potential $F\zeta/RT < 1$.

Note that in the case of oppositely charged surfaces and at relatively small distances the following expression for the electrostatic component of the disjoining pressure is valid [1]:

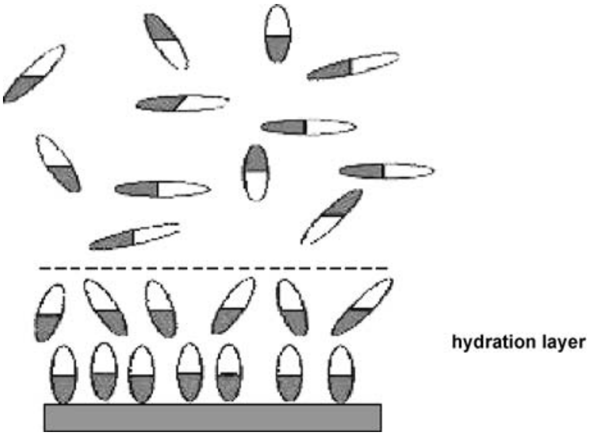
$$\Pi_e(h) = -\frac{\varepsilon}{8\pi}\,\frac{(\varsigma_1-\varsigma_2)^2}{h^2}\,, \tag{7}$$

which is always attraction. It is necessary to be very careful with this expression because in this case the attraction changes to repulsion at distances smaller than some critical distance [1].

Equations (6) and (7) show that the disjoining pressure does not vanish even in the case when only one of the two surfaces is charged (for example, $\zeta_1 = 0$). The physical reason for this phenomenon is the deformation of the electrical double layer if the distance between the surfaces is smaller than the Debye radius.



Disjoining Pressure, Figure 5 ζ_1 and ζ_2 are electrical potentials of charged surfaces. ζ_1 and ζ_2 are both negative. (**a**) The distance between two negatively charged surfaces, h, is bigger than the thickness of the Debye layers, R_d. Electrical double layers do not overlap and there is no electrostatic interaction between these surfaces. (**b**) The distance between two negatively charged surfaces, h, is smaller or comparable with the thickness of the electrical double layer, R_d. Electrical double layers of both surfaces overlap, which results in an interaction, which is repulsion in the case under consideration



Disjoining Pressure, Figure 6 Formation of a hydration layer of water dipoles in the vicinity of a negatively charged interface. Darker parts of water dipoles are positively charged, lighter parts are negatively charged

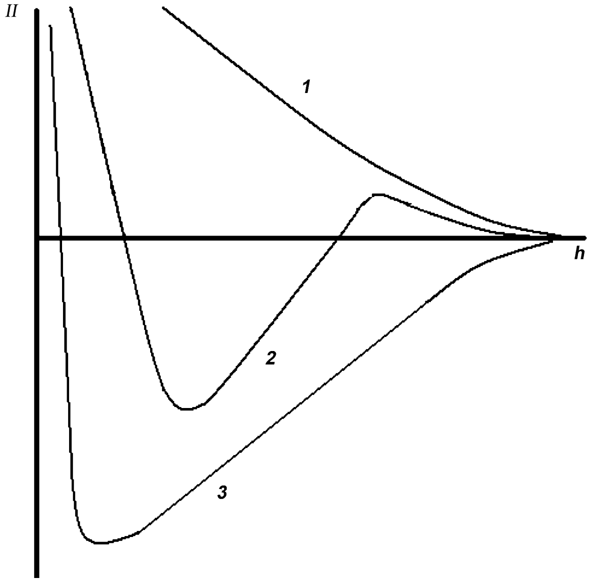
The theory based on the calculation of the disjoining pressure involving the two components discussed above, i. e. dispersion $\Pi_m(h)$ and electrostatic $\Pi_e(h)$ components, is referred to as the DLVO theory. According to the DLVO theory the total disjoining pressure is the sum of the two components, i. e. $\Pi(h) = \Pi_m(h) + \Pi_e(h)$. The DLVO theory made possible an explanation of a range of experimental data on the stability of colloidal suspensions/emulsions [1, 2], as well as the static and the kinetics of wetting [5]. However, it has since been understood that these two components only are insufficient for explaining the phenomena in thin liquid films and layers as well as in colloidal dispersions.

Structural Component of the Disjoining Pressure

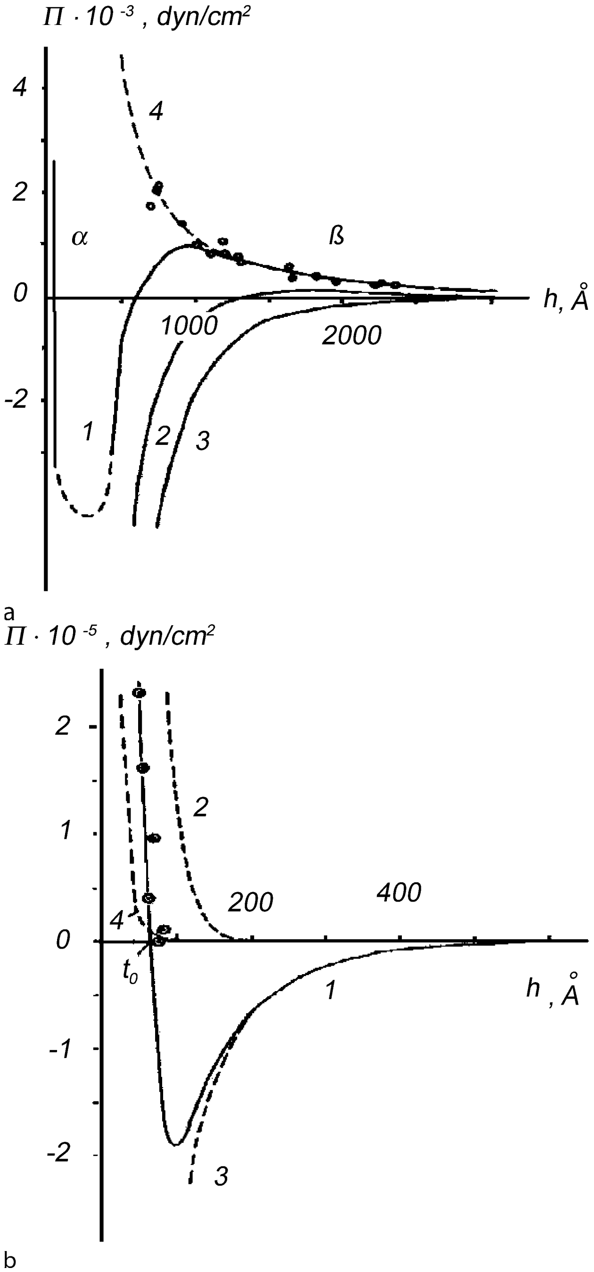
This component of the disjoining pressure is caused by orientation of water molecules in the vicinity of an aqueous solution–solid interface or aqueous solution–air interface. Water molecules can be modelled as an electric dipole.

In the vicinity of a negatively charged interface the positive part of water dipoles is attracted to the surface. That is, the negative part of dipoles are directed oppositely and the next water dipoles are facing a negatively charged part of dipoles, which in its turn results in the orientation of the next layer of dipoles, and so on.

The thermal fluctuations try to destroy this orientation (Fig. 6). As a result of these two opposite trends a finite layer forms where the structure of water dipoles differs



Disjoining Pressure, Figure 7 Types of isotherms of disjoining pressure: 1, complete wetting, observed for oil films on quartz, glass, metal surfaces [1]; 2, partial wetting, observed for aqueous films on quartz, glass, metal surfaces [1]; 3, non-wetting case



Disjoining Pressure, Figure 8 Calculated and experimentally measured isotherms of disjoining pressure, $\Pi(h)$, of films of water on a quartz surface at KCl concentration of $C = 10^{-5}$ mol/l, $pH = 7$, and dimensionless potential ζ of the quartz surface equal to -6 [1]. (**a**) Within the region of large thicknesses: dimensionless potential ζ of the film–air interface equals -2.2 (curve 1), -1 (curve 2) and 0 (curve 3); (**b**) within the region of small thicknesses: dimensionless potential ζ of the film–air interface equals -2.2 (curve 1). The structural component, $\Pi_S(h)$, of the disjoining pressure isotherm and electrostatic component, $\Pi_e(h)$, are shown by curves 2 and 3, respectively. Curves 4 in (**a**) and (**b**) are calculated according to Eq. (9)

from the random bulk structure. This layer is frequently referred to as a *hydration layer*. If now we have two interfaces with hydration layers close to each of them (or even one of them), then at a close separation, comparable with the thickness of the hydration layer, these surfaces "feel each other", that is, hydration layers overlap. This results either in attraction or repulsion of these two surfaces.

There is no firm theoretical background of the structural component of disjoining pressure and there is no reliable way to deduce theoretically in which case the structure formation results in an attraction and in which case in a repulsion. As a consequence only a semi-empirical equation exists, which gives the dependence of the structural component of disjoining pressure on the thickness of the liquid film [1]:

$$\Pi_S(h) = K e^{-\Lambda h} , \tag{8}$$

where K and Λ are constants. There is a clear physical meaning of the parameter $1/\Lambda$, which is the correlation length of water molecules in aqueous solutions. The latter gives $1/\Lambda \sim 10 - 15$ Å, which is the characteristic thickness of the hydration layer.

However, the pre-exponential factor K can be extracted on the current state of knowledge only from experimental measurements of the disjoining pressure.

Currently it is assumed [1] that the disjoining pressure of thin aqueous films is equal to the sum of the three components:

$$\Pi(h) = \Pi_m(h) + \Pi_e(h) + \Pi_s(h) \, . \quad (9)$$

In Fig. 7 a qualitative dependence of the disjoining pressure on the thickness of a flat liquid film is presented for the cases of complete wetting (curve 1, which corresponds to a dispersion or molecular component of disjoining pressure, $\Pi_m(h)$) and partial wetting (curve 2), which corresponds to a sum of all three components of the disjoining pressure, according to Eq. (9). The disjoining pressure shown by curve 1 in Fig. 7 corresponds to the case of complete wetting, for example, oil droplets on glass substrates, while curve 2 corresponds to the case of partial wetting, for example, aqueous electrolyte solutions on glass substrates. In [1–4] a number of experimental data on measurement of disjoining pressure are presented. The dependency of Eq. (5) has been firmly confirmed in the case of oil thin films on glass, quartz or metal surfaces, which corresponds to the case of complete wetting. In Fig. 8 experimental data and calculations according to Eq. (9) for aqueous thin films are presented.

All necessary details concerning experimental data presented in Fig. 8 are given in [1].

Examples of Application

The stability of colloidal suspensions, emulsions and foams as well as their transport properties are determined by the type of disjoining pressure, which acts between particles, droplets and bubbles. Equilibrium and kinetics of wetting is completely determined also by the shape of the disjoining pressure isotherm [5]. One of the most important applications is an expression of the equilibrium contact angles of either droplets on solid substrates or menisci in thin capillaries via the disjoining pressure isotherm [5]:

$$\cos\theta = 1 + \frac{1}{\gamma} \int_{h_e}^{\infty} \Pi(h) \, dh \, , \quad (10)$$

where the equilibrium thickness h_e is determined as a solution of the following equation [5]:

$$\Pi(h_e) = P \, . \quad (11)$$

Note that the excess pressure P is positive in the case of menisci and negative in the case of droplets and is determined by the vapor pressure in the ambient air. Note, according to Eq. (11) equilibrium film thicknesses differ for drops and menisci of identical liquids in contact with identical solids and so do the equilibrium contact angles according to Eq. (10).

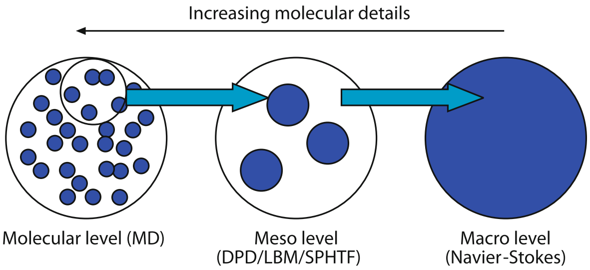
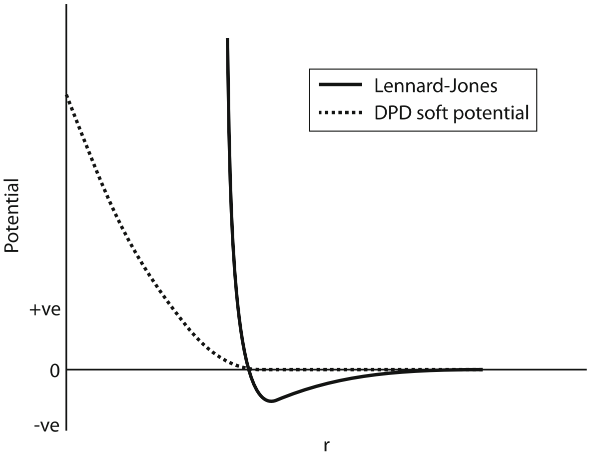
Definition

Dissipative particle dynamics refers to a particle-based numerical method in which the dynamics of particles that interact through conservative, dissipative, and random forces are computed. The method is coarse-grained molecular dynamics, and has the ability to capture flow at mesoscopic scales, i. e. those scales that lie between microscopic and macroscopic ones.



Dissipative Particle Dynamics, Figure 1 A schematic showing coarse-graining from molecular to macro level



Dissipative Particle Dynamics, Figure 2 A schematic illustrating the hard-core nature of Lennard–Jones potential and the soft-core nature of DPD inter-particle potential

Overview

Dissipative particle dynamics (DPD) is a mesoscopic numerical method in which Newton's laws of motion are solved for interacting particles. The method may be conceptually visualized as coarse-grained molecular dynamics (MD), i. e. each DPD particle is a collection of many real molecules or atoms. This may be conceptually visualized as illustrated in Fig. 1. Coarse graining changes the force potential between atoms/molecules from one with a hard-core nature, like a Lennard–Jones (L–J) potential, to a soft-core one as illustrated in Fig. 2. This coarse-graining makes it possible to employ longer time steps in the numerical integration, but it also results in loss of some information accessible at the molecular level. Hence, models have to be introduced to compensate for the missing physics. This is achieved through addition of force terms to the conservative force $\boldsymbol{F}^{\mathrm{C}}$. A dissipative force $\boldsymbol{F}^{\mathrm{D}}$ is introduced to account for viscous effects. The randomness which exists at the molecular level, and manifests as Brownian motion, is modeled through a random force $\boldsymbol{F}^{\mathrm{R}}$. The $\boldsymbol{F}^{\mathrm{D}}$ and $\boldsymbol{F}^{\mathrm{R}}$ can be selected to maintain an isothermal system.

DPD belongs to the general class of mesoscopic numerical methods which includes lattice-gas automata (LGA), lattice-Boltzmann methods (LBM), smooth particle hydrodynamics with thermal fluctuations (SPHTF), Brownian dynamics, direct-simulation Monte Carlo (DSMC) methods, and stochastic rotation dynamics (SRD). In LGA, particles are constrained to move along the links of a lattice with prescribed velocities and respect specified collision rules. The collective properties of density and momentum at a given time and location are obtained by integrating the information carried by the particles over all particles at that time and location. In LBM, instead of solving the motion of particles, an equation for the transport of the single-particle distribution function of velocity is solved. This reduces the oscillations resulting from the Boolean nature of the LG calculations. In general, LG and LB methods have difficulties preserving Galilean invariance and isotropy. The lattice structure has to be appropriately selected to minimize this effect. DPD, on the other hand, preserves these properties. The DSMC method, a particle-based method for solving the Boltzmann equation, has been widely employed for the simulation of rarefied gas dynamics problems. The SRD method has features common to the DSMC method, but the treatment of the collision of particles differ. In many ways, DPD has the characteristics of the smooth-particle-hydrodynamics particle (SPH) method employed for fluid-flow simulations, and may be viewed as SPH with thermal fluctuations (SPHTF). Since the seminal work of Hoogerbrugge and Koelman [1, 2], there have been several contributions to clarify and strengthen the theoretical underpinnings of DPD. Espanol and Warren [3] showed that the DPD method is associated with a Fokker–Planck equation, and when the fluctuation-dissipation theorem is applied to derive an expression relating terms in the dissipative and random force components, the temperature of the system is related to the noise amplitude in the limit of vanishingly small numerical time steps in the updating algorithm. The system relaxes to the Gibbs–Boltzmann distribution under these conditions. The Langevin equation for Brownian motion is applicable to the system. Groot and Warren [4] further studied the model developed by Espanol and Warren and developed useful range of values for the parameters of the model from physical considerations. It has been shown that the equilibrium temperature of the system has a strong dependence on the integration time step, an important consideration if the method is employed to investigate equilibrium thermodynamic properties. An H-theorem for the free energy of the DPD system has

been proven, and the Fokker–Planck–Boltzmann equation for the single-particle distribution function derived and solved using Chapman–Enskog expansion to derive the hydrodynamic equations [5]. Extensions of the isothermal DPD model to include energy conservation have been presented [6, 7].

Basic Methodology

The governing equations of DPD are Newton's laws of motion given for particle i by

$$\frac{\mathrm{d}\boldsymbol{r}_i}{\mathrm{d}t} = \boldsymbol{v}_i\,, \tag{1}$$

$$\frac{\mathrm{d}\boldsymbol{v}_i}{\mathrm{d}t} = \boldsymbol{f}_i\,, \tag{2}$$

where $\boldsymbol{r}_i$, $\boldsymbol{v}_i$, and $\boldsymbol{f}_i$ are position, velocity, and force vectors, respectively. The force vector $\boldsymbol{f}_i$ is the sum of the internal, $\boldsymbol{f}_i^{\text{int}}$, and external, $\boldsymbol{f}_i^{\text{ext}}$, force components, i. e.

$$\boldsymbol{f}_i = \boldsymbol{f}_i^{\text{int}} + \boldsymbol{f}_i^{\text{ext}}\,, \tag{3}$$

where $\boldsymbol{f}_i^{\text{ext}}$ represents contributions from external sources, such as gravitational and electromagnetic forces, and

$$\boldsymbol{f}_i^{\text{int}} = \sum_{j \neq i} \left(\boldsymbol{F}_{ij}^{\text{C}} + \boldsymbol{F}_{ij}^{\text{D}} + \boldsymbol{F}_{ij}^{\text{R}} \right) \tag{4}$$

where $\boldsymbol{F}_{ij}^{\text{C}}$, $\boldsymbol{F}_{ij}^{\text{D}}$, $\boldsymbol{F}_{ij}^{\text{R}}$ are the conservative, dissipative, and random force components, respectively. While in principle all other particles interact with particle i, only interactions with those that are close to it, i. e. within a sphere of influence with a radius r_c, the cut-off radius, are important. This cut-off radius fixes the length scale of the system. The general form of $\boldsymbol{F}^{\text{C}}$ is given by

$$\boldsymbol{F}^{\text{C}} = -\frac{\partial \psi\left(\boldsymbol{r}_{ij}\right)}{\partial \boldsymbol{r}_{ij}} \boldsymbol{e}_{ij} \tag{5}$$

where ψ is the inter-particle interaction potential, and $\boldsymbol{e}_{ij} = \boldsymbol{r}_{ij}/\left|\boldsymbol{r}_{ij}\right|$. The form of conservative force which has been chosen by many researchers for single-phase and binary-fluid simulations is a linear function of the interparticle separation. This form of $\boldsymbol{F}_{ij}^{\text{C}}$ is given by

$$\boldsymbol{F}_{ij}^{\text{C}} = a_{ij} w^{\text{C}}\left(\boldsymbol{r}_{ij}\right) \boldsymbol{e}_{ij}\,, \tag{6}$$

where a_{ij} is a repulsion parameter between particles i and j. It is the maximum value of the conservative force and is related to the compressibility of the fluid [4]. The variable w^{C} is a weight function that has a form which reproduces the thermodynamic state of the system. It is usually taken to have the form

$$w^{\text{C}}(r) = \begin{cases} \left(1 - \dfrac{\boldsymbol{r}_{ij}}{r_c}\right) & \boldsymbol{r}_{ij} < r_c \\ 0 & \boldsymbol{r}_{ij} \geq r_c \end{cases} \tag{7}$$

In Eqs. (5–6), $\boldsymbol{r}_{ij} = \boldsymbol{r}_i - \boldsymbol{r}_j$, $\boldsymbol{r}_{ij} = \left|\boldsymbol{r}_{ij}\right|$. The dissipative force is given by

$$\boldsymbol{F}_{ij}^{\text{D}} = -\gamma w^{\text{D}}\left(\boldsymbol{r}_{ij}\right)\left(\boldsymbol{e}_{ij} \cdot \boldsymbol{v}_{ij}\right) \boldsymbol{r}_{ij}\,, \tag{8}$$

with the negative sign indicating that the particles are decelerated, and the random force is given by

$$\boldsymbol{F}_{ij}^{\text{R}} = \sigma w^{\text{R}}\left(\boldsymbol{r}_{ij}\right) \theta_{ij} \boldsymbol{e}_{ij}\,, \tag{9}$$

where w^{D} and w^{R} are weight functions which are dependent on the distance between particles and vanish for $|\boldsymbol{r}_{ij}| > r_c$, γ and σ are constant coefficients, $v_{ij} = v_i - v_j$, and θ_{ij} is a randomly fluctuating variable with Gaussian statistics, i. e. $\langle \theta_{ij}(t) \rangle = 0$ and $\langle \theta_{ij}(t)\theta_{k\ell}(t') \rangle = (\delta_{ik}\delta_{j\ell} + \delta_{i\ell}\delta_{jk})\delta(t - t')$. The random variable is independently selected for each pair of particles. The dissipative force reduces the system temperature by reducing the particle velocities, whereas the random forces increases the temperature. The two forces can be selected so that an isothermal system is described. In this case, it can be shown by employing the fluctuation dissipation theorem that the relation

$$w^{\text{D}}(r) = \left[w^{\text{R}}(r)\right]^2\,, \tag{10}$$

between the weight functions, and

$$\sigma^2 = 2\gamma k_B T\,, \tag{11}$$

between the coefficients, holds. Groot and Warren, and others, have suggested

$$w^{\text{D}}(r) = \left[w^{\text{R}}(r)\right]^2 = \begin{cases} \left(1 - \dfrac{r_{ij}}{r_c}\right)^2 & \boldsymbol{r}_{ij} < r_c \\ 0 & \boldsymbol{r}_{ij} \geq r_c \end{cases} \tag{12}$$

for the weight functions. Since the dissipative and random forces act to balance the temperature, DPD can be viewed as thermostated molecular dynamics if the appropriate potential is selected for the fluid.

DPD has been extended to two-phase flows [8–11]. The essential ideas employed to do this will now be briefly described. The general form of the conservative force that

gives rise to phase segregation and surface tension may be written as

$$\boldsymbol{F}_{ij}^{\mathrm{C}} = -\nabla\psi_{\text{non-ideal}} + \boldsymbol{F}_s\,, \tag{13}$$

$$\boldsymbol{F}_s = \kappa\nabla\nabla^2\rho\,, \tag{14}$$

where $\psi_{\text{non-ideal}}$ is the non-ideal part of the interaction potential and $\boldsymbol{F}_s$ is responsible for the surface tension effects in the two-phase system. The variable κ is a parameter that is dependent on the long-range attractive forces leading to surface tension. The first term in Eq. (13) can be derived once an equation of state (EOS) is selected. The EOS selected must be one which has a Maxwell loop. The determination of the non-ideal part of the free energy is dependent on the density of particles. The density in the vicinity of a particle i is calculated as the weighted average of contributions from its neighbors within the cut-off radius, i. e.

$$\rho_i = \sum_{j=1}^{N} w(r_{ij})\,,$$

where N is the number of particles and w is a weight function. The weight function has to be appropriately selected to have the desired properties. For example, Tiwari and Abraham [11] selected the Lucy weight function commonly used in smooth particle hydrodynamics. This weight function is given by

$$w(r, r_c) = \begin{cases} \dfrac{5}{\pi r_c^2}\left(1+\dfrac{3r}{r_c}\right)\left(1-\dfrac{r}{r_c}\right)^3 & r < r_c \\ 0 & r \geq r_c \end{cases}\,. \tag{15}$$

As an example, if the van der Waals EOS

$$p = \frac{\rho k_B T}{1-b\rho} - a\rho^2\,, \tag{16}$$

is adopted, then the non-ideal part of the free energy can be shown to be

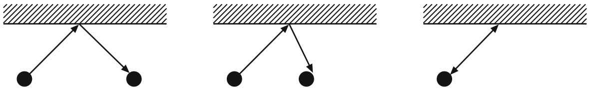
$$\psi_{\text{non-ideal}} = -k_B T\ln(1-b\rho) - a\rho\,, \tag{17}$$

by employing the relation

$$\psi = -\frac{\partial p}{\partial v}\,, \tag{18}$$

$$\boldsymbol{F}^{\mathrm{C}} = -\nabla\psi_{\text{non-ideal}}\,, \tag{19}$$

where v is the specific volume.



Dissipative Particle Dynamics, Figure 3 Three rules for reintroducing the DPD particle that penetrate the boundary

With substitutions, the overall expression, Eq. (13), for the inter-particle conservative force becomes [11]

$$\boldsymbol{F}_{ij}^{C} = \left[-\left\{\left(\frac{bk_BT}{1-b\rho_i}-a\right)+\left(\frac{bk_BT}{1-b\rho_j}-a\right)\right\} \times\frac{w'_{ij}}{[w]} + \kappa\frac{\partial^3 w(r_{ij})}{\partial r_{ij}^3}\right]\boldsymbol{e}_{ij}\,. \tag{20}$$

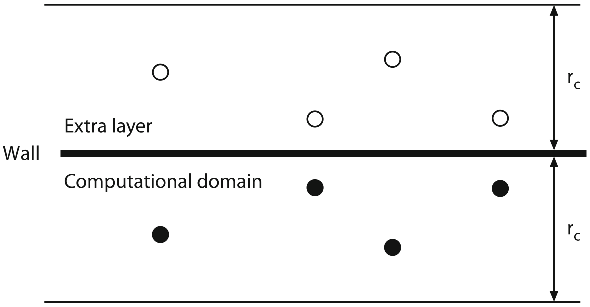
The approach to two-phase modeling described above is based on mean-field theory, and it breaks down in the vicinity of the critical point.

Boundary Conditions

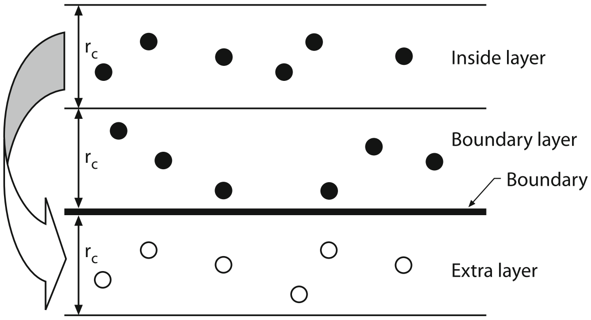
Periodic boundary conditions may be implemented in DPD just as in MD. There are different approaches taken to implement wall boundary conditions in the solution of the DPD equations. Some of these will now be discussed. Two common methods are adopted to implement no-slip boundary conditions. In the first one, a layer of frozen particles is placed at the boundary and interaction of fluid particles with this layer obeys certain rules. In the second one, an extra layer of particles reflected from the DPD particles in the fluid are used for achieving no-slip.

In the frozen-layer scheme, a continuum limit is applied to the group of frozen layer particles to analytically obtain the effective form of the dissipative and random forces of interactions between the wall particles and the DPD fluid particle. An explicit rule is employed to maintain the impermeability of solid walls. Three possible rules for achieving this are illustrated in Fig. 3. For free-slip, specular reflection instead of bounce-back reflection for particles that cross the free-slip boundaries are employed.

In the extra-layer approach, all particles that lie within the cut-off radius r_c from the boundary are mapped into an extra layer that extends beyond the simulation domain. Figure 4 illustrates the concept. The velocities of the particles in the extra layer are chosen such that the mean of the velocity of the mirrored particle and the velocity of the original DPD particle gives the velocity at the wall. This algorithm has been reported to work well when used for calculating the dissipative force and the random force between the particles. But, if the conservative force



Dissipative Particle Dynamics, Figure 4 The extra-layer scheme



Dissipative Particle Dynamics, Figure 5 Extra layer scheme for conservative component

is calculated using this method, oscillations are observed in the density near the wall. This problem arises because of the lack of spatial correlation between the particles in the boundary layer and the mirror layer. To overcome this problem, an additional layer for calculating the conservative component alone can be employed, as illustrated in Fig. 5.

The density fluctuations arising near the boundary from the implementation of the conservative force at the wall is a cause of concern when implementing the no-slip boundary condition. To address this, a no-slip scheme based on the equivalent force between the wall and fluid particles may be introduced. In this method, layers of frozen particles are chosen as in the frozen-layer scheme, but a key difference is that the coefficient for the conservative force is adjusted in a manner so as to incorporate wall and fluid particle interactions. This leads to a correct no-slip implementation without fluctuations in density. Another proposal to reduce density fluctuations near the walls represents the boundary with two layers of frozen particles. The particles that penetrate the boundary are made to bounce back into the computational domain. No-slip at the wall is produced by using a twin image of the system being simulated. The second image has the same configurations and dynamics as the first, but operates with a different set of random numbers. Smooth particle and velocity distributions across the wall boundary are generated in this approach. Bounce-back reflection is used for particles that cross the system boundary. An extension of the approach for curved geometries has also been presented.

Numerical Integration

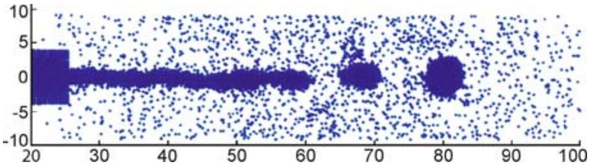
A suitable time-stepping algorithm may be employed to solve the governing equations. The pioneering work of Hoogerbrugge and Koelman [1] employed an Euler algorithm. However, this is first-order accurate in time and the cumulative effect of truncation errors can lead to a drift in the energy of the system. Since then, more robust schemes have been proposed. A popular integration scheme is the modified-Verlet scheme of Groot and Warren [4]. This scheme is given by

$$\begin{aligned}
\boldsymbol{r}_i(t+\delta t) &= \boldsymbol{r}_i(t) + \delta t \boldsymbol{v}_i(t) + \frac{1}{2}(\delta t)^2 \boldsymbol{f}_i(t)\,,\\
\tilde{\boldsymbol{v}}_i(t+\delta t) &= \boldsymbol{v}_i(t) + \lambda \delta t \boldsymbol{f}_i(t)\,,\\
\boldsymbol{f}_i(t+\delta t) &= \boldsymbol{f}_i(r(t+\delta t), \tilde{\boldsymbol{v}}(t+\delta t))\,,\\
\boldsymbol{v}_i(t+\delta t) &= \boldsymbol{v}_i(t) + \frac{1}{2}\delta t(\boldsymbol{f}_i(t) + \boldsymbol{f}_i(t+\delta t))\,,
\end{aligned} \tag{21}$$

where all symbols have the meaning as in the previous equations and λ is a variable parameter. A choice of $\lambda = 0.5$ would give the standard velocity-Verlet algorithm. In the above algorithm, the intermediate velocity $\tilde{\boldsymbol{v}}$ is chosen to give an estimate of velocities required in the calculation of forces. These velocities are finally corrected in the last step of the algorithm. Properties such as the system temperature are calculated after the last step. Vattulainen et al [12] have carried out a study in which they critically examined different integration schemes and concluded that the best schemes are those in which the velocity-dependence of the dissipative force is taken into account during the integration.

Parallelization Methods

A DPD simulation may involve as few as 1000 particles for simple equilibrium simulations to several million particles for simulations of complex fluids. Hence, it is important to run DPD codes in a parallel environment. There are several parallelization strategies, such as domain decomposition and force decomposition methods. One method that is appealing because of the particle-based nature of the method is the atom decomposition algorithm in which the computations for the N particles are split among P processors. Further advantage can be taken from the fact that DPD is a short-range method, i. e. each particle does



Dissipative Particle Dynamics, Figure 6 Simulations of nanojet breakup

not interact with all particles in the domain. This fact is exploited by creating neighbor lists for each particle. The neighbor lists are refreshed at specified intervals. Examples of neighbor lists include the Verlet neighbor list and the cell-based neighbor list.

Examples of Applications

Many applications of the DPD method exist in the literature. The following is not an exhaustive list. The DPD method is attractive for simulating systems where there is the motion of a chain of molecules, as in polymer solutions. The chain can be treated as a string of DPD particles interacting through force potentials. Obviously, not all the detail can be predicted with this approach. In many problems, however, information on picosecond time scales and Angstrom length scales may not be required to justify the use of full molecular simulations. Koelman and Hoogerbrugge [3] employed the method they developed to simulate hard-sphere suspensions subjected to a shear flow. DPD has been applied to study the flow of DNA molecules through microfluidic devices [13], simulate polymer solutions and colloidal suspensions [14], DNA chains in dilute suspensions [15], multiphase systems [8–11] including the simulation of pendant drops and drops in shear field [16], and liquid nanodrops, nanocylinders, and nanojets [17], biological membranes including cell damage [18], and domain growth and phase separation in binary immiscible fluids [19]. Figure 6 shows an illustration of a liquid nanojet breakup [17]. DPD has been shown to be capable of reproducing the influence of thermal fluctuations. The method has been employed in combination with MD to study colloidal systems, whereby the colloid itself is simulated using MD but the solvent using DPD [20]. DPD also has the flexibility to be combined with other models to capture multiple scales and this is an area of research that needs to be exploited.

Future Directions for Research

Since the DPD method is fairly new, there are areas for research in theoretical formulations especially as applied to multiscale problems and energy conserving schemes, formulation of adaptable boundary condition to minimize density fluctuations, numerical integration schemes which improve accuracy and efficiency, and a wide range of applications as illustrated by the examples above.

DNA Hybridization

Definition

Hybridization is the process where two complementary, single-stranded nucleic acids are combined into a single molecule. Nucleotides will bind to their complement, so two perfectly complementary strands will bind or hybridized to each other. The hybridization process may be reversed by heating the double stranded molecule of DNA to break the hydrogen bonds between the nucleotides and separate the two strands. This is called melting or denaturation.

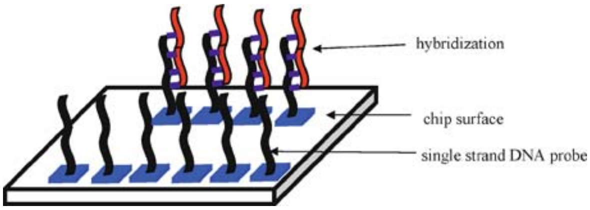
DNA chip; Gene chip

Definition

Microarrays are plastic, glass or silicon chips often used for gene expression and DNA sequencing and contain an array of single-stranded DNA segments known as probes attached to their surface to which a complementary DNA or RNA specifically binds.

Overview

Microarrays are devices made using processes such as photolithography, ink-jet printing, etc. and consist of many single-stranded DNA probes attached to the surface to which a complementary DNA or RNA of interest specifically binds as shown in Fig. 1 [1–4]. This binding or hybridization is then detected through various means such as through fluorescence tagging of the probes or mass spectroscopy. Microarrays allow DNA and RNA hybridization analysis in a parallel fashion on miniaturized platforms. The number of test sites in microarrays



DNA Microarrays, Figure 1 DNA microarray with capture probes. The microarray is made using photolithography or ink-jet printing process and consist of many single-stranded DNA probes attached to the surface to which a complementary DNA or RNA of interest specifically binds

varies from a few hundred to several hundreds of thousands. Depending on the type of attached probes, DNA microarray could determine genetic sequence (DNA) or gene expression level (mRNA). Since the first application of microarrays was in DNA sequencing, microarrays are often called DNA microarrays. However, with the extension of the microarray technology to proteomics, cell and tissue biology, a distinction is necessary between DNA, cell, protein and tissue microarrays. Here DNA microarrays are discussed.

DNA microarrays work by exploiting the ability of a given mRNA sequence to bind specifically to, or hybridize to, its cDNA template from which it originated. By using an array containing many cDNA samples, it is possible to determine the expression levels of the numerous genes within a cell by measuring the amount of mRNA bound to each site on the array. With the aid of software, the amount of mRNA bound to the spots on the microarray could be determined, generating a profile of gene expression in the cell.

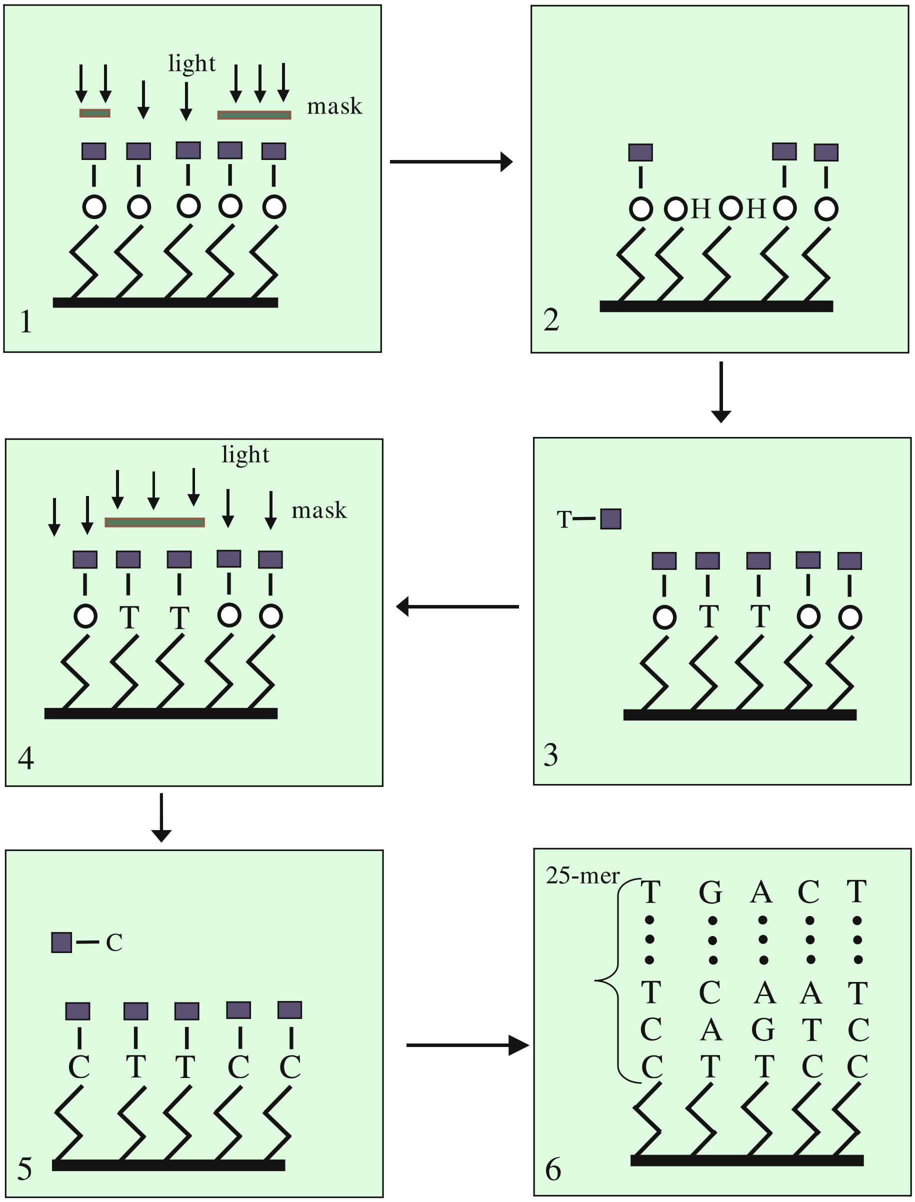
Basic Methodology

There are three major steps involved in DNA microarray analysis. The first is creating a single strand DNA with fluorescence tag from either genomic DNA or mRNA sequences. The fluorescently tagged sample is then hybridized against targeted probes that have been previously printed or micromachined on the DNA chip. An imaging system that usually consists of lasers or camera is then used to detect the level of fluorescence intensity emitted by the attached probes. The array reader is very similar to confocal microscopy technology.

DNA hybridization microarrays are generally fabricated on glass, silicon, or plastic substrates. Oligonucleotide DNA are the most common probes used in DNA microarrays. Amine or thiol linkers are added to these oligonucleotide probes to enable attachment to the glass, plastic or silicon surface of the chip. The attachment of these probes to the surface can be done mechanically through automated means. In a laboratory set-up, manual array spotters could be used.

Several methods exist for fabricating these microarrays. Photolithography techniques using masks have been used successfully such as in Affymetrix's (Santa Clara, CA) GeneChip® and Nanogen's (San Diego, CA) NanoChip®. Ink-jet printing technology where a precise amount of liquid is expelled onto the surface has also been used by companies like Agilent (Santa Clara, CA). Different printing techniques such as fine-pointed pins can also be used along with mechanical spotting where the sample is loaded to a pin by capillary action. As an overview, we will look at two prominent and technologically interesting technologies, namely that of GeneChip® by Affymetrix and NanoChip® by Nanogen.

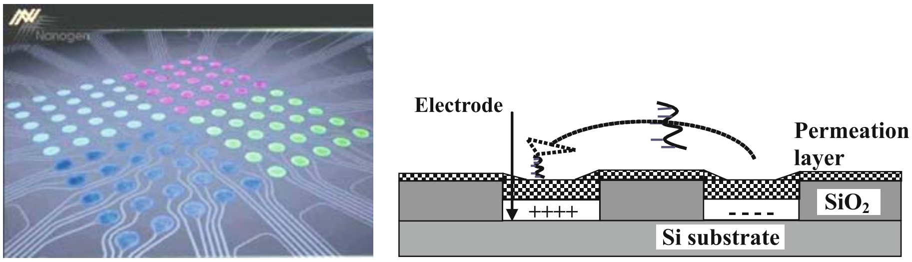
The Affymetrix process consists of a light-directed synthesis of oligonucleotides on a substrate [5]. As shown in Fig. 2, the first step is exposing a surface to a UV light through a mask that contains the desired pattern. The surface consists of hydroxyls. In the illuminated regions, free hydroxyl groups are generated which then couple to a deoxynucleoside phosphoramidite which has the 5′-hydroxyl protected by a photolabile group. This is followed by capping and oxidation. The substrate is then rinsed and the surface subsequently exposed to UV light through a second mask to expose additional hydroxyl groups for coupling. Then, a second 5′-protected 3′-O-phosphoramidite-activated deoxynucleoside is brought to the surface. This process of selective photodeprotection and coupling cycles is repeated until the probes reach their desired full length, usually 25 nucleotides. As a rule, in this parallel process, $4n$-mers chemical synthesis steps (and hence a maximum of $4n$ photo masks) are required to synthesize a complete set of all probe sequences of length n-mers. For example, 20 process cycles are needed to synthesize 5-mer probes. The Affymetrix parallel fabrication process for microarrays is particularly suitable for making high-density microarrays. Commercially available arrays are typically manufactured at a density of over 1.3 million unique features per array. Densities as high as 10^6 unique sequences/cm^2, which correspond to feature sizes of less than 100 μm, have been reported [6]. The reported average stepwise efficiency of oligonucleaotide synthesis – which is affected by the average yield of the photochemical deprotection step after photolysis – is in the range of 90%–95% [7]. In terms of hybridization enabling process, the Affymetrix microarray depends on diffusion of target DNA to the array sites [8]. However, diffusion dependent transport scales with the square root of time and often takes several hours to achieve efficient hybridization of DNA molecules to capture probes. Further, this passive hybridization is known to exhibit some cross-hybridization



DNA Microarrays, Figure 2 Light-directed parallel chemical synthesis of peptides and oligonucleotides on solid supports of Affymetrix's DNA microarray [5, 6]. A photo-protected glass substrate is selectively exposed to UV light through a mask that contains the desired pattern (1). The deprotected areas are activated in step (2) followed by nucleoside incubation where chemical coupling occurs at activated positions (3). In step (4), a new mask pattern is applied. The coupling step is repeated in step (5). The deprotection and coupling process is repeated until the desired set of probes is obtained as shown in step (6)

between mismatched probes and targets [9]. Efforts are continuing to minimize this nonspecific binding [10].

The Nanogen electronic microarray consists of an array of electrodes fabricated on silicon using standard photolithography and deposition processes [11–13]. As shown in Fig. 3, the base structure of the array consists of silicon substrate over which an insulation layer of silicon dioxide is grown. A 20 nm Cr adhesion layer and 500 nm platinum are deposited and patterned to form electrodes and the electrical traces. The traces form electrical contact pads at their ends. Additional 2 μm of silicon dioxide and low-stress silicon nitride are deposited to provide electrical insulation for the platinum electrodes and traces. Finally, a 1–10 μm thick coating of hydrogel (agarose or polyacrylamide) is spin-coated over the chip surface to provide a permeation layer which allows the



DNA Microarrays, Figure 3 Nanogen's DNA microarray with capture probes. 100-site electronically active NanoChip® is shown in **a** [14]. A cross-section of the chip is shown in **b**. An insulation layer of silicon dioxide is grown over a silicon substrate over which Cr adhesion layer and platinum are deposited and patterned to form electrodes. A coating of hydrogel is spin-coated over the chip surface to provide a permeation layer. Shown also is the electrophoretic transport of charged molecules (DNA, RNA, etc) on an active microelectronic array [12]

arrays to be run at current levels (> 100 nA) and voltages (> 1.2 V) by protecting the sensitive DNA hybridization reactions from adverse electrochemical effects at the electrodes. The permeation layer which contains linked streptavidin also acts as a matrix for the attachment of DNA capture probes and target DNA sequences. It further elevates the anchored probes above the electrodes [11, 12]. The chips are then flip-bonded to a ceramic substrate which is subsequently mounted in a plastic cartridge housing that contains a flow cell for liquid sample handling and an optical window for fluorescence measurements. The Nanogen technology uses electronically active DNA microarrays and involves electronically addressing biotinylated DNA samples, hybridizing complementary DNA reporter probes and applying stringency to remove unbound and nonspecifically-bound DNA after hybridization. An important feature of the recent generation of Nanogen's chip is the presence of on-board circuitry that permits the current or potential of each electrode to be individually controlled and measured. Electrophoresis, which has the advantage of speed which scales linearly with time and electric field, is used as a transport mechanism for the DNA samples. Consequently, typical transport times are two minutes or less [14]. The maximum number of array size reported so far in Nanogen's technology is 10,000 [1].

DNA Microarray Applications

The use of microarrays has expanded into several areas outside traditional genetic sequencing and gene profiling. The most important areas where microarrays are increasingly being used for are pharmacogenomics research, infectious and genetic disease and cancer diagnostics, and forensic and genetic identification applications [1]. Four important application areas are discussed here with some details.

Drug Discovery/Pharmacogenomics

Pharmacogenomics is the study of the genetic basis of the therapeutic responses of patients to drugs. Microarrays can be used in this area by predicting drug efficacy and toxicity through the monitoring of gene expressions in response to drug treatment. Microarrays enable querying expressions of thousands or tens of thousands of genes simultaneously. For example, gene expression changes in cells exposed to the anticancer chemotherapeutic agent doxorubicin has been studied using DNA microarrays [15].

Disease Diagnosis

Microarray technology finds application in disease diagnosis by providing information on the genetic basis to diseases. For such diseases as diabetes, heart diseases, cancer, and mental illnesses, research has shown that certain genetic sequences are associated with susceptibility to the expression of these diseases. Specifically, tiny variations in nucleotides (called SNPs for single nucleotide polymorphisms) which occur in about 0.1% of the sequence that comprises human DNA are responsible for the traits that distinguish one individual from another – including differences in disease susceptibility. Some of these SNPs are shared by large sections of the population, which make them highly attractive targets for disease research. Researchers have used microarrays to genotype hundreds of thousands of SNPs enabling whole-genome association studies of disease genetics [16, 17]. High-density microarrays for disease mapping studies have already enabled the identification of genes linked to sudden infant death syndrome, neonatal diabetes, bipolar disorder, age-related macular degeneration and other inherited diseases [18].

Gene Discovery

One of the interesting applications of microarrays is in the identification of new genes together with their func-

tions and expression levels under different conditions. For example, microarrays have been used to identify new genes that can contribute to vaccine initiatives or as targets for development of new drugs [19] and in protozoan parasites such as plasmodium falciparum, the causative agent of human malaria [20].

Toxicological Research

Microarrays can be used in toxicogenomics where a correlation between responses to toxicants and the changes in the genetic profiles of the cells exposed to such toxicants is studied. The measurements of gene expression levels upon exposure to a chemical can be used both to provide information about the mechanism of action of the toxicant and to form a sort of "genetic signature" for the identification of toxic products. A comprehensive review of the application of microarrays to compare the effects of chemicals such as arsenic and nickel in human bronchial cells as well as sodium arsenite on the expression of genes involved in transcription factors, inflammatory cytokines, kinases, and DNA repair, etc., is given in [21].

Major DNA Microarrays in the Market

An increasing number of companies have entered the DNA microarray market. Some of the most prominent players are: ACLARA Bio Sciences (Mountain View, CA) which specializes in microfluidics chips for biochemical processes, Affymetrix (Santa Clara, CA) which is the developer of the GeneChip™ microarray that is fabricated using lithographic techniques to directly synthesize targeted probes onto quartz wafer [5], Caliper Technologies (Mountain View, CA) the maker of LabChip, a microfluidics array used in high-speed DNA separation, Gamera Bioscience (Medford, MA) which is the maker of LabCD system, a centrifugal-based compact-disk (CD) platform, Genetix Ltd., a UK-based company specializing in microarrays with 16-pin microarraying head for spotting slides, Agilent (Santa Clara, CA) with its thermal jet probe-attachment system for cDNA microarrays, Illumina (San Diego, CA) a maker of self-assembled arrays of beads, Incyte Microarray Systems (Fremont, CA), a maker of gene expression microarrays, Nanogen (San Diego, CA) which develops electronically active microarray spots, Sequenom (San Diego, CA) which develops a high-throughput array used for genotyping, and Vysis Inc. (Downers Grove, IL) which markets GenoSensor used in genotyping.

The most commonly used application for microarray is gene expression analysis. Affymetrix is the leader in this market with its GeneChip®. As explained in detail before, Affymetrix utilizes lithographic techniques to directly synthesize targeted probes onto quartz wafer. Starting with a 5 inch quartz wafer, masks are used to initiate coupling of nucleotides. For 25 bases chip, a maximum of 100 masks are required. Agilent Technologies (Palo Alto, California USA), one of the other competitors, uses inkjet printing technology for probe attachment. Whole oligos or cDNA are first synthesized and printed onto a glass substrate. To increase hybridization efficiency, Nanogen (San Diego, California USA) developed an active hybridization method for sample analysis rather than using traditional passive hybridization as Agilent and Affymetrix [1].

Key Findings and Future Directions for Research

A significant amount of research and product development efforts are being carried out in three key areas in DNA microarrays, namely, (1.) preparing oligos and DNA probes, (2.) immobilization on attachment surface, and (3.) detection of hybridization on surfaces.

1. preparing oligos and DNA probes – One of the promising techniques is what is called "FAST slides" where a glass slide with a polymeric surface that binds DNA and proteins in a noncovalent but irreversible manner [22]. FAST slides have a much higher binding capacity for DNA. Automated liquid handling system for reagent-jet nanoliter dispensing [23] and ink-jet oligo synthesizers [24] are some of the methods being explored in new microarray techniques.
2. immobilization on attachment surface – Work on the use of polyacrylamide gel-immobilized microarrays for nucleic acids have been reported by Zlatanova and Mirzabekov [25]. The use of unmodified oligos to fabricate DNA microarrays where acid-washed slides are coated with epoxy-silane before probe deposition has also been reported [26].
3. detection of hybridization on surfaces – Improvement in fluorescent detections is a focus of many development efforts. Improvements in confocal scanning devices [27], high-resolution near-infrared imaging techniques [28], the use of surface plasmon resonance imaging for DNA and RNA hybridization adsorption with smaller hardware [29] are some of the efforts. Use of radioactive probes [30], the technique of primer elongation reaction [31] and direct electrical detection system through impedance or other electrical properties change is ongoing.

Definition

Droplet based Lab-on-Chip devices represent a class of microfluidic systems that have been developed to miniaturize chemical, biochemical or cellular analysis. These devices utilize various droplet dispensing and manipulation mechanisms to isolate and control liquid-phase droplets of samples and/or reagents surrounded by a gas or an immiscible liquid. The droplets may be completely surrounded by the medium or may be placed onto a solid surface whose material properties are chosen to provide droplet confinement, chemical functionalization, or control of droplet motion. The devices also have some type of assay read-out method with associated hardware, software and data display.

Overview

Several reasons are routinely cited for developing Lab-on-a-Chip devices including reagent savings, use of smaller samples, ease of automation, and reduction of analysis time. Other reasons include the potential for reduction in the size of instrumentation, compatibility with laboratory automation equipment, the ability to provide portable instruments, and the ability to provide point-of-care clinical diagnostics.

The choice of using droplets is a natural progression associated with miniaturization of traditional laboratory methods of manipulating distinct chemical or biochemical reagents and samples to be analyzed. The traditional methods include the use of pipettes, glass beakers, tubes, pneumatic and piezoelectric automated dispensers, as well as standard (as defined by Society for Biomolecular Screening (SBS)) wells and plates. As the size of a liquid sample is reduced, the effect of surface tension increasingly dominates other physical effects and free surfaces tend to take on highly curved shapes. Thus, surface tension acts to confine the liquid in the form of discrete droplets that can be contained and manipulated without requiring the same degree of confinement by solid structures as is traditionally used.

A benefit associated with droplet based systems is the ability to automate dispensing, aliquoting, mixing, and movement of the droplets ranging from sub-nanoliter to several microliters in volume. Channel-based microfluidic systems using a single fluid medium have been developed for electrophoretic molecular analysis, molecular reaction rate determination using surface plasmon resonance, high pressure liquid chromatography and many other applications. These systems typically require that samples be prepared external to the instrument. Thus, there are often aliquoting, dilution, mixing, purification, centrifugation, and other steps that require multiple pipetting steps to be performed off-chip. With a goal of integrating many of these steps, a primary benefit of droplet based Lab-on-Chip devices is that they offer the potential for useful new sample-to-answer capabilities that are difficult to perform in single-fluid channel-based systems.

Most of the research and development for droplet based Lab-on-a-Chip technology has focused on methods of manipulating the droplets that also enable steps of sample preparation to be performed before the bio/chemical analysis. There are, however, examples of droplet based analysis systems for high-throughput biochemical analysis that use automated pipette-based or other dispensing systems which are completed without requiring any further droplet manipulation after spotting. These include gene-expression microarrays, protein arrays, and MALDI mass spectrometry plates. This article will not address these array-based systems further but will focus on droplet manipulation methods and several integrated droplet based labchip systems.

Basic Methodology

Automated droplet based manipulation methods described in this article include electrowetting, dielectrophoretic, thermocapillary, surface acoustic wave (SAW), and

pressure-driven channel-based droplet systems. Fabrication of arrays of elements to control these droplet manipulation methods typically involves the use of photolithography. The methods of addressing of the elements have become increasingly sophisticated with several efforts to utilize passive- and active-matrix control strategies. Trends and issues associated with each method are described.

Electrowetting

Perhaps the most well-developed droplet manipulation method is that of electrowetting. Electrowetting involves an electrostatic reduction of the contact angle of a sessile droplet or a droplet sandwiched between plates. If electrowetting is applied to one side of the droplet, translational motion can be induced. As shown in Fig. 1, the droplet will move to the activated electrode. Additionally, for droplets covering several electrodes, under appropriate conditions, if opposite sides of the droplet are electrowet, it can be split into two. A photograph of an electrowetting labchip droplet manipulation system using dedicated home-run wiring to each electrode is shown in Fig. 2. In this particular chip, a transparent array of three 2×8 Indium Tin Oxide (ITO) electrodes, plus 2 electrodes connecting these arrays, are coated with a Parylene dielectric layer and then thin gold lines are formed to surround the underlying ITO electrodes. Thus, no top plate is required to ground the droplet since the gold lines provide electrical grounding to sessile droplets residing on the surface.

A design of an active-matrix driving of an electrowetting chip with optical detection of the droplets is shown in Fig. 3. This so-called *Active Matrix Microfluidic* (AMM) design offers the use of TFT manufacturing processes that are commercially well-developed as well as use of active matrix addressing standards that are also well-developed for use in flat panel displays. Numerous researchers have fabricated arrays of electrodes and demonstrated droplet manipulation by electrowetting [2, 5, 9, 10]. Recent efforts have also made use of *optoelectrowetting* which holds promise as a method of using sequences of light images projected onto a photoconductive substrate to activate electrowetting [4].

Dielectrophoresis

Generation of non-uniform electric fields, either DC or AC, can impart forces on droplets or particles having a different dielectric constant from the surroundings. Gascoyne's research group [7] have developed arrays of electrodes for manipulating droplets by this method. In their system, aqueous droplets are suspended in 1-bromododecane and motion is induced without requiring any droplet spreading on a surface. The distinction between dielectrophoresis and electrowetting is subtle and the electromechanical fundamentals are described by Jones [8].

Thermocapillary

Thermocapillary droplet control is based on the principle that surface tension is a function of temperature. By using an array of sub-surface heaters or other means of controlling the temperature distribution around the periphery of a droplet, an imbalance of forces can be imposed on the droplet resulting in motion towards the cold regions [6]. Temperature increases of less than approximately 6 K were used by Darhuber et al. to move droplets of several different liquids. Their fabrication of metal electrodes involved photolithographic patterning and metal evaporation followed by coating with silicon dioxide.

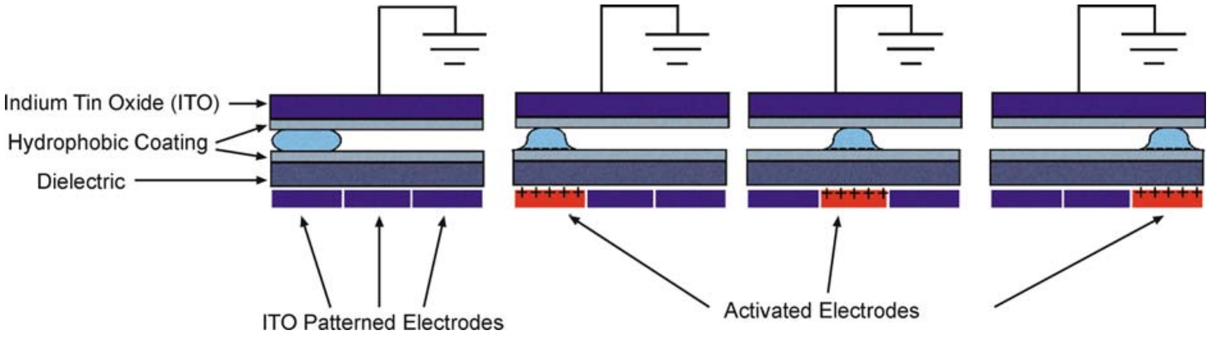
Surface Acoustic Waves (SAW)

Generation of traveling surface acoustic waves across the surface supporting a droplet can result in the transfer of energy into translational motion of the droplet. Wixforth and coworkers [12] have studied the use of SAW systems combined with surface patterns of varying hydrophobicity to generate the desired droplet motion. Lithium Niobate $LiNbO_3$ piezoelectric with gold interdigitated transducers were used to generate SAWs using RF excitation of 100–800 MHz with resulting wavelengths from about 5 μm to 35 μm. They have shown the ability to dispense small droplets from a larger one and to control the movement of the droplets.

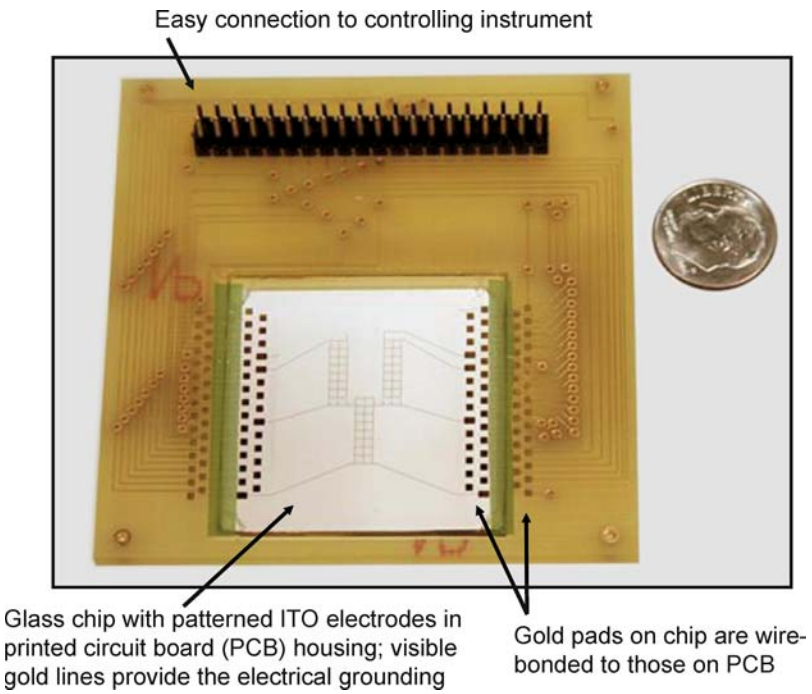
Droplets in Channels

There has been a spate of recent activity associated with the formation and flow of aqueous droplets in channels surrounded by immiscible oil [1]. The typical configuration is similar to that used for flow cytometry in which a sample flow is injected into a co-flowing sheath flow. In this chip-based manifestation, however, photolithography is used to fabricate a four-way intersection of channels and the sheath fluid is immiscible. Therefore the water-oil interfacial tension results in the formation of droplets. Typically, the aqueous sample flow enters the intersection head-on and the two side channels provide the flow of immiscible oil. These three flows then exit the single remaining channel. The flow rates are controlled such that droplets pinch-off within the oil to provide a series of droplets whose spacing can be controlled.

Clearly, there has been substantial research into droplet formation and control methods. Although these droplet manipulation methods are critical to the development of Lab-on-Chip systems, integration issues associated with



Droplet Based Lab-on-Chip Devices, Figure 1 Layout of electrowetting chip with droplet translation onto actuated electrodes

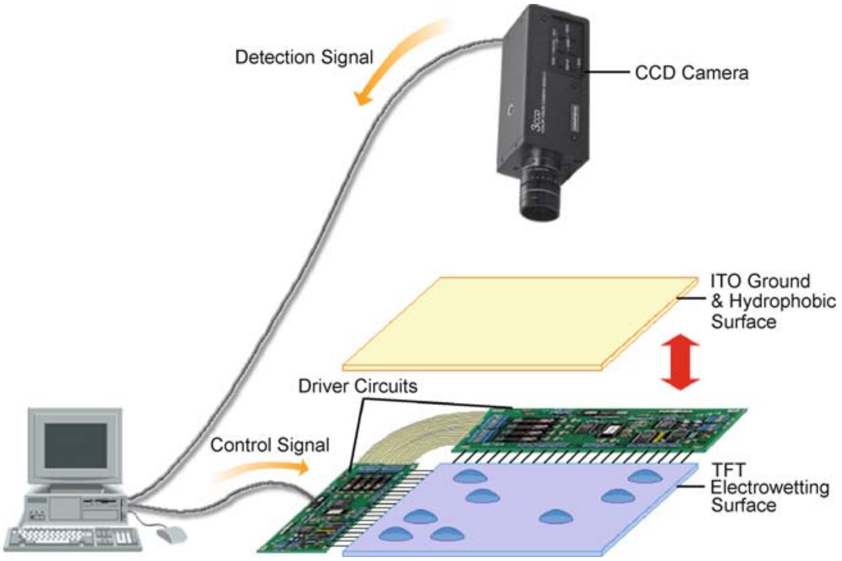


Droplet Based Lab-on-Chip Devices, Figure 2 Typical electrowetting droplet Lab-on-Chip design using *home-run* wiring with switching electronics off-chip. Chips of this type have been used to initiate DNA amplification reactions shown below

the read-out method for particular analytical techniques also represent significant challenges. Thus, in the following section we describe the research findings associated with droplet Lab-on-Chip systems that implement real analytical methods.

Key Research Findings

Several research efforts have been reported that utilize droplet Lab-on-Chip systems to perform chemical or biochemical assays with a high degree of automated control. The use of physiological fluids in electrowetting droplet systems has been demonstrated by Fair's group at Duke University [11], who also performed glucose assays and manipulated solutions used in polymerase chain reaction (PCR). Integrated steps of mixing reagents and samples as well as performing on-chip heating have been performed for PCR-based DNA amplification [3]. The company Advanced Liquid Logic, Inc. (www.liquid-logic.com) is currently commercializing this type of digital microfluidic system for applications such as neonatal blood diagnostics and protein crystallization. Systems that are based on droplets in channels driven by pumps are being commercialized by the company RainDance Technologies, Inc. (www.raindancetechnologies.com) with applications anticipated in various fields such as enzyme development,



Droplet Based Lab-on-Chip Devices, Figure 3 Design of an electrowetting Lab-on-Chip utilizing active-matrix addressing of a high-density array of thin-film transistors (TFTs) similar to those used in Active Matrix Liquid Crystal Displays (AMLCDs) for Flat Panel Displays (FPDs). There is promise for these Active Matrix Microfluidic (AMM) designs to be used to perform complex protocols by generating row-column addressing with video signals in standard formats (e. g. SVGA, UXGA, QSXGA, ...)

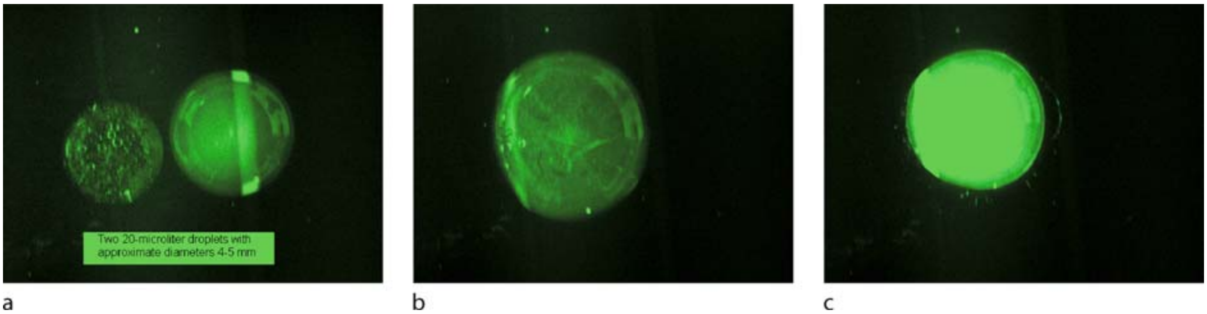
proteomic assays, cancer diagnostics, and on-chip chemical synthesis.

Microcalorimetry has been performed on several sample biochemical reactions using electrowetting to initiate the reactions that are then monitored by on-chip embedded thermistors [13]. The differential temperature rise between adjacent sample-control pairs was used and 96 of these pairs were microfabricated on 9 mm spacing consistent with SBS 96-well format for compatibility with laboratory automation. Examples of reactions that were used to validate this platform were the binding of 2′-CMP to RNase A and the binding of biotin to streptavidin. Phosphorylation of glucose by hexokinase and the power output of mitochondrial respiration were also monitored.

In a similar effort involving real-time monitoring of a biochemical reaction, the amplification of DNA using an isothermal amplification method has been performed by our group at KGI. Electrowetting is used to initiate the coalescence of droplets and the fluorescence associated with DNA amplification is monitored. This isothermal DNA amplification method is called *EXPAR* and is described by Van Ness et al. [14]. Initiation of the reaction occurs upon coalescence and heating of (1) a master mix droplet containing the essential enzymes, dNTPs, and a single-stranded DNA template with (2) a sample droplet containing a short ssDNA sequence *trigger* that is unique to the organism or gene of interest.

The ssDNA template in the master mix is designed to include two identical sequences complementary to the trigger. These two identical sequences are separated by a short region complementary to an enzyme recognition sequence. The trigger ssDNA sequence is short enough that it only transiently binds to one end of the template at the temperature of the reaction (in our case 53°C). If, however, during the transient binding, the polymerase extends the double stranded portion several bases to form the enzyme recognition sequence, the duplex gains stability and the polymerase continues to extend the duplex to the end of the template. At this point, the N.BstNb$_1$ nicking-enzyme binds to the recognition site on the newly-formed dsDNA and nicks (cleaves a phosphodiester bond on) the newly-formed strand of the DNA to create an oligonucleotide that is below the threshold of stability leading to the release of a new trigger that is identical to the first. The polymerase can then re-extend the template-duplex such that new triggers are generated by these partial-duplex *trigger-generator* molecules at a rate of about 1 trigger/2.5 s for the conditions used in this study. As the ssDNA triggers are released into solution, they can bind to other ssDNA templates to create new trigger-generators. This process can be shown to provide an exponential increase in the number of trigger-generators in time leading to the name *Exponential Amplification Reaction*, or EXPAR. The progress of the reaction can be monitored using an intercalating dye, Sybr Green II, that binds to the duplex region of the trigger-generators.

The master mix was prepared with the following constituents:



Droplet Based Lab-on-Chip Devices, Figure 4 Fluorescence images of DNA exponential amplification reaction in a heated droplet using Sybr Green II to indicate formation of double-stranded DNA templates. (**a**) Image of two 20 μL droplets before coalescence. The droplet on the left is a trigger/sample droplet containing a single-stranded DNA 12-mer and the droplet on the right contains a ssDNA 33-mer template with the enzymes and dNTPs required for exponential amplification. Note the gold ground line underneath the right droplet that reflects incident excitation light. (**b**) Image of droplet, 1 s after coalescence. (**c**) Image of droplet after 42 s of isothermal amplification. (Experiment performed by Mr. Peter Qu)

- 274 μL nuclease free water
- 100 μL Thermopol buffer
- 50 μL N.BstNb1 buffer
- 25 μL dNTP mix
- 40 μL N.BstNb1 enzyme
- 10 μL Bst polymerase
- 1 μL Sybr Green II dye
- 0.75% by weight of PEG 8000

In the reaction shown in Fig. 4, two 20 μL droplets are shown before and after coalescence and DNA amplification is evident by the clear increase in fluorescence. The concentration of template DNA in the amplification master mix was 0.4 μM and the template sequence was 5′–CCT CAT CGC GGG CTT CGA CTC CCT CAT CGC GGG–3′. The trigger DNA droplet had 0.2 μM of the sequence 5′–CCC GCG ATG AGG–3′. The chip was heated to 53°C and 50 V was applied to initiate motion of the trigger-containing droplet. The microscope was a Nikon Eclipse E800 with an excitation wavelength of 488 nm with long-pass filtered emission beyond 560 nm. The three images in Fig. 4 are taken from a movie of the amplification reaction. The droplet coalescence event takes less than 0.5 s from the initial droplet contact to the time that motion apparently ceases. The reaction is maintained at 53°C throughout the reaction and there is a dramatic increase in fluorescence indicating DNA amplification. The reaction is nearly complete at the time the final image was taken 42 s after droplet coalescence.

We note that the coalescence was a result of the motion of the trigger/sample droplet moving to join the master mix/template droplet. The contact lines of the latter droplet remained pinned, a phenomenon that is observed for droplets containing proteins of sufficiently high concentration. One method of avoiding this line pinning effect is to immerse the aqueous droplets in oil, allowing droplet motion even for high protein concentrations.

Future Directions for Research

There are several systems-level issues that must be addressed in the development of integrated Lab-on-Chip systems. Ultimately, every step of an assay, including sample preparation, reagent mixing, biochemical reaction, signal transduction, and readout technology should be integrated into such biosensors or diagnostic systems in order for them to prove useful and reliable to the end-users. This is expected to involve requirements-driven engineering for particular applications including immuno-assays, nucleic acid diagnostics, and cell-based systems. Trade-offs for particular applications require design decisions to be made regarding flexible/reprogrammable arrays vs. pre-determined droplet pathways, inexpensive disposable systems vs. reusable chips with cleaning protocols, and integration of all processes or modular or decoupled functional units. The high risk areas of these technologies are primarily associated with the integration issues and the degree to which the systems can be reused and cleaned between uses.

Definition

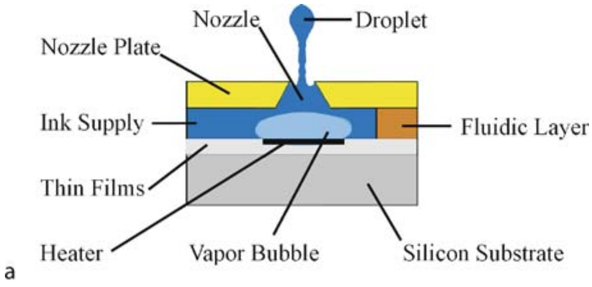
Droplet dispensing is the procedure of ejecting single droplets or small jets out of a nozzle of a dispensing apparatus. Here we only consider liquid droplet dispensing into a gaseous environment. Dimensionless numbers like the Reynolds, the ►Weber and the ►Ohnesorge numbers are well suited to describe the droplet formation qualitatively.

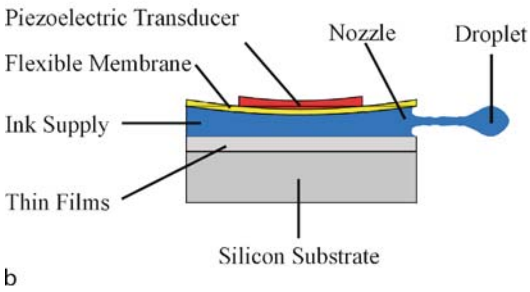
Overview

Liquid droplets of different volumes are used in many applications in various areas of interest. This is the reason why much research work has been dedicated to understand and to describe the numerous existing droplet generation mechanisms. There are many applications exploiting droplet generating devices and applications with increasing market potential. Due to the huge amount of available techniques, only some of them are selected as example and are presented in the following. Distinction is made between printing and coating, life sciences, electronics manufacture, optics and other main applications.

Printing and Coating

Printing and coating certainly is the biggest industrial market using single droplets or sprays, starting with the huge market of well-known home and office printers



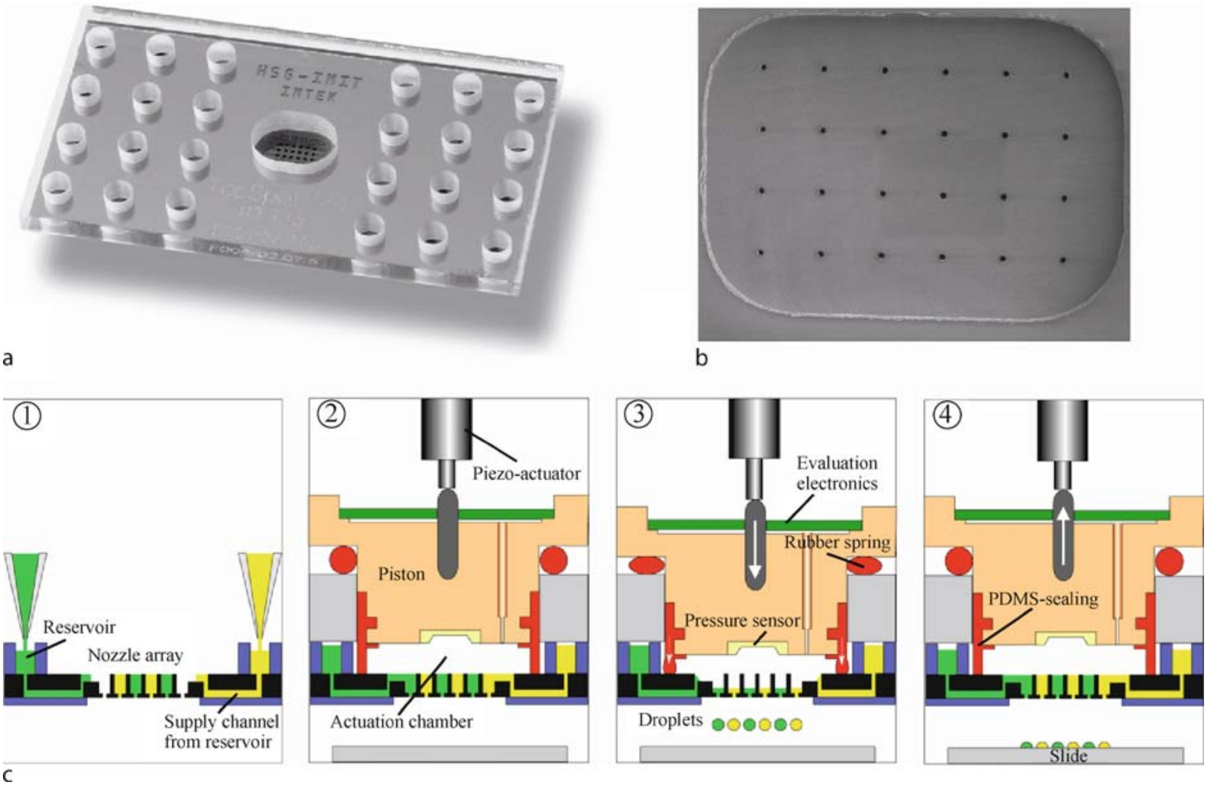


Droplet Dispensing, Figure 1 Principle of (**a**) a thermal bubble jet printhead and (**b**) a piezo-actuated inkjet printhead

based either on the ▶bubble jet or the piezo principle, and followed by many industrial large-format printers for the packaging of materials and direct labeling. High-quality color images, low machine cost and low printing noise are basically the main advantages of such ▶inkjet printers producing droplets in the 1 – 100 pl range. The two competing technologies in this field are the thermally actuated ▶bubble jet commercially available from Hewlett Packard, Canon, Olivetti I-Jet and others; and the piezoelectric-driven printheads commercially available from Epson, Xaar, Spectra and others. Both methods have made remarkable progress in the last two decades. Furthermore, there are thousands of applications of spray units used for spraying of colors, adhesives, oils and many more.
The functional principle of a thermal ▶bubble jet printhead is displayed in Fig. 1a. A current pulse applied to a microheater leads to a very short heating pulse at the solid–liquid interface. This heating pulse leads to a small vapor bubble which expands explosively. The increasing vapor bubble leads to a volume displacement of the ink towards the nozzle and finally to a droplet ejection. The detaching of the vapor bubble from the hot surface results in a concurrent cooling down of the bubble which results in condensation and collapse of the bubble. The suction of the collapsing bubble and the capillary forces inside the printhead lead to refilling of the nozzle chamber that is finished before the next shot within approximately 10 μs. The fast explosion of the bubble leads to a characteristic pressure behavior inside the liquid. Starting instantaneously with a very high pressure of about 7 to 9 MPa right at the beginning of the vaporization, the pressure decreases exponentially during a few microseconds.
The functional principle of a piezoelectric printhead is displayed in Fig. 1b. A bending of a piezoelectric transducer attached on a flexible membrane or similar leads to a volume displacement of the ink and a subsequent droplet ejection.

Life Sciences

Various examples of the use of droplet dispensing within the life sciences [1] are droplet-based Lab-on-a-Chip systems, fabrication of microarrays, combinatorial chemistry and high-throughput screening in drug discovery, inhalers in medical therapeutics, and many more.
The principal idea behind the use of droplet-based Lab-on-a-Chip implementations is the use of single droplets as reaction confinements for biological assays or chemical reactions. Dominant interfacial and surface tensional forces at the microscale enable the precise generation and spatial stabilization of these droplets. Since the droplets are kept isolated within an immiscible surrounding fluid like air or oil, lateral dispersion (Taylor dispersion) can be avoided while moving the droplets to different locations.
Droplets as reaction confinements can be regarded as nanoliter-sized batch reactors for mixing and reacting in contrast to the merely flow-through concept of the other platforms described so far. A multitude of parallel screening reactions, each consuming only a minute amount of reagents, are enabled inside the small-sized droplets. The reproducibility of the reaction conditions is very high, since the droplet volume as well as the reaction conditions within the droplet, i. e. temperature and mixing conditions, can be controlled precisely.
The droplet-based microfluidic platforms for Lab-on-a-Chip applications can be fundamentally divided into two basic setups, the channel-based and the planar surface approach [2]. The channel-based systems are mostly pressure driven with droplet generation and manipulation relying on actuation via liquid flows within closed microchannels. For the planar surface-based platforms, droplets can be arbitrarily moved in two dimensions representing planar programmable Lab-on-Chips. They are actuated by electrowetting (EWOD) or surface acoustic waves (SAW).
Furthermore, droplet generators are a key technology for fabricating so-called microarrays. A microarray is a two-dimensional arrangement of hundreds or even thousands of different DNA fragments or proteins immobilized on a surface. Microarrays are used as a highly parallel ana-



Droplet Dispensing, Figure 2 (**a**) A 24-channel TopSpot® printhead. (**b**) SEM image of the 24 nozzles at a pitch of 500 µm on the bottom side of the printhead. lytic detection method to rapidly detect genetic patterns or the rapid identification of microorganisms. The microarray technology has revolutionized the fields of biotechnology and the life sciences. It has opened new perspectives for decoding the human genome, for molecular gene and DNA diagnostics, proteomics as well as for new ways in pharmacogenetics. Due to the high complexity and diversity of proteins, production of protein microarrays is a major technological challenge and requires very flexible printer systems.

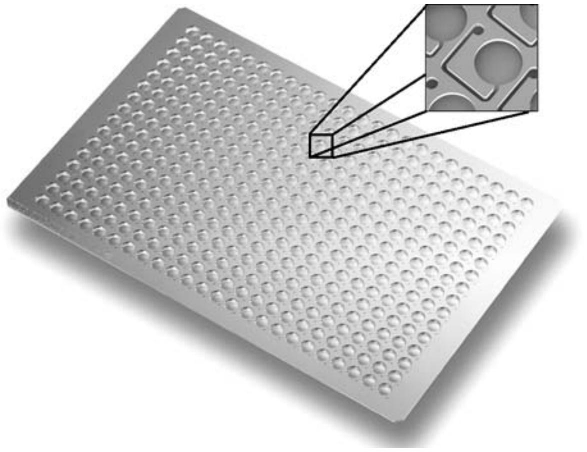
For example, the TopSpot® technology [3, 4] has been developed for the fast mass production of low- and medium-density microarrays. The system enables highly parallel non-contact printing of different media like oligonucleotides, DNA or protein solutions. It is based on a micromachined printhead which is driven by a separate actuation unit. The printhead formats allow the simultaneous application of 24, 96 and even 384 different reagents in one step. A 24-channel TopSpot® printhead and the corresponding working principle are displayed in Fig. 2.

In modern drug discovery, potential drug candidates have to be identified from a huge number of different chemical compounds. This process is called high-throughput screening (HTS). It allows the testing of several hundred thousand chemicals per day. In HTS, biochemical assays are performed in standardized containments termed microwell plates. Due to the ongoing miniaturization smaller amounts of liquid have to be handled. Therefore, non-contact dispensing becomes increasingly important because of the increasing surface tension effects of small liquid droplets. Thus microdroplet generators are an appropriate solution for non-contact liquid handling. They can decrease the necessary amount of liquid and the processing time for drug discovery experiments where typically thousands to hundreds of thousands of tests involving novel biologically active reagents are required.

The Dispensing Well Plate (DWP™), as shown in Fig. 3, for example, is a dispensing system of up to 1536 dispensing units for the massive parallel delivery of liquid volumes in the volume range of 50 nl [5, 6]. One key application for the DWP system within HTS is the rapid compound reformatting by direct addition of nanoliter volumes to an assay in microwell plates. In that case the dispensing volume is defined by the geometrical volume of the micro-



Droplet Dispensing, Figure 3 Dispensing Well Plate offering 384 dispensing units in parallel made by silicon bulk micromachining (pitch of 4.5 mm)

machined nozzle, leading to a very high reproducibility of dispensing volume with a CV of 2 – 5% and a homogeneity within individual droplet arrays of 1 – 2%. Advantages of the DWP system are the small dispensing volumes which can be handled accurately and in a highly parallel way and the possibility of an extremely high integration density up to a 1536-well plate format.

Another interesting field of research is cell sorting. Cell sorting can be used either to deposit single cells (cloning mode) or to collect large numbers of cells with similar properties (enrichment mode). A small droplet of several micrometers in diameter can contain a single cell. Due to this, such small droplets can be used to handle and sort cells. Cell sorting is a technique that typically includes a droplet generator, a droplet charging and deflecting system and sensors for measuring cell properties by fluorescence and light scattering.

A large application field in medicine is aerosol atomizers for drug delivery. Aerosolized droplets in the range of a few micrometers in diameter containing therapeutic reagents can be used to administer drugs to the lungs to treat various diseases.

In Fig. 4 the droplet ejecting technologies mentioned above are arranged in a graph indicating the suitable volume range of the different technologies and the number of *different reagents* that can be dispensed simultaneously and in parallel.

Electronics Manufacture

The main application using droplets in electronics manufacture is the deposition of molten solder on circuit boards. This technology can be used to make direct solder connections of components, vertical and horizontal conductive lines and solder bumps for flip chip bonding. Due to this, manufacturing technologies can be driven toward further automation, miniaturization and reductions in costs and cycle times. As a non-contact deposition method, this technology may also be applied to print on nonplanar and curved surfaces. A further application is the printing of adhesives for sealing and bonding of devices. This can be accomplished quite efficiently by drop-on-demand as well as continuous droplet generators.

D

Optics

Small droplets can be used to fabricate lenses and lens arrays suitable for use in fiber optics, laser diodes, imaging arrays, displays and optical switches. Cured optical plastics are used instead of glass to produce lenses where the curvature of the lens can be adjusted by control of surface tension and contact angle of droplets deposited on flat substrates.

Large-area displays like LCDs or TFTs usually are fabricated by screen printing or lithographic techniques. However, with increasing display resolution at reduced fabrication costs, non-contact droplet deposition of the colors could be a promising alternative.

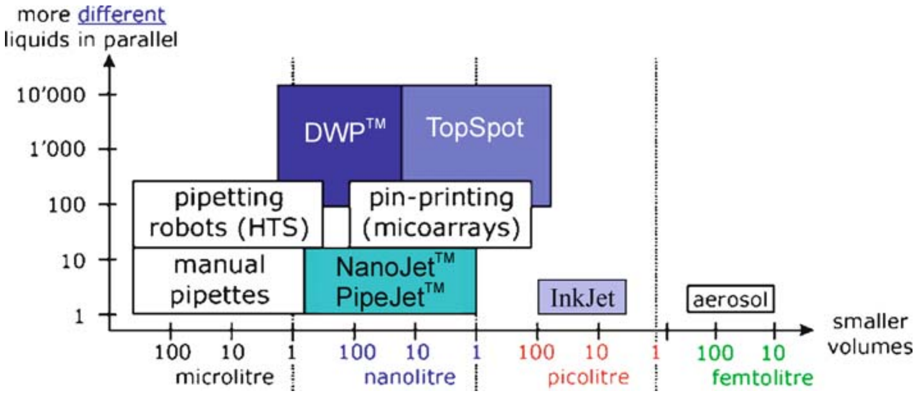
Moreover polymer-based displays can also be manufactured using droplet dispensing systems. Organic polymers are usually used due to their potential low costs. They are typically deposited by spin coating or evaporation. The patterning of the necessary multiple organic layers for red, green and blue is difficult. A direct deposition of patterned luminescent doped polymers by droplet generators like ► inkjets provides a more simple manufacturing method. A further advantage using droplet generators is the reduction of the amount of material used. The polymer solutions of the three colors are printed directly in the required positions without any losses as is the case for spin coating.

Others

Another important application using droplet generators is in fuel injection systems which are the heart of modern combustion engines. The fuel is atomized into a spray of small droplets provided by a fuel injector. The droplet size distribution as well as the fuel–air ratio are crucial for optimum combustion.

A further application using microdroplets is the rapid prototyping of three-dimensional industrial objects making use of the ejection of high-temperature liquid metals, ceramic suspensions or hardenable polymers.

Besides these high-throughput applications, droplet generators can also be used in the drop-on-demand mode. They can be used to deposit lubricants where needed



Droplet Dispensing, Figure 4 Classification of droplet ejectors depending on the ejected volume and the amount of liquids which can be handled in parallel

during manufacture, assembling or operating. For example special oils can serve as lubricants in small spindle motors without ball bearings. Therefore, the lubricant has to be provided with precise control of quantity and position.

Basic Methodology

Understanding and Describing Droplet Formation Processes

The state of the art in understanding and describing droplet formation processes is divided into two different perspectives: the continuum mechanics or fluid dynamics approach and the particle-based approach. Whilst the continuum mechanics approach is based usually on the Navier–Stokes equation, the continuum equation and the energy equation, the particle-based approach is based on the interconnecting forces between neighboring particles like molecules or pseudo particles.

Lord Rayleigh was the first who derived an analytical description of droplet generation caused by jet instabilities as early as the late 19th century [7]. After that at the beginning of the 20th century, the experimental study of droplet generation became increasingly important. However, even today analytical descriptions for the droplet formation process are still being refined and improved. These studies mostly use simplifications of the Navier–Stokes equations like axisymmetric, steady flows with a free surface to describe simple examples of droplet formation [8, 9]. A general analytical description of droplet generation, however, is inhibited by the complexity of the underlying differential equations like the Navier–Stokes equation and others. Therefore numerical techniques such as network descriptions, based on lumped elements or compact models, computational fluid dynamic (CFD) simulation or particle-based approaches like molecular dynamics (MD) or dissipative particle dynamics (DPD) are used to describe the droplet dispensing process.

Droplet Breakup Regimes

The breakup of droplets released from a nozzle into the air mainly can be categorized according the following different regimes.

Drop-on-Demand Breakup

This droplet breakup regime is characterized by an ejection of a single droplet with a diameter equal to or slightly bigger than the nozzle diameter. The ejected droplet can be followed by smaller satellite droplets or a tail which could also disperse into single satellite droplets after a while. In such a system the droplet can be ejected on demand which means that every actuation pulse produces one single droplet. The required actuation for such a droplet breakup should provide a fast actuation, if possible with a counter movement to enforce droplet breakup. The actuation force should be strong enough to overcome substantially the capillary forces.

Jet-on-Demand Breakup

The jet-on-demand regime is similar to the drop-on-demand regime with the main difference being that a jet is ejected rather than a single droplet. However, this jet could possibly also disperse into single droplets after jet tear-off. Nevertheless, the ejected volume is much bigger compared to single droplets produced in drop-on-demand mode. But the ejected jet is still on demand which means that also in this case every actuation pulse produces one single jet. Compared to drop-on-demand breakup the actuation takes longer which leads to the jet.

Rayleigh Breakup

Rayleigh breakup is a continuous mode rather than an on-demand mode which means that a liquid jet is ejected out of a nozzle continuously. This jet disperses into single droplets due to the so-called Rayleigh instability after a certain distance from the nozzle. This Rayleigh instability is either caused by naturally occurring disturbances on the jet or by additionally applied external disturbances. In this case the droplet volume almost only depends on the nozzle diameter. The actuation has to be applied for much longer compared to the on-demand modes and can be relatively small.

Atomization Breakup

Atomization breakup is mainly characterized by a liquid high-speed jet which disperses into a fine spray of many single droplets directly behind the nozzle exit. A further characteristic is the arising spray cone so that the droplet trajectory is not inevitably in line with the nozzle. The ejected droplets usually exhibit a droplet size distribution rather than a constant droplet volume. The actuation is continuous and very strong which leads to very high velocities inside the nozzle.

Classification of Droplet Generators

The aim of this section is to derive a clear classification of droplet generating devices releasing droplets from a nozzle into the air based on the applied actuation boundary condition. This is different from the majority of publications which consider the obvious construction elements of droplet generators (e. g. *piezo-dispenser*) or provide classifications based on historical reasons that are often misleading for understanding the real physical principle behind the individual dispensers.

Grounded on the concept applied in CFD simulations where either a *pressure boundary condition* or a *flow boundary condition* is used, real droplet generators can be distinguished using the type of boundary condition resulting from the actuation mechanism. However, there exist also droplet generators where a combination of pressure and flow represents the correct boundary condition. In this case neither an ideal pressure source nor an ideal flow source is the correct assumption. The pressure inside the system is influenced by the flow and vice versa. Due to this also a third group of droplet generators with a *combined pressure and flow boundary condition* has to be established. Finally, a fourth group is listed involving *acoustic actuation* which is a special kind of pressure boundary condition. The reason for the distinction is that the acoustic boundary condition has a totally different physical background compared to the other boundary conditions.

The presented classification, however, is not absolutely fixed by the fluidic setup because single-droplet generators can even change categories when being operated in different modes. For example, a device of the pressure or flow boundary condition class can convert to the combined pressure and flow boundary condition class or vice versa.

Pressure Boundary Condition

A pressure boundary condition exists when the nozzle chamber is pressurized by some kind of actuation producing a constant or transient pressure gradient. This results – according to the Navier–Stokes equation – in a volume flow depending on the geometry and the liquid properties. A feedback from the volume flow to the actuation pressure is neglected. In real devices the way the pressure is produced depends on the system under investigation. This group especially includes all droplet generators using a constant pressure with subsequent Rayleigh breakup or a constant pressure switched by a fast valve. In these cases the pressure can be considered to be provided from a large pressure reservoir which is not influenced by the small volume change caused by the droplet ejection.

Flow Boundary Condition

In the class of flow boundary condition-based devices predominantly the flow is generated by a fixed volume displacement within a certain period of time which leads to a preset volume flow. The pressure inside the system follows from the Navier–Stokes equation and depends on the geometry and the liquid properties. Feedback from the pressure gradient that builds up to the volume flow is neglected in this case. Such a volume displacement can be achieved by displacing a membrane or a piston or by squeezing a tube or a capillary by a very powerful actuator that is not affected by the pressure that is built up internally in the dispensing system.

Combined Pressure and Flow

Some droplet generators do fit in any of the above mentioned classes because neither the pressure nor the flow can be controlled independently. In these devices only a combination of quantities can be influenced. Either the actuator is not strong enough to impose a predefined boundary condition or the device is designed in a way to support coupling between liquid flow and pressure. The best example for this class is the thermal ▶ bubble jet printhead where the actuation is created by a heating pulse and

the resulting vapor bubble. This bubble represents a pressure as well as a flow boundary condition. In the first actuation period of the bubble creation a very high pressure is generated due to the explosive vaporization of the ink. In this period a pressure boundary condition dominates the actuation. After that the growing bubble generates a volume displacement due to its increasing size. In this period a flow boundary condition dominates the actuation. However, the vapor bubble is compressible and due to this the size of the bubble depends on the pressure inside the nozzle chamber as well as on the volume flow. Hence, the ► bubble jet principle involves definitely a combined pressure and flow boundary condition.

Acoustic Actuation

Acoustic actuation is a special kind of pressure boundary condition. There is a pressure involved for actuation, but in contrast to a pure pressure boundary condition creating a convective flow, acoustic actuation does not lead to a substantial liquid flow inside the device during droplet ejection. The spreading velocity of the induced density fluctuations is approximately the speed of sound in the liquid which is much faster than the liquid flow in the case of a pure pressure boundary condition. In practice the acoustic pressure is mostly generated with a piezoelectric transducer. The created shock wave travels through the liquid where it can be influenced by reflections from the channel walls. In some cases such reflections are intended to make use of constructive interferences by establishing a standing wave for a short period of time. When the shock wave hits the meniscus at the nozzle the pressure is transformed into kinetic energy and a droplet is ejected. This principle is very reproducible if all parameters are kept constant; however, it is very sensitive to the liquid properties and especially sensitive to trapped gas bubbles.

Key Research Findings

Droplet Generation Fundamentals

"The process of drop ejection is not as simple as taking a fluid chamber with a small hole and pressurizing it enough for fluid to start emerging from the ejection nozzle hole" [10]. To accomplish monodisperse droplets ejected out of a nozzle, one needs the ability to produce high-speed fluid jets of approximately the diameter of the desired droplets. Additionally, the behavior of the jets has to be controlled precisely enough to cause them to consistently disperse into uniformly sized droplets.

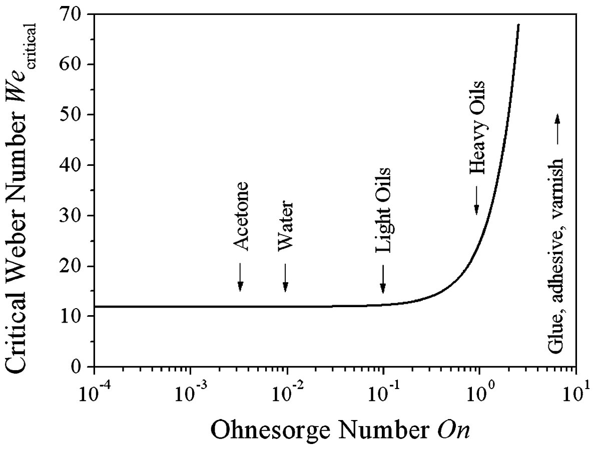
In general there are two different methods to eject monodisperse droplets. The first method, the continuous jet method, is to break up a continuously flowing fluid jet. This is done either by driving the fluid with a source of acoustic energy in order to form standing wave nodes along its length, or by disturbances that occur naturally. The ejected jet finally disperses into discrete droplets. The second method, the drop-on-demand method, is to generate single droplets instead of breaking up a continuous jet. This is mainly done by short pressure pulses, small volume displacements or acoustic actuation of single or multiple nozzles to eject a droplet on demand. These actuation principles are capable of producing droplets in the kilohertz range with random accessibility.

The main differences of the two methods are the maximum frequencies that can be achieved, the amount of liquid which is necessary, the random accessibility of droplets and the complexity of the system setup. While the continuous jet dispenser is capable of producing droplets in the megahertz range, the drop-on-demand method produces droplets with a frequency of several kilohertz. The advantage in terms of throughput of the continuous jet method is balanced by the disadvantages of the minimum amount of liquid which is needed and the relatively high complexity of the system setup compared to the drop-on-demand technique. However, the random accessibility of droplets, the smaller amount of liquid that is required and the simpler system setup are reasons why the drop-on-demand method is the more common method nowadays in most printing as well as in medical or biological dispensing applications. But nevertheless the continuous jet method is still used for some applications.

Critical Weber number

The creation of spherical droplets has been the focus of numerous studies over the years [11–14]. These show conclusively that for both steady and transient flows the onset and mechanisms of droplet breakup can be correlated with the non-dimensional ► Weber number. It is the most important dimensionless number characterizing droplet formation and can be applied to determine the threshold of droplet formation. However, the critical Weber number is only a sufficient condition for droplet breakup and not a necessary condition. This means that if the critical Weber number is surpassed in a process certainly droplet breakup will occur. But droplet ejection is also possible at lower Weber numbers. The only necessary condition for droplet formation is that the supplied energy is sufficient to overcome friction losses and the surface energy of an ejected droplet.

The dimensionless Weber number is considered as the ratio of kinetic energy E_{kinetic} and surface energy E_{surface}



Droplet Dispensing, Figure 5 Critical Weber number $We_{critical}$ depending on the Ohnesorge number On and typical Ohnesorge regimes for different media

of a droplet ejected out of a nozzle:

$$\mathrm{We} \sim \frac{E_{\text{kinetic}}}{E_{\text{surface}}} = \frac{\frac{1}{2} \cdot m \cdot v^2}{A_{\text{droplet}} \cdot \sigma} = \frac{\frac{1}{12} \cdot \rho \cdot D^3 \cdot \pi \cdot v^2}{D^2 \cdot \pi \cdot \sigma} = \frac{1}{12} \cdot \frac{\rho \cdot D \cdot v^2}{\sigma} \quad (1)$$

$$\Rightarrow \mathrm{We} = \frac{\rho \cdot D \cdot v^2}{\sigma} \quad (2)$$

where v is a characteristic velocity of the liquid and D is a characteristic length. For droplet ejection out of a nozzle, these correspond to the velocity of the liquid inside the nozzle and the nozzle diameter, respectively.

The Weber number can be used for two different descriptions. On the one hand it describes whether a droplet can leave a nozzle at all due to higher kinetic energy compared to surface energy. On the other hand it can describe whether a droplet has a tendency for splashing when the kinetic energy is released at the impact on a surface. The higher the Weber number the more dominant is the kinetic energy. This means that most of the inserted energy converts into kinetic energy, i. e. an ejected droplet is faster with higher Weber number. The lower the Weber number the more dominant is the surface tension energy. This means that most of the inserted energy converts into surface tension energy, i. e. droplet formation is critical or even impossible.

The shortcoming of the Weber number is that it does not consider the effects from the viscosity of the fluid. Therefore the Weber number is not adequate to describe the release of droplets from highly viscous liquids which are known to be challenging to dispense. To account for the liquid viscosity in droplet formation, the appropriate nondimensional number is the ▶ Ohnesorge number which represents the ratio of internal viscosity dissipation to the surface tension energy [15]. The Ohnesorge number may be written in terms of the Reynolds and Weber numbers:

$$\mathrm{On} = \frac{\sqrt{\mathrm{We}}}{\mathrm{Re}} = \frac{\eta}{\sqrt{\rho \cdot D \cdot \sigma}} \quad (3)$$

The Ohnesorge number is sometimes also referred to as the stability number, viscosity number, Laplace number or Z number. It is independent of the velocity and therefore only adequate to describe droplet ejection in conjunction with the Weber number. The lower the Ohnesorge number the weaker are the friction losses due to viscous forces. This means that most of the inserted energy converts into surface tension energy, i. e. a droplet can be formed. The higher the Ohnesorge number the more dominant is the internal viscous dissipation. This means that most of the inserted energy converts into internal viscous dissipation, i. e. that droplet formation is critical or even impossible.

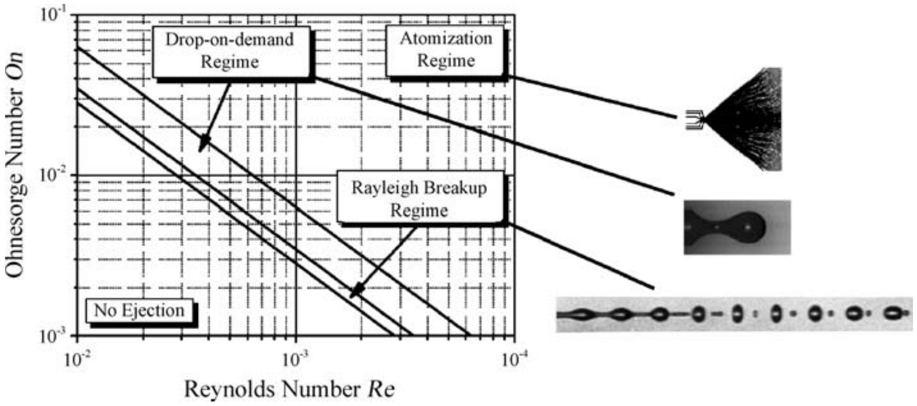
According to Eq. (2), a Weber number larger than 12 signifies that the disruptive hydrodynamic forces are larger than the stabilizing surface tension forces. Additionally this crucial Weber number, at which a droplet breakup first can occur, can also be determined empirically. This empirical crucial Weber number is also around $\mathrm{We} = 12$. However, a constant crucial Weber number is only valid for liquids with low viscosity such that the Ohnesorge number is small, $\mathrm{On} < 0.1$. This is the case for viscosities $\eta < 10\,\mathrm{mPa\,s}$ for appropriate spatial dimensions in the microscale. For higher viscosity fluids a viscosity-dependent expression has to be added to this crucial Weber number known as the critical Weber number $\mathrm{We}_{\text{critical}}$. A useful empirical expression for the critical Weber number with increasing viscosity is [13, 14]

$$\mathrm{We}_{\text{critical}} = 12 \cdot \left(1 + 1.077\,\mathrm{On}^{1.6}\right) \quad (4)$$

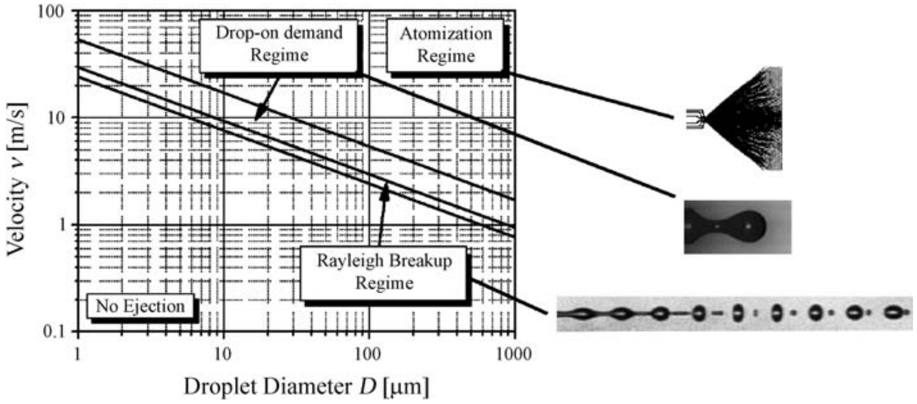
The dependency of the critical Weber number on the Ohnesorge number is displayed in Fig. 5.

In addition to the critical Weber number for a drop-on-demand breakup, the criterion of $\mathrm{We} > 8$ for a Rayleigh breakup has also been reported [16]. This limit can also be motivated by the lower limit of jet formation in the case of dripping out of a vertical capillary with diameter D_{nozzle} under the action of gravity. The static pressure p_{stat} inside a hanging droplet is

$$p_{\text{stat}} = \frac{4 \cdot \sigma}{D_{\text{droplet}}} \quad (5)$$



Droplet Dispensing, Figure 6 Different breakup regimes represented by the relationship of the Ohnesorge number versus the Reynolds number



Droplet Dispensing, Figure 7 Different breakup regimes represented by the relationship of the velocity v versus the droplet diameter D for water as ejected liquid

The dynamic pressure p_{dyn} due to a velocity v yields

$$p_{\mathrm{dyn}} = \frac{\rho}{2} \cdot v^2 \tag{6}$$

Considering both pressures to be equal also leads to a correlation with the Weber number:

$$\frac{p_{\mathrm{dyn}}}{p_{\mathrm{stat}}} = \frac{1}{8} \cdot \frac{\rho \cdot D_{\mathrm{droplet}} \cdot v^2}{\sigma} = \frac{1}{8} \cdot \mathrm{We} \tag{7}$$

Hence, a Weber number of 8 arises from the equilibrium of dynamic and static pressure.

Furthermore, an additional criterion $\mathrm{We} > 40$ to predict the onset of the atomization regime has been suggested [16]. In contrast to the Rayleigh breakup regime and the drop-on-demand regime, during atomization the ejected jet breaks up completely within a short distance from the discharge nozzle exit in a chaotic and irregular manner forming a conical spray. The aerodynamic interaction, i. e. the very fast relative motion combined with air friction, causes irregularities in the originally smooth liquid jet surface. This leads to unstable wave growth on the jet surface producing unstable ligaments. The average droplet diameter generated by atomization is much smaller than the jet diameter.

In conclusion it is possible to distinguish between different mechanisms of droplet breakup. These breakup mechanisms are [16]:

$8 < \mathrm{We} \leq 12$ Rayleigh breakup regime

$12 < \mathrm{We} \leq 40$ Drop-on-demand regime

$40 < \mathrm{We}$ Atomization regime

However, this classification originally was introduced for jet breakups and not for drop-on-demand breakups with short pressure pulses. Since the Weber number can be written using the Reynolds number and the Ohnesorge number the different breakup regimes can be illustrated in a diagram of Ohnesorge number versus Reynolds number, as

displayed in Fig. 6. Due to the hyperbolic dependency of the Ohnesorge number on the Reynolds number, the critical values are represented by lines in the logarithmic plot. Furthermore, in Fig. 7 the different breakup regimes are displayed depending on the velocity v and the droplet diameter D for water as ejected liquid ($\rho = 1\,\mathrm{g/cm^3}$, $\sigma = 72.5\,\mathrm{mN/m}$ and $\eta = 1\,\mathrm{mPa\,s}$).

Using an energetic approach, two necessary conditions for a given system can be deduced which are sufficient for droplet ejection of one single droplet with the diameter of the nozzle D_{nozzle} to take place. The critical pressure p_{critical} has to be exceeded during at least the critical time t_{critical} to enforce single-droplet formation. If the critical time is exceeded by far a jet rather than a single droplet is ejected. Both these criteria can also be expressed in the form that the critical power has to be surpassed to enforce single-droplet formation.

Future Directions for Research

The general aim of future research is the further optimization of droplet generation concerning minimum droplet volume, maximum print frequency, maximum throughput, maximum accuracy and precision, minimum pitches and maximum droplet quality. Due to this, it is essential to understand the basics of droplet generation mechanisms in detail and in three dimensions. Furthermore the development of new applications using different kinds of droplet dispensers is also part of current research work.

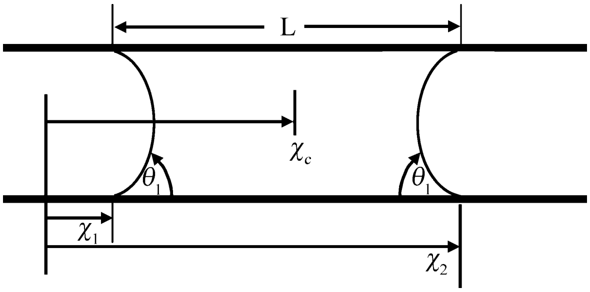
Definition

Droplet dynamics in microchannels refer to the description of motion and deformation of droplets in capillaries or conduits of hydraulic diameters of the orders of microns.



Droplet Dynamics in Microchannels, Figure 1 A deformable slug (droplet) in a micro-tube

Overview

Microscopic droplet formation and manipulation are key processes in many biomedical and biotechnological applications, involving the analysis of DNA, proteins and living biological cells. Droplets are also used to enhance the mixing efficiency in small volumes of fluids. In many of these applications, it is critical to understand the fundamentals of droplet dynamics through microchannels in a detailed manner, so as to impose stringent controls and optimization strategies for advanced bio-microfluidic arrangements.

Basic Methodology

To analyze the basics of droplet motion through microchannels, one may first consider a liquid slug of mass m and volume $\forall$ in a capillary tube of radius R, with the contact angles at its receding and advancing ends as θ_1 and θ_2, respectively. Let x_c be the centre of mass of the slug (refer to Fig. 1) and V_{r1} and V_{r2} be the contact line velocities of the two end caps. Neglecting inertial effects, the equation of motion of the slug can be written as

$$m\ddot{x}_c = (\cos\theta_2 - \cos\theta_1)\, 2\pi R - c\frac{V_{r1} + V_{r2}}{2} \tag{1}$$

where c is an equivalent frictional coefficient for the slug ($c = 8\pi\eta L$, for a fully developed flow with viscosity η). The volume, $\forall_{\text{sph}}$, enclosed by the spherical end caps and the plane that includes the contact line is determined by the contact angle, as

$$\forall_{\text{sph}}(\theta) = \frac{\pi R^3}{3}\frac{\cos\theta\,(2+\sin\theta)}{(1+\sin\theta)^2} \tag{2}$$

The centroid of the volume of the end cap, as measured from the plane of the contact line, can be obtained as

$$h(\theta) = \frac{3 - 2\sin\theta - \sin^2\theta}{4\cos\theta\,(2+\sin\theta)}R \tag{3}$$

To maintain the total volume of the slug as constant, the instantaneous slug length, i.e. $L(\theta_1, \theta_2)$, is determined by the initial slug length L_s and the static contact angle θ_s as

$$\begin{aligned}\forall &= \pi R^2 L_s - 2\forall_{\text{sph}}(\theta_s)\\ &= \pi R^2 L(\theta_1,\theta_2) - \forall_{\text{sph}}(\theta_1) - \forall_{\text{sph}}(\theta_2)\end{aligned} \tag{4}$$

$$\Rightarrow L(\theta_1,\theta_2) = L_s + \frac{1}{\pi R^2} \times \left[\forall_{\text{sph}}(\theta_1) + \forall_{\text{sph}}(\theta_2) - 2\forall_{\text{sph}}(\theta_s)\right] \tag{4a}$$

Position of the centre of mass of the slug can be obtained as

$$x_c = x_1 + \frac{\frac{\pi R^2 L(\theta_1,\theta_2)^2}{2} - \forall_{\text{sph}}(\theta_1)\, h(\theta_1)}{\forall} - \frac{\forall_{\text{sph}}(\theta_2)\,[L(\theta_1,\theta_2) - h(\theta_2)]}{\forall} \tag{5a}$$

and

$$x_c = x_2 - \frac{\frac{\pi R^2 L(\theta_1,\theta_2)^2}{2} - \forall_{\text{sph}}(\theta_2)\, h(\theta_2)}{\forall} - \frac{\forall_{\text{sph}}(\theta_1)\,[L(\theta_1,\theta_2) - h(\theta_1)]}{\forall} \tag{5b}$$

The contact line velocities at the two end caps (V_{r1} and V_{r2}) are related to the corresponding instantaneous positions as

$$V_{r1} = \frac{dx_1}{dt} \tag{6a}$$

and

$$V_{r2} = \frac{dx_2}{dt} \tag{6b}$$

Also, $\dot{x}_c$ is related to x_c as

$$\dot{x}_c = \frac{dx_c}{dt} \tag{7}$$

Equations (1), (4), (5a), (5b), (6a), (6b), (7) represent seven independent equations with nine unknowns, namely, $\theta_1, \theta_2, x_c, \dot{x}_c, V_{r1}, V_{r2}, x_1, x_2$ and L. To match the number of independent equations with the number of unknowns, two

additional independent constraining equations are necessary. These additional equations are available from the considerations of contact line slip, which can be generally described in the form of

$$\theta_{1,2} = f\,(V_r, \mathrm{Ca})_{1,2} \tag{8}$$

where Ca is the Capillary number ($\mathrm{Ca} = \eta V/\gamma_{lv}$). Detailed expressions for Eq. (8) depend on the particular slip models chosen. For a comprehensive physical description of the physical basis of 'contact line slip', the article on 'Electrocapillary' can be referred to.

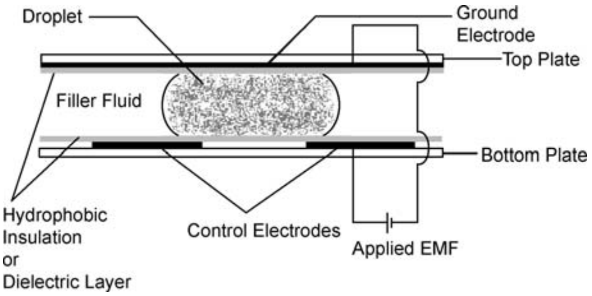
The one-dimensional droplet transport model, presented as above, is somewhat generic in nature, and can take special forms depending on the specific modes of droplet motion actuation. For example, one may consider the thermocapillary driven droplet motion in a cylindrical capillary, in which the surface tension varies as a function of the local temperature. For small temperature variations, this dependence is approximately linear, and can be described as

$$\gamma_{lv} = \gamma_{lv,0} - a\,(T - T_0) \tag{9}$$

where $\gamma_{lv,0}$ and a are constants, depending on the specific fluid being transported. Under these conditions, a simple analytical solution of Eq. (1) can be obtained, by neglecting the droplet deformation and contact line slip, as

$$\dot{x}_c = \frac{R}{4\eta L}\left(1 - \exp\left(-\frac{8\eta t}{\rho R^2}\right)\right)\left[\{\gamma_{lv,0} - a\,(T - T_0)\cos\theta\}_2 - \{\gamma_{lv,0} - a\,(T - T_0)\cos\theta\}_1\right] \tag{10}$$

Identical equations can also be derived in case the droplet motion is actuated electrically (voltage modulated contact angle variation). For the derivation of a fundamental model on electrocapillary dynamics of liquid droplets, one may refer to the work of Chakraborty and Mittal [1]. In their work, a novel theoretical approach was devised to analyze the droplet dynamics in a microchannel subjected to electrocapillary actuation mechanisms. For mathematical modeling, a droplet of polarizable and conductive liquid was taken to be sandwitched between two parallel plates constituting a microfluidic channel. The upper plate contained a single continuous ground electrode and the lower plate contained an array of independently addressable controlling electrodes. The electrode surfaces were covered with a thin layer of hydrophobic insulation. The physical situation pertaining to this arrangement is depicted in Fig. 2. The contact angles at the rear and the front ends of



Droplet Dynamics in Microchannels, Figure 2 A schematic layout of the analyzed microfluidic apparatus, showing the droplet of a liquid sandwiched between the electrodes and insulators

the advancing droplet, along with the other pertinent geometrical features are depicted in Fig. 3. From their analysis, it was revealed that there exists a threshold limit on the value of the inter-electrode pitch, beyond which the overall microfluidic transport rates are substantially lowered. On the other hand, with inter-electrode spacings below the threshold limit, unnecessarily large number of electrodes might be necessary to achieve a desired droplet transport rate.

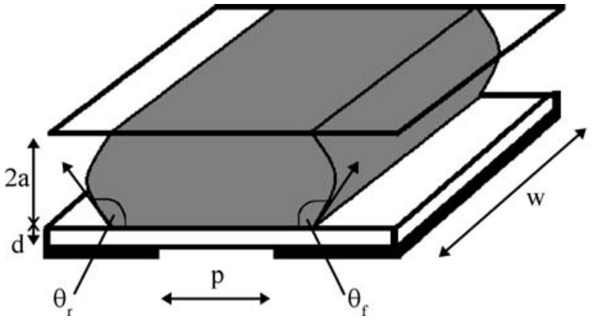
Key Research Findings

Mathematical models for describing the droplet dynamics in microchannels can turn out to be substantially more involved in case the multi-dimensionalities in the flow patterns need to be adequately resolved. One can demonstrate such a situation by describing the two-dimensional motion of a deformable droplet in a microchannel. The initial position and shape of the droplet are geometrically specified. Viscosity of the droplet is taken to be η_b and that of the continuous phase is taken to be η_c. For simplicity, the density of the two phases is taken to be the same ($= \rho$). The equations governing the flow-field in the microchannel, in this case, can be described as

$$\nabla \cdot \boldsymbol{V} = 0 \tag{11a}$$

$$\frac{\partial \boldsymbol{V}}{\partial t} + (\boldsymbol{V} \cdot \nabla)\,\boldsymbol{V} = \frac{1}{\rho}\left[-\nabla p + \nabla \cdot \left(2\eta \underline{\underline{\mathrm{D}}}\right) + \underbrace{\gamma \kappa \delta\,(d)\,\boldsymbol{n}}_{\text{surface tension force}}\right] \tag{11b}$$

where $\boldsymbol{V} = (u, v)$ is a two-dimensional velocity field, γ is the surface tension coefficient, κ is the curvature of the interface, $\underline{\underline{\mathrm{D}}}$ is the rate of deformation tensor, d is the normal distance to the interace, δ is the Dirac-delta function and $\boldsymbol{n}$ is the unit outward normal vector to the



Droplet Dynamics in Microchannels, Figure 3 A schematic diagram specifying the contact angles at the rear and the front ends of the advancing droplet, along with the other pertinent geometrical features

interface. For an accurate prescription of the surface tension force term in Eq. (11b), an appropriate interface coupling method needs to be employed, such as the volume of fluid (VOF) method [2], or the level set method [3–5]. Here, we briefly describe the later one, in context of the present problem under concern. In the level set method, a level set function, ϕ, is defined at each point in the flow-field such that at each point P, the absolute value of ϕ equals the distance from the same to the droplet interface. If P is inside the droplet, ϕ is assigned a negative value, whereas if it is outside the droplet, ϕ is assigned a positive value. The droplet interface corresponds to the points for which $\phi = 0$. The evolution of ϕ satisfies the condition $D\phi/Dt = 0$, or equivalently

$$\frac{\partial \phi}{\partial t} + (\boldsymbol{V} \cdot \nabla)\,\phi = 0 \tag{12}$$

It is important to note here that while ϕ is initially defined as a distance function from the droplet interface, it needs to be reinitialized at the end of each time step to preserve the same physical meaning. If ϕ_0 be the solution of Eq. (12) at the beginning of each time step under concern, the re-initialization can be achieved by solving the following problem to the steady state:

$$\frac{\partial \phi}{\partial t} = S\,(\phi_0)\left(1 - \sqrt{\left(\frac{\partial \phi}{\partial x}\right)^2 + \left(\frac{\partial \phi}{\partial y}\right)^2}\right) \tag{13}$$

where $S\,(\phi_0)$ is the sign function. Equation (13) is coupled with the following initial condition:

$$\phi\,(\boldsymbol{x}, 0) = \phi_0\,(\boldsymbol{x}) \tag{13a}$$

For numerical computations, $S\,(\phi_0)$ can be smoothened as

$$S\,(\phi_0) = \frac{\phi_0^2}{\sqrt{\phi_0^2 + \varepsilon^2}} \tag{13b}$$

Eq. (13) has the property that ϕ remains unchanged at the interface, which implies that zero level sets of ϕ and ϕ_0 are identical. Away from the interface, ϕ will converge to a value consistent with the condition $\nabla\phi = \sqrt{(\partial\phi/\partial x)^2 + (\partial\phi/\partial y)^2} = 1$, thereby replicating the true distance function. It is also important to note here that there is expected to occur a sharp discontinuity in the fluid viscosity across the droplet interface, for which special numerical considerations need to be invoked. In order to accommodate this feature, the interface is usually smeared out over a finite thickness of $2a$, so that a smooth variation of the viscosity can be represented as

$$\eta\,(\phi) = \begin{cases} \eta_c & \text{if } \phi > a \\ \eta_b & \text{if } \phi < -a \\ \bar{\eta} - \Delta\eta \sin\left(\dfrac{\pi\phi}{2a}\right) & \text{otherwise} \end{cases} \tag{14}$$

where $\bar{\eta} = (\eta_b + \eta_c)/2$, $\Delta\eta = (\eta_b - \eta_c)/2$. The delta function appearing in Eq. (11b) can also be smoothened accordingly, as

$$\delta\,(\phi) = \begin{cases} \dfrac{1}{2a}\left(1 + \cos\left(\dfrac{\pi\phi}{a}\right)\right) & \text{if } |\phi| < a \\ 0 & \text{otherwise} \end{cases} \tag{15}$$

where a is a small number related to the grid spacings, as mentioned earlier. Once the value of ϕ is numerically obtained, the surface tension force term in Eq. (11b) can be evaluated in a straight forward manner, with $\kappa = \nabla \cdot \boldsymbol{n}$, where $\boldsymbol{n} = \nabla\phi / |\nabla\phi|$ and δ is defined in accordance with Eq. (15).

The physical situation represented by the above description can get substantially more complicated in case the droplets are formed as a consequence of the instabilities associated with the evolution of a phase-separated binary fluid AB, which flows past the chemically patterned walls of a microchannel. The microchannel walls are assumed to be decorated with a checkerboard pattern [5]; each checkerboard being composed of two A(B)-like patches. These patches are preferentially wetted by the A(B) fluid. Two separate fluid streams (A and B streams) are introduced into the microchannel such that the A stream first encounters a B surface patch whereas the B stream first encounters a A surface patch. The binary fluid, in general, can be characterized by an order parameter $\psi\,(\boldsymbol{r}, t) = n_A\,(\boldsymbol{r}, t) - n_B\,(\boldsymbol{r}, t)$, where $n_i\,(\boldsymbol{r}, t)$ represents the local thermodynamic behaviour of the component i (often expressed in terms of the corresponding number density). For such

a syste, the free energy functional can be described as

$$F = \underbrace{\int \left[-\frac{a}{2}\psi^2 + \frac{b}{4}\psi^4 + \frac{k}{2}|\nabla\psi|^2 \right] \mathrm{d}\boldsymbol{r}}_{\text{Ginzburg–Landau free energy for a binary mixture}}$$
$$+ \underbrace{\int \mathrm{d}\boldsymbol{r} \int \mathrm{d}\boldsymbol{s} \left[\frac{1}{2}\xi(\boldsymbol{s}) \exp\left(-\frac{|\boldsymbol{r}-\boldsymbol{s}|}{r_0} \right) \right] [\psi(\boldsymbol{r}) - \psi(\boldsymbol{s})]^2}_{\text{interaction of a fluid element at a point } \boldsymbol{r} \text{ within the patterned substrate}} \quad (16)$$

In Eq. (16), a and b are positive constants. The fluid may considered to be in the two-phase coexistence regime, where the equilibrium order parameter is given by $\psi_{A(B)} = \pm\psi_{\text{eq}} = \pm\sqrt{a/b}$. The term $k/2|\nabla\psi|^2$represents the cost of order parameter gradients. The parameter $\xi(\boldsymbol{s})$ represents the strength of interaction at each point on the checkerboard pattern. On the patterns, one may introduce a noise in these interactions as $\xi(\boldsymbol{s}) = \xi(1 + \alpha\chi(\boldsymbol{s}))$, where $\chi(\boldsymbol{s})$ are independently distributed random numbers in the range $[-1, 1]$. The parameter ξ is a constant on the patterns and is zero, otherwise. In Eq. (16) the parameter r_0 represents the range of the substrate pattern. Some typical values of the above-mentioned parameters are as follows [5]: $r_0 = 5$, $\xi = 0.003$, $\alpha = 0.03$. Physically, the free energy functional is reduced when the fluid is A(B) rich near A(B)-like patterns. The evolution of the order parameter, as appearing in Eq. (16), is described by the Cahn–Hillard equation, in which the flux of ψ is proportional to the gradient of the chemical potential, μ, such that

$$J_\psi = -M\nabla\mu \quad (17)$$

where $\mu = \partial F/\partial\psi$ and M is the mobility of the order parameter. In dimensionless units, the evolution of ψ satisfies the following equation:

$$\frac{\partial\psi^*}{\partial t} + \boldsymbol{V}^* \cdot \nabla\psi^* = \nabla^2\mu^* \quad (18)$$

where the normalizing length scale is taken as the thickness of the interface between A and B, i. e. $l_{\text{ref}} = \sqrt{k/a}$, and the time scale is taken as $t_{\text{ref}} = l_{\text{ref}}^2/aM$. The governing equation for fluid flow, with negligible inertia effects, can be described in the following non-dimensional form:

$$0 = -\nabla\Pi^* + \nabla^2\boldsymbol{V}^* + \boldsymbol{H} + C\frac{\partial F^*}{\partial\psi^*}\nabla\psi^* \quad (19)$$

where $\boldsymbol{H} = H_x\hat{i}(x$ being the axial direction of microchannel flow), with $H_x = (P_{\text{in}} - P_{\text{out}})(l_{\text{ref}}t_{\text{ref}}/\eta L)$ and L is the length of the microchannel. The last term in Eq. (19) is the non-dissipative part of the stress tensor, representing the hydrodynamic interactions. The parameter C is estimated as $\gamma l_{\text{ref}}/aM\eta$, where the interfacial tension $\gamma \approx k\psi_{\text{eq}}^2/l_{\text{ref}}$, and aM is the diffusivity. For a fluid with high viscosity, one has $C \ll 1$, which implies that the hydrodynamic interactions can be neglected. The parameter Π^* (non-dimensional pressure) mathematically acts like a Lagrange multiplier, which generates the incompressibility condition $\nabla \cdot \boldsymbol{V} = 0$. The boundary conditions on μ andψ are as follows (where $\boldsymbol{n}$ represents a normal direction to the boundary surface):

$$\left.\frac{\partial\mu}{\partial n}\right|_{\text{wall}} = 0 \quad (20a)$$

$$\frac{\partial\psi}{\partial n} = 0\,, \text{ for unpatterned surfaces} \quad (20b)$$

$$\frac{\partial\psi(\boldsymbol{s})}{\partial n} = \int \mathrm{d}\boldsymbol{s}_i \left\{ \xi(\boldsymbol{s}_i) [\psi(\boldsymbol{r}) - \psi(\boldsymbol{s}_i)] \right\}\Big|_{\boldsymbol{r}\to\boldsymbol{s}}\,,$$
$$\text{for patterned surfaces} \quad (20c)$$

Equation. (20c) arises explicitly from the minimization of free energy in presence of the substrate patterning. At the microchannel entry and exit, one may write

$$\frac{\partial\psi}{\partial n} = 0 \quad (20d)$$

The dynamic evolution of the droplet, in such systems, strongly depends on the parametr H. For more details, one may refer to the work of Kuksenok et al. [5].

So far we have discussed the droplet dynamics in single straight microchannels only. Droplet dynamics in other microchannel geometries, on the other hand, may be associated with certain distinctive features that are not usually apparent with flows in single straight microchannels. As an example, one may cite the case of droplet motion in a microchannel geometry that is characterized with a sudden contraction in the cross sectional area. Rosengarten et al. [6] have recently presented an interesting study on this aspect, especially dealing with the cases in which the droplet size is larger than the contraction but is smaller than the original microchannel section. The droplet transport can be of a filament type or a slug type, depending on the contraction Capillary number (Ca_{con}) and the Reynolds number (Re) of flow. The average extensional strain rate due to a contraction can be approximated as $(\bar{u}_2 - \bar{u}_1)/L$, where $\bar{u}_2 - \bar{u}_1$ is the difference in mean velocity between the upstream and the downstream channels and L is the distance over which this change takes place. If $\beta = d_1/d_2$ be the contraction ratio of the two capillaries then it can be inferred that the entry length and the upstream vortex attachment length for the flow through the contraction are $0.25d_2$ and $0.17d_1$, respectively [6].

Assuming $L \approx 0.25d_2 + 0.17d_1$, accordingly, the extensional strain rate becomes

$$\dot{\varepsilon} = \frac{\bar{u}_2 - \bar{u}_1}{0.25d_2 + 0.17d_1} \tag{21}$$

For an axisymmetric contraction, $\bar{u}_2 = \beta^2 \bar{u}_1$ (from continuity), which implies

$$\dot{\varepsilon} = \frac{\bar{u}_1 \left(\beta^2 - 1\right)}{0.25d_2 + 0.17d_1} \tag{21a}$$

Hence, the contraction Capillary number can be described as

$$\mathrm{Ca}_{\mathrm{con}} = \frac{\eta_c \dot{\varepsilon} R_0}{\gamma} \tag{22}$$

where R_0 is the original radius of the initially-spherical droplet and $\dot{\varepsilon}$ is given by Eq. (21). Beyond a threshold value of $\mathrm{Ca}_{\mathrm{con}}$, there occurs a transition of the droplet morphology in the contraction, from the slug shape to the filament shape. The transitional value of $\mathrm{Ca}_{\mathrm{con}}$ decreases as the flow Reynolds number is increases. For details of the droplet shape and contact angle evolution under these circumstances, one may refer to the work of Rosengarten et al. [6].

Another interesting feature of droplet dynamics in microchannels can be observed in the T-junctions, across which the droplets can be sheared, extended and split. In order to elucidate the underlying dynamics from a fundamental perspective, one may consider an underformed droplet (with viscosity η_b) of radius R in a matrix fluid of viscosity η_c, with a local velocity gradient of magnitude G and surface tension γ. The stresses scale as $\eta_c G$ and the drop extension time-scale is as $(1 + \eta_b/\eta_c)/G$. The surface tension, on the other hand, tends to relax a deformed droplet back to its spherical shape. Scaling analysis reveals that the capillary velocity scale is as γ/η_c, the drop relaxation time-scale is as $(1 + \eta_b/\eta_c)\eta_c R/\gamma$, and the capillary stresses scale as γ/R. The corresponding extensional flow Capillary number is as $\mathrm{Ca}_{\mathrm{ext}} = \eta_c GR/\gamma$, which physically represents the ratio of the viscous to the capillary stresses, or equivalently, inverse of the ratio of the corresponding time-scales. For the onset of droplet break-up, $\mathrm{Ca} = \mathrm{O}(1)$. Since $G \sim Q_0/R_i^3$, where R_i is the hydraulic radius of the microchannel and Q_0 is the volumetric flow rate, the above condition implies

$$R \sim \frac{\gamma R_i^3}{\eta_c Q_0} \tag{23}$$

Expression (23) reveals that larger the flow rate, smaller is the droplet size. It is important to mention here that this expression is applicable only when $R < R_i$, i.e., when the droplets are small enough so that the hydrodynamic forces exerted by the channel walls are rather inconsequential and the breakup solely relies on the straining of the imposed flow. Identical considerations can be corroborated by the trends of the droplet breakup phenomena that can be observed across the microchannel T-junctions [7]. For an extensional flow in the neighbourhood of a T-junction, $G \sim u/w_0$, where w_0 is the channel width. One may note here that $\mathrm{Ca}_{\mathrm{ext}} = \eta_c GR/\gamma = \mathrm{Ca}R/w_0$, where $\mathrm{Ca} = \eta_c u/\gamma$ is the standard deformation Capillary number. Extensional stress at the stagnation point, being much larger than the shear stresses upstream of the junction, change the droplet length from l_0 to l_e. For the critical condition at which the droplet just breaks, one may write

$$(l_e - l_0) \propto (G - G_0)^{1/2} \tag{24}$$

where G_0 is the upstream shear rate. When $G_0 \ll G$,

$$\mathrm{Ca}_{\mathrm{ext}} \propto \left(\frac{l_e - l_0}{R}\right)^2 \tag{24a}$$

At the stability limit of the droplet,

$$\frac{l_e}{\pi w_w} \sim 1 \tag{24b}$$

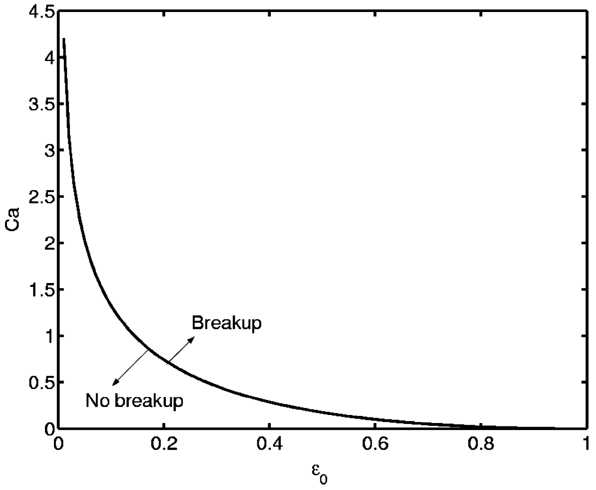
where w_e is the width of the stretched droplet. This criterion is consistent with the classical Rayleigh–Plateu instability, in which a cylindrical liquid thread can reduce its total surface area by breaking when its length (l_e) exceeds its circumference (πw_e). Further, from the considerations of volume conservation of the incompressible droplet, one may write

$$l_0 w_0^2 = l_e w_e^2 \tag{24c}$$

Using (24b) and (24c) in (24a) and denoting the initial extension as $\varepsilon_0 = l_0/\pi w_0$, a critical capillary number of droplet breakage at the T-junction can be estimated as

$$\mathrm{Ca}_{\mathrm{cr}} = \alpha \varepsilon_0 \left(\frac{1}{\varepsilon_0^{\frac{2}{3}}} - 1\right)^2 \tag{25}$$

where α is a dimensionless constant, which is a function of η_b/η_c and the geometry of the channel. For symmetrical T-junctions, $\alpha \sim 1$ has been found to excellently match with the experimental observations corresponding to the critical conditions for the breaking of droplets [7]. It is also important to note here that with $\varepsilon_0 > 1$, droplets are always found to break in the T-junction, even for the lowest achievable values of Ca (see Fig. 4). On the other hand,



Droplet Dynamics in Microchannels, Figure 4 Critical conditions for droplet breaking at T-junctions

they never break up upstream in the straight portion of the channel preceeding the T-junction, despite satisfying the breaking criterion mathematically. This can be attributed to the fact that before the onset of breaking, the droplet may be perturbed with associated crests and troughs. The portions of the greatest lateral extensions (i. e., the crests) are characterized with pressures that are higher than the pressures at the regions of greatest lateral contractions (troughs). To restore the equlibrium, liquid would flow from higher pressure to lower pressure, thereby stabilizing the droplet. Physically, the confinement of the channel walls imparts the stabilizing effect to the droplet at the upstream locations, preventing the droplet breakup. At the T-junction, however, the droplet is offered with a provision of being free of any confinement over at least one portion of its lateral faces, allowing the perturbations to grow and the droplet to break up.

The development of fundamental models on droplet dynamics through microchannels has lead to a number of analytical and numerical studies reported in the literature in the recent past. Scheeizer and Bonnecaze [8] employed the boundary-integral method to numerically simulate the displacement of a two-dimensional droplet attached to a solid surface when the inertial and gravitational forces are negligible. These authors showed that as the capillary number was increased, the deformation of the droplet increased until a critical value was reached. Beyond this limit, no steady droplet shapes were observed. Increasing the droplet size resulted in an increase in the deformation of the interface at a given capillary number. The deformation of the droplet was found to be more severe with higher viscosity ratios. Both shear and pressure-driven flow regimes were examined and were shown to have similar values of the critical capillary number. Further, addition of surfactants was shown to reduce the deformation of the pinned droplets, as the surface Péclet number was increased.

Future Directions for Research

A comprehensive review on theoretical modeling and simulation of droplet dynamics in microchannels has been presented by Cristini and Tan [9]. In their paper, theoretical considerations relevant to controlled droplet generation, breakup and coalescence in micro channels were discussed. In particular, theoretical and numerical investigations of droplet breakup and coalescence in imposed flows were reviewed, including the methodologies commonly employed for simulating droplet generation, dynamics, breakup and coalescence in micro channels. From their review, following major conclusions could be drawn:

1. The magnitude and type of flow are both important in determining generation, breakup and coalescence times and droplet sizes. Detailed quantitative estimates in this regard are yet to be made.
2. The local velocity gradient imposed on a droplet is a function of position in the micro channel, and is a strong function of the channel geometry. This also needs to be studied from a more rigorous theoretical perspective.
3. The microchannel geometry and flow conditions can be optimised using adaptive simulations. More extensive research can be directed towards this aspect.
4. One open area on droplet based microfluidics research is the issue of droplet–wall interactions. For droplets of size comparable to the microchannel width, the hydrodynamic forces exerted by the wall on the droplet may exceed those exerted by the imposed channel flow. Under these situations, the droplet deformation, breakup and coalescence criteria and rates may be strongly affected, which are yet to be theoretically well-resolved.

Synonyms

Liquid–vapor phase change; Vaporization

Definition

The difference in the vapor pressure immediately above a droplet surface and the ambient (partial) pressure of the vapor far away from the drop, drives a diffusive flux leading to a gradual decrease of the liquid volume, which is termed droplet evaporation. Within a molecular picture, the probability of highly energetic liquid molecules going over into the gas phase is higher than that of them being re-adsorbed (condensating) in the course of the subsequent random walk (Brownian motion). Thus, there is a net-flow of molecules from the liquid to the gaseous phase. The associated transferred energy is termed the latent heat or enthalpy of vaporization.

Overview

Droplet evaporation plays a vital role in various fields of natural science and engineering such as: cloud physics, burning liquid-fuels, air/fuel-premixing, (biological) crystal growth, and painting. Moreover, the high heat transfer rates associated with evaporation suggests its use in contexts with a variety of thermal applications, such as spray-cooling or in the electronics industry for cooling of integrated circuits with high heat dissipation rates. Probably the most common application involving droplet handling and evaporation is ink-jet printing. Using piezo or thermally actuated print heads droplet sizes down to a few picoliters are generated. While home and common office applications rely on aqueous inks containing dyes or pigments, versatile printers suitable for polymer substrates use solvent inks with volatile organic liquids. Yet, ink-jet technology has a potential far beyond these applications, for instance in (bio-)chemistry or electronics, where circuit boards can be inexpensively manufactured by printing the electronic components.

Generally, phase change is governed by two counteracting aspects. On the one hand attractive intermolecular interactions which give rise to interfacial tension keep the liquid molecules together. Due to this surface tension small liquid volumes attain a minimum surface, i. e., a spherical shape for a free-floating drop. On the other hand the liquid molecules obey an energy distribution. A fraction of the molecules have energies above a certain threshold allowing them to overcome the cohesive forces within the liquid. These molecules give rise to the vapor pressure above the liquid surface. Moreover, when the *highly* energetic molecules go from the liquid to the vapor phase thermal energy (latent heat) is removed from the bulk liquid.

Besides these applications, droplet evaporation reveals several intriguing phenomena and is a prime example of a microfluidic *multiphysics* system, which is noticeably complex due to the interplay of mass and heat transfer, hydrodynamics of multiphase flow, interface energy effects as contact angle hysteresis, volumetric forces as gravity, and Marangoni flows.

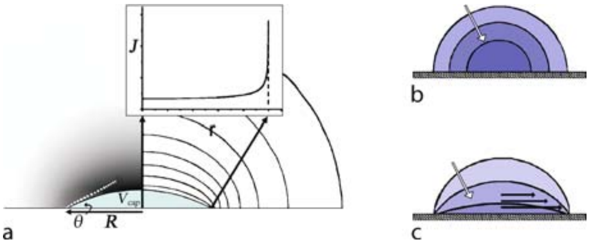
In the present essay we focus on a commonly encountered case of slow evaporation of sessile drops, with an initial volume ranging from a few pL to some μL, typical evaporation times between 10^{-1} s and 10^{2} s, and we assume a stagnant ambient gaseous phase. Within the chosen model approach the restriction to sessile drops does not impose any major limitations since the dynamics of evaporating levitated spherical drops are recovered for the special case of a 90° contact angle. Moreover, slow evaporation of minute drops on a relatively *thermally heavy* substrate implies that typical temperature changes are small and may be neglected within qualitative modeling approaches.

Furthermore, we neglect forced or natural (buoyancy-driven) convection, surface oscillations and spreading phenomena; not to mention more sophisticated aspects such as Leidenfrost effects, i. e., retardation of evaporation on a hot substrate due to droplet levitation by the vapor, or aspects of thin film evaporation in the microregion, where the material properties deviate considerably from the bulk properties.

Basic Methodology

The experimental methods used to observe droplet evaporation which have been reported in the literature, may rely on the monitoring of successive silhouettes of sessile drops by video-microscope imaging, or on ultraprecision weighing with electronic microbalances and with quartz crystal microbalances, or on the use of atomic force cantilevers. What all these methods typically have in common is that data are provided which allow, among other possibilities, monitoring the decrease in the droplet volume over time. From this, material properties such as the vapor diffusion coefficient (D), the saturation pressure (p_{sat}), or likewise the saturation vapor concentration (c_{sat}), or for instance the solid–liquid contact angle (θ), may be deduced. But, the physical interpretation of the data requires some mathematical considerations. We will therefore outline the basic governing equation revealing the dependence of the volume change on the above-mentioned properties.

A comprehensive overview of the mathematical description has been given in [1] and in the original work cited therein. Here, we just present a brief outline along with the basic considerations. Small droplets with dimensions well below 1 mm take the shape of a spherical cap which in the present case is assumed to rest on a planar surface. The droplet volume V_{cap} can be expressed in terms of the contact angle θ and the contact line radius R, i. e., the radius of the circular three-phase contact line (cf. Fig. 1a):



Droplet Evaporation, Figure 1 (**a**) Left side: simulated vapor concentration (gray-scale encoded) above a spherical-cap shaped droplet. Right side: iso-lines of vapor concentration. The inset shows the local evaporation rate (J) as function of the radial coordinate. The large concentration gradient (narrow iso-lines) leads to a diverging flux close to the three-phase contact line. (**b**) Sketch of an evaporating droplet in the constant contact angle mode. The arrow denotes the shrinkage of the droplet in the course of the evaporation. (**c**) Sketch of the pinned-contact line evaporation mode. Black arrows indicate the internal convective flow caused by the large evaporation rate at the rim

$$V_{\text{cap}} = \pi R^3 \frac{\beta(\theta)}{3\sin^3\theta}\,, \text{ with } \beta(\theta) = 2 - 3\cos\theta + \cos^3\theta \tag{1}$$

Examining the various timescales involved shows that droplet evaporation is commonly diffusion limited. Since the characteristic vapor diffusion times are well below the typical droplet evaporation times [2] the vapor concentration is assumed to adapt *instantaneously* to a droplet deformation, and within the so-called quasisteady approach the dynamics of the evaporation is controlled solely by the diffusional mass transport from the droplet surface into the ambient gas phase. A characteristic vapor distribution above the droplet, obtained by finite-element simulations, is shown in Fig. 1a. The local evaporation rate (with dimensions of mass per area and time), which is proportional to the gradient of the concentration at the droplet surface, is a function of the radial coordinate and the contact angle. But for the time being we leave these details aside. To determine the volume decrease of the droplet we need the total evaporation rate (mass per time), which is obtained by integrating the local evaporation rate over the droplet surface. Without going through the few intermediate steps we will simply discuss some consequences of the resulting equation which governs the decrease in droplet volume

$$-\left(\frac{\mathrm{d}V_{\text{cap}}(\theta,R)}{\mathrm{d}t}\right) = \frac{4\pi}{\rho_{\text{L}}}\left(\frac{3V_{\text{cap}}(\theta,R)}{\pi\beta(\theta)}\right)^{\frac{1}{3}} D\Delta c f(\theta) \tag{2}$$

where ρ_{L} denotes the liquid density, D is the diffusivity of vapor molecules in the gas phase, and Δc is the difference

between the saturation concentration c_{sat} and the ambient vapor concentration far away from the droplet. The function $f(\theta)$ contains the dependence of the total evaporation flux on the contact angle. A simple expression which approximates the exact dependence to within a few percent over almost the entire contact angle range is [1]

$$f(\theta) \approx -\frac{\cos\theta}{2\ln(1-\cos\theta)} \tag{3}$$

The temperature dependence of the evaporation is basically governed by two effects: the strong increase in the vapor pressure (and saturation pressure) with temperature (Antoine correlation) and the relatively weak temperature dependence of the diffusivity ($D \sim T^{1.75}$).

To recap, the evolution of the droplet volume in the course of evaporation obeys Eq. (2). However, the volume depends on the parameters θ and R, which may vary independently as function of time. Hence, the evaporation dynamics is not fully determined by a single equation. There are, however, two important limiting cases which are often encountered in experiments where Eq. (2) is sufficient.

Case (I): fixed contact angle $\theta(t) = \theta_0 = \text{const}$, $R(t)$ variable. On smooth, ideal surfaces in the absence of any contact angle hysteresis and dynamic effects the contact angle remains constant independent of the contact line radius, i. e., independent of the contact line position, and the radius of curvature of the interface (Fig. 1b). In this case Eq. (2) can readily be integrated, thus yielding the explicit volume decrease

$$V_{\mathrm{cap}}^{\frac{2}{3}} = V_{\mathrm{cap;init}}^{\frac{2}{3}} - \frac{2}{3} K f(\theta_0) \cdot t \tag{4}$$

where $V_{\mathrm{cap;init}}$ denotes the initial droplet volume and remaining constants have been lumped together into K ($\approx 12.37 \cdot D\Delta c/\rho_L \cdot \beta^{1/3}$). Note that Eq. (4) also covers the case of a floating evaporating droplet for the particular case $\theta_0 = \pi (f = 0.5)$ and $V_{\mathrm{drop}} = 2V_{\mathrm{cap}}$.

Case (II): pinned contact line $\theta(t)$ variable, $R(t) = \text{constant}$. On the other hand for inhomogeneous surfaces or under other nonideal conditions the contact line can be perfectly pinned. The contact line radius and thus the wetted area stay constant and the contact angle decreases over time, as sketched in Fig. 1c. In this case Eq. (2) has to be numerically integrated.

In both cases the complete evaporation dynamics is governed by Eq. (2) since the droplet volume only depends on one variable. In the case of slip-stick behavior, i. e., alternating behavior alternating between cases I and II, the data analysis can also be performed based on the above equation.

Key Research Findings

In this section we focus on some of the most important features of evaporating sessile drops: the scaling resulting from the above model and the consequences of the spatial nonuniform evaporation current commonly known as the *coffee stain* or *donut effect*.

For case I, Eq. (4) facilitates the determination of any of the involved quantities from experimental data of the droplet volume provided that all remaining parameters are known. Specifically, the predicted linear dependence of $V_{\mathrm{cap}}^{2/3}$ on time is commonly observed and allows for a reliable determination of parameters. As an example, the evaporation data of toluene, butanol and two alkanes are shown in Fig. 2. The factors $K \cdot f(\theta)$ are readily determined by linear fitting, cf. Eq. (4). But, in order to increase the quality of the parameter fits, a more accurate correlation than Eq. (3) is recommended [1]. Such a data analysis can be used to estimate the cooling of droplets during evaporation.

Furthermore, Eq. (4) implies the scaling of the total evaporation time (T_{evap}), the time it takes until the droplet has vanished, with the initial droplet volume, namely

$$T_{\mathrm{evap}} \propto V_{\mathrm{cap;init}}^{\frac{2}{3}} \tag{5}$$

This may also be exploited to determine the material constants. Eq. (5) also holds in the pinned (constant-radius) mode. In this case a faster evaporation is to be expected, due to the larger specific evaporation area. However, the precise value of the model-predicted proportionality constant is beyond analytical means and has to be computed numerically.

Further interesting physics is revealed by considering the evaporation rate in more detail. Exploiting the analogy between the concentration field outside an evaporating drop and the electrostatic potential of a similar-shaped charged body, as proposed by Maxwell more than a century ago, one can show that the evaporation current (J) is not constant all over the drop surface (cf. Fig 1a, right-hand side). In particular a diverging evaporation current is found at the outer edge near the contact line. This can be qualitatively explained within the molecular picture of the diffusion process, i. e., Brownian motion. Molecules which diffuse into the vapor phase leaving the drop at the center perform a random walk and thus have a high probability of being re-adsorbed at the liquid surface. Yet, for contact angles less than 90° the probability of re-adsorption at the liquid surface is lower for molecules which escape at the edge leading to a higher net evaporation flux near the contact line [3]. Moreover, as mentioned above, the contact lines are likely to be pinned on nonideal

Droplet Evaporation, Figure 3 (**a**) Coffee stain arising from a nearly spherical cap droplet. (**b**) Ring stain after deposition of a larger drop showing a more (less) pronounced perimeter ring of deposited particles for a convex (concave) curvature of the contact line. (**c**) and (**d**) coffee stains showing less accentuated perimeter rings in regions where vapor concentration fields interfere

surfaces. Due to the large evaporation at the pinned contact line fluid has to be replenished from the drop interior leading to a radial outward flow within the drop as shown in Fig. 1c. This flow can be directly observed in experiments if, for instance, fluorescence particles are suspended in the drop. However, its consequence for the deposition of dispersed material after complete droplet evaporation is more obvious. Due to the outward flow material is constantly transported to the outer rim where the fluid evaporates most rapidly and the suspended material is deposited. This leads to the well-known *coffee stain* phenomenon: an evaporating droplet leaves a deeply colored outer rim of the initially suspended material whereas the interior of the wetted area is observed to stay almost coffee-free [3]. Corresponding experimental images of coffee stains are shown in Fig. 3. Fig. 3a shows a typical stain arising from a nearly spherical-cap droplet. Fig. 3b shows the influence of the contact line curvature for noncircular drops and Figs. 3c and 3d indicate that the stains of evaporated drops are altered due to the influence of droplets in the near vicinity [3]. As discussed above, the accumulation of suspended material during evaporation is driven by an internal convective flow within the drop which, in turn, is caused by the large evaporation near the contact line. Consequently, if evaporation at the contact line is decreased by locally increasing the ambient vapor concentration, e. g. by placing a second drop in the near vicinity, the tendency toward ring formation is suppressed (cf. Figs. 3c and 3d). The same arguments hold in the context with more (less) pronounced material accumulation near convex (concave) contact lines, as shown in Fig. 3b.

Coffee stains are a very clear example of surface patterning by means of evaporation. Since the patterns are predominantly created in the vicinity of the contact line, high-resolution patterns are achievable by surprisingly simple means. However, what has been discussed so far is just one particular scenario, generally various mechanisms are involved in pattern formation. A list of the most important ones is given below [4].

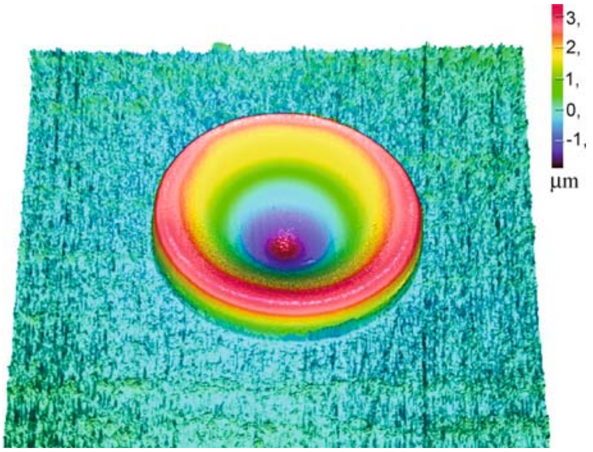
- High (diverging) evaporation rate of liquid near the contact line for contact angles less than 90°, which induces a radial outward flow toward the drop periphery, as discussed above.
- Pinning and depinning phenomena: the prerequisite for pronounced ring formation to occur is the pinning of the contact line. In many experiments pinning is observed right at the beginning of the evaporation, whereas the contact line may be released in the later stages and evaporation proceeds in the constant contact angle mode. The formation of ring stains, i. e., the deposition of solute at the three-phase contact line, strength-

ens an initial pinning or it may even initiate it. This so-called self-pinning mechanism can lead to various deposition patterns from cellular to almost fractal structures [3].

- Evaporation-induced higher solute concentration and lower temperature near the contact line cause the so-called Marangoni flows. These flows occur since the surface tension depends on various parameters such as the concentration of dissolved species and the temperature. Any gradient in these quantities induces a spatial variation of the surface tension and a corresponding pressure variation within the liquid which manifests itself in a convective flow.
- The temperature gradient within the droplet perpendicular to the substrate can induce Rayleigh–Bénard convection cells. The corresponding convective cells grow stronger near the drop periphery due to smaller thickness and a corresponding higher temperature gradient there.
- Interactions within the suspended material, such as colloidal nanoparticles [5, 6] and interactions between the suspended material and the susbstrate (see below).

The presence of surfactants, which adsorb at the liquid–vapor interface and reduce the surface tension, can also have a large impact on the evaporation-driven pattern formation. Inhomogeneities in the surfactant distribution create a surface tension gradient and a corresponding (additional) Marangoni flow. With respect to the Rayleigh–Bénard convection it has been shown that the surfactant-driven flow can favor the formation of convection cells and considerably alter the deposition patterns [7].

In the context of particle–particle interaction (the final point in the above list) it has been reported that subsequently to the accumulation of material at the outer rim capillarity mediated interaction can drive the particles into regular assemblies [5]. These self-organized patterns vary from the previously discussed *coffee* rings built up from particle monolayers for relatively low initial particle concentrations to plane crystal multilayers for higher particle volume fractions. Large, highly regular arrays of complex aggregates of nanoparticles are obtained by means of template-assisted methods, where patterned arrays of hydrophilic spots are used for regular arrangements of droplets and self-organization occurs within the droplets. Generally any kind of particle can be arranged by this technique provided that it has been well wetted by the evaporating carrier fluid [5, 6]. In this sense droplet evaporation provides additional features for evaporation-based colloidal crystallization. Furthermore, even the self-assembly of DNA in the so-called starburst pattern by deposition from evaporating drops has been observed [8, 9].



Droplet Evaporation, Figure 4 False-color surface plot of a microcrater caused by a toluene drop on polystyrene (molar mass 210 kDa, PDI = 1.07) after evaporation. The drop was deposited on the polymer substrate with a syringe, and the resulting microstructure was imaged with a confocal white-light microscope. (Figure provided by K Graf, Max-Planck-Institute for Polymer Research, Mainz, Germany)

Future Directions for Research

The patterning methods mentioned so far all involve nondissolving substrates. But, using dissolving substrates instead opens up a new field of research. For a solvent drop on a polymer surface, the substrate is locally softened and dissolved. Similar to the above-mentioned case of liquid suspensions, molecules from the substrate are transported to the rim. Close to the contact line the solute concentrations increases and piles up due to precipitation. Thus, by means of evaporation-driven internal convection, the topography of the substrate is changed. Within the given scenario the above list of mechanisms has to be expanded by dissolving/precipitation and phenomena resulting from the interaction with other effects. A typical microcrater formed by the deposition and subsequent evaporation of toluene on a polystyrene substrate is shown in Fig. 4. Similarly, microcraters of optical quality which can be utilized as concave lenses have been realized by Bonaccurso et al. [10] using ink-jet deposition of solvent droplets. Lenses with diameters between 20 µm and 200 µm and depths ranging from 100 nm to 8 µm could be realized, depending on the choice of droplet volumes and the number of deposited drops. This method provides a simple and inexpensive way of fabricating microvessels and microlenses, whose properties can be tailored by an appropriate choice of substrate materials, pure solvents or mixtures with different volatilities, number of droplets and dimensions.

Definition

A droplet microreactor is a reaction platform that enables chemical reactions to be carried out inside a microdroplet with a volume on the order of a few microliters or less. The droplets are formed and suspended in an immiscible phase such as an oil. Mixing is achieved inside the droplet on the basis of chaotic advection, which is induced by either droplet motion or the channel shape.

Overview

The main advantages of droplet microreactors are the small amount of reagents, the enclosed reaction environment, and rapid mixing. Droplet microreactors are often

protected by an immiscible phase such an oil which prevents evaporation of the droplets. Thus, besides fast reactions, long processes such as protein crystallization can also be carried out in droplet microreactors.

There are two basic platforms for droplet microreactors: the planar platform and the in-channel continuous platform. In a planar platform, the droplet can move freely on a planar surface, while the motion of the droplet in an in-channel continuous platform is restricted by microchannels. The actuation of droplets in a planar platform is based on nonmechanical concepts such as electrowetting, thermocapillary forces, and magnetic forces. Most in-channel continuous platforms rely on pressure to move the droplets.

Both platforms for droplet microreactors require the following key functions for manipulating droplets: droplet formation, droplet transport, mixing inside droplets, droplet merging, and droplet splitting. In the following, the basic methods for obtaining these functions are discussed.

Basic Methodology

Planar Platform

Electrowetting

Direct electrowetting and electrowetting on dielectric are best suited for planar droplet microreactors. Electrowetting can be used for dispensing and transporting a liquid droplet [1]. Figure 1a depicts the general concept of electrowetting on dielectric. The aqueous-droplet microreactor is surrounded by an immiscible phase. For actuation, the droplet should be aligned with the control electrodes on the bottom surface. Applying a voltage to the electrode changes the hydrophobicity of the solid/liquid/liquid contact line. The difference in interfacial stress across the droplet causes its motion. An insulating layer and a hydrophobic layer function as the dielectric. The hydrophobic layer is made of a polymer with a low surface energy such as Teflon. The top electrode is made of transparent indium tin oxide (ITO) for optical access to the droplet reactor. Figures 1b–e show the various handling operations of a droplet microreactor: dispensing, merging, cutting, and transport. These basic operations allow merging and fast mixing of liquid droplets. The concept also works with liquid droplets surrounded by air. However, the liquid/air system may have the disadvantage of evaporation. A droplet microreactor based on electrowetting needs an electrolyte as a working fluid.

Thermocapillarity

Thermocapillary forces can be used to manipulate a droplet microreactor in the same way as electrowetting does [2]. However, the elevated temperature required may cause evaporation and, in the worst case, boiling of the droplet. Thermocapillary stresses caused by spatial variations of the surface tension at a gas/liquid interface can induce spontaneous flow of a liquid film to a cooler position. The surface tension at the cooler position is higher and induces a tangential force that moves the liquid droplet to the cooler place. Figure 2 depicts the device concept for a droplet microreactor based on thermocapillarity. The droplet is positioned on a homogeneous, partially wetting surface. The wetting surface also functions as an electrical insulator from the underlying heater. A heater array controls the temperature gradient at the surface and consequently the motion of the droplet. Compared with electrowetting, thermocapillarity is much slower owing to the relatively large heat capacity of the surface.

Magnetism

Magnetic forces can also be used for manipulating droplet microreactors [3]. Magnetic beads or a ferrofluid are needed for this actuation concept. Instead of electrodes or heaters, microcoils are integrated on the surface. Figure 3 shows the basic configuration of a magnetically actuated droplet microreactor. A pair of permanent magnets polarizes the magnetic particles in the droplet. A coil array induces a magnetic gradient, which moves the droplet.

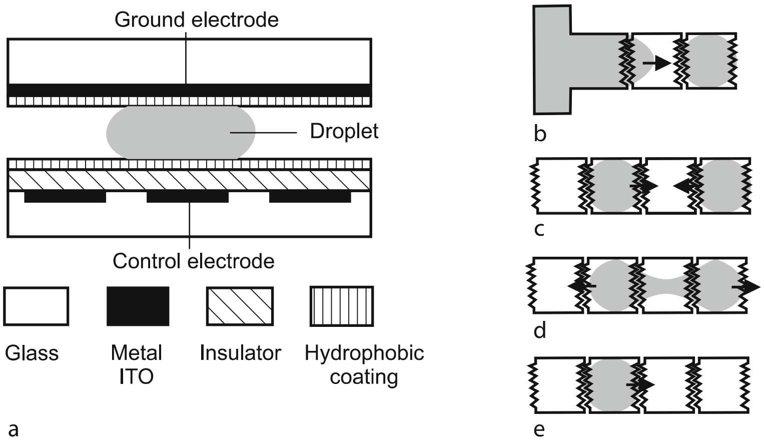
In-Channel Continuous Platform

Droplets are formed by shear stress or a pressure drop in an in-channel continuous platform. The two basic configurations for droplet formation are shown in Fig. 4. The cross-junction configuration is similar to that for hydrodynamic focusing. The carrier fluid enters the channel from the middle inlet, while the droplet liquids join from both sides (Fig. 4a). The T-junction configuration lets the droplet liquids join perpendicular to the carrier flow (Fig. 4b). The formation behavior of droplets depends on the Capillary number, which represents the ratio between the friction force and the surface tension in a two-phase system,

$$\mathrm{Ca} = \frac{u\mu}{\sigma}, \tag{1}$$

where u is the mean velocity, μ is the dynamic viscosity, and σ is the interfacial tension between the two liquid phases, and on the sample fraction, which is defined as the ratio between the volumetric flow rate of the aqueous droplet liquid and the total volumetric flow rate of both phases,

$$r = \frac{\dot{Q}_{\mathrm{solution}}}{\dot{Q}_{\mathrm{solution}} + \dot{Q}_{\mathrm{Carrier}}}, \tag{2}$$



Droplet Microreactor, Figure 1 Droplet microreactor based on actuation by electrowetting. (**a**) Device concept. (**b**) The liquid is pulled in by activating the two electrodes on the right. When the middle electrode is turned off, surface tension breaks up the droplet, allowing precise dispensing. (**c**) Turning on the second electrode from the right lets the two droplets merge. (**d**) Turning on the first and the third electrode from the right causes the droplet to split. (**e**) Subsequent activation of the electrodes allows droplet transport

where $\dot{Q}_{\text{solution}}$ and $\dot{Q}_{\text{Carrier}}$ are the flow rates of the reactant solution and the carrier fluid, respectively.

Key Research Findings

Mixing in Droplet Microreactors

Planar Platforms

Mixing in planar platforms can generally be obtained by use of three actuation modes: merging, splitting and moving (Fig. 1c–e). Because of the small size of the droplets, coalescence alone allows mixing based on molecular diffusion within the droplet. Paik et al. reported a mixing time of 90 s for an approximately 2 μl droplet [1]. Moving the droplet around induces internal flow inside the droplet, which allows folding and stretching of the fluid, with short, chaotic advection. Chaotic advection created by a periodic split-and-merge action as shown in Fig. 1c, d reduces the mixing time to approximately 2 s at a 16 Hz switching frequency. Chaotic advection inside the droplet can also be induced by moving the merged droplet around (Fig. 1e). The droplet can be moved along a line with a $1 \times N$ electrode array or in a loop with a $2 \times N$ electrode array. The best mixing time, of 3 s, with this merge-and-move concept was achieved with a 2×4 electrode array [4].

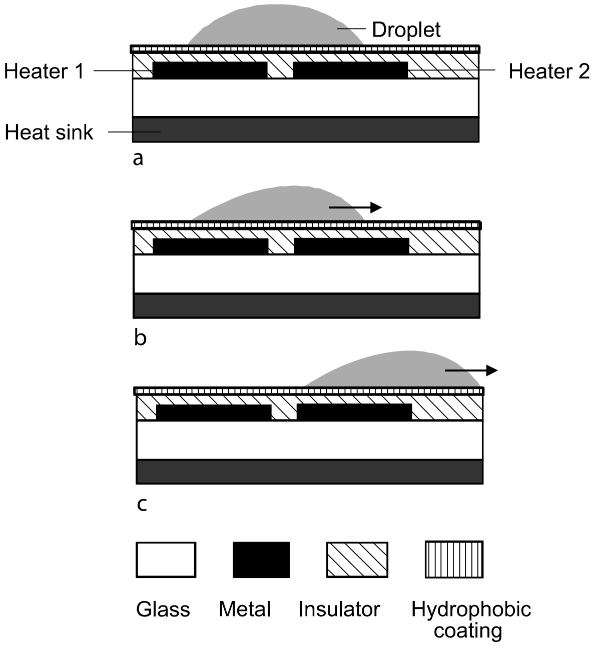
In-Channel Continuous Platforms

Because the droplets are formed directly in the microchannel, very small droplet microreactors with sizes in the range 1 pl to 100 nl can be formed in an in-channel continuous platform. The confined environment removes the residence time distribution due to the nonuniform velocity profile that occurs in continuous-flow platforms, also known as dispersion. When a droplet moves in a microchannel, the shear stress on the droplet wall induces an internal flow pattern, which can be used to produce chaotic advection to improve mixing. However, if the microchannel is straight, as depicted in Fig. 5a, the flow pattern inside the droplet is symmetric and steady. The two vortices containing the reactants A and B exist in separate halves of the droplet and mixing is not improved significantly. If the microchannel has bends as depicted in Fig. 5b, the droplet has different velocities at the walls on the two sides owing to the different radii of curvature. Thus, the internal flow pattern is asymmetric and periodic. While moving through this repeating channel pattern, each side of the droplet takes its turn to have the faster vortex. Chaotic advection and, consequently, faster mixing can be achieved. In this concept, the larger vortex is dominant over the smaller vortex for each bend; this resembles the reorientation, stretching, and folding needed for micromixers based on chaotic advection. Since the number of cycles depends on the number of bends n, the improvement of mixing time compared with the case of a straight channel is 4^{n-1}. Compared with diffusive mixing with parallel lamination, the improvement of the mixing time can be described as follows:

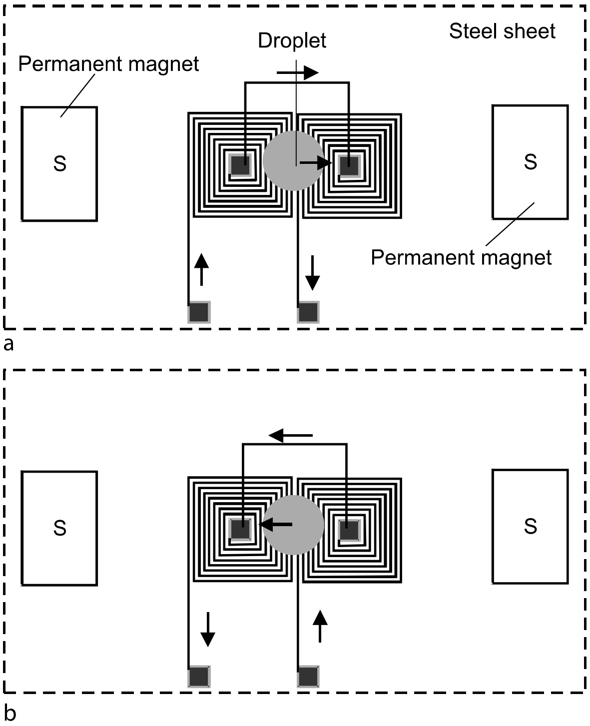
$$\frac{t_{\text{chaotic}}}{t_{\text{diffusive}}} = \frac{\text{Pe}}{L^* \log \text{Pe}} \qquad (3)$$

where

$$\text{Pe} = \frac{uW}{D} \qquad (4)$$



Droplet Microreactor, Figure 2 Droplet microreactor based on thermocapillary actuation. (**a**) Without a temperature gradient, the droplet is at equilibrium and does not move, (**b**) If heater 1 is on, the induced temperature gradient propels the droplet owing to the difference in surface stress between the sides of the droplet. (**c**) If the droplet moves out of the temperature field of heater 1, heater 2 is activated to propel the droplet further



Droplet Microreactor, Figure 3 Experimental setup for controlling ferrofluid droplets. The permanent magnet and the soft magnetic steel sheet create a permanent magnetic field that polarizes the magnetic particles in the ferrofluid droplet. The coils are wired in such a way that their generated magnetic fields have opposite signs. The magnetic gradient generated by the two coils drives the ferrofluid. The direction of motion is determined by the direction of the current: (**a**) motion to the right, (**b**) motion to the left

is the Péclet number, and

$$L^* = \frac{L}{W} \tag{5}$$

is the dimensionless droplet length normalized by the channel width W.

Applications of Droplet Microreactors

Droplet microreactors find their main applications in analytical chemistry and chemical synthesis.

Chaotic advection inside droplet microreactors on a planar platform allows efficient mixing of large molecules such as DNA. A planar platform can accommodate both a droplet mixer and a reaction chamber for the polymerase chain reaction [6]. Droplets containing DNA samples and primer are merged and moved in a loop. Chaotic advection inside a droplet leads to fast mixing. The merged droplet is subsequently transported to a temperature-controlled region and undergoes thermal cycles. Both sample consumption and analysis time can be reduced significantly with droplet microreactors. In combination with an optical detection system, droplet microreactors can be used for biomedical diagnosis. Srinivasan et al. have demonstrated the detection of glucose in a planar platform based on merging and mixing with electrowetting [7].

Owing to their high throughput, in-channel continuous-flow platforms are more suitable for chemical synthesis. One popular application is the synthesis of colloidal nanoparticles such as CdS and CdS/CdSe particles [8]. Transporting the nanoparticles as reaction products in microdroplets prevents them from aggregating on the channel wall. Furthermore, a double emulsion could form an encapsulating layer around the droplet. Pills containing nanoscale drug particles can be synthesized with this reaction platform. Continuous-flow platforms allow one to form an array of alternate droplets in a capillary. This configuration allows diffusion of water from a droplet to a neighboring droplet containing a concentrated salt solution, owing to osmotic pressure. Protein crystallization can be achieved with this concentration method [9].

The droplets formed have the shape of a sphere to minimize their surface energy. Thus, polymerization reactions in droplets can be used for the synthesis of functional poly-

mer beads. In this application, droplets of monomers are formed by use of a shear stress. The polymerization reaction is subsequently activated by UV radiation or by an elevated temperature. The droplets harden and become spherical polymer beads [10].

Droplets formed in a in-channel continuous-flow platform provide an attractive solution for analysis of single cells [11]. First, cells are captured and encapsulated in droplets. Subsequently, a droplet containing a cell can be transported and trapped with optical tweezers. Photolysis can be used to release the organelles. Finally, an enzymatic assay can be carried out within the aqueous droplet.

Future Directions for Research

Droplet reactors are basic components of digital microfluidics. There are still a number of opportunities in droplet reactor research. The future directions can be categorized into fundamentals and applications. Fundamental research could result in other platforms for droplet reactors. While electrowetting has been widely reported in the past, microfluidic platforms based on thermocapillary and other forces are still underrepresented. More research on the systematic design of droplet-based reactors is needed to secure industrial adaptation and commercial success. The applications of droplet reactors have still not been fully exploited. The use of droplets as a reaction platform for cells and biomimetic applications is an interesting topic for future research.

Time-dependent Density Functional Theory (TDFT)

Definition

Dynamic Density Functional Theory (DDFT) is, on the one hand a time-dependent (dynamic) extension of the static Density Functional Theory (DFT), and on the other hand, the generalization of Fick's law to the diffusion of interacting particles. The time evolution of the ensemble-averaged density of Brownian particles is given as an integro-differential equation in terms of the equilibrium Helmholtz free energy functional (or the grand canonical functional). DDFT resolves density variations on length scales down to the particle size but only works for slow relaxing dynamics close to equilibrium.

Overview

One can prove that in thermal equilibrium, in a grand canonical ensemble (i. e., volume, chemical potential, and temperature are fixed), the grand canonical free energy $\Omega(\rho(\boldsymbol{r}))$ of a system can be written as a functional of the one-body density $\rho(\boldsymbol{r})$ alone, which will depend on the position $\boldsymbol{r}$ in inhomogeneous systems. The density distribution $\rho_{\text{eq}}(\boldsymbol{r})$ which minimizes the grand potential functional is the equilibrium density distribution. This statement is the basis of the equilibrium density functional theory (DFT) for classical fluids which has been used with great success to describe a variety of inhomogeneous fluid phenomena, in particular the structure of confined liquids, wetting, anisotropic fluids, and fluid–fluid interfaces. For a historical overview and further references see [1, 2].
Out of equilibrium there is no such rigorous principle. However, macroscopically one can find a large variety of phenomenological equations for the time evolution which are based on macroscopic quantities alone, e. g., the diffusion equation, the heat transport equation, and the Navier–Stokes equations for hydrodynamics. A microscopic dynamical theory for the time evolution of slow variables such as the momentum density or the particle

density with molecular spatial resolution is highly desirable.

In perhaps one of the simplest microscopic cases, a system of interacting Brownian (i. e., diffusing) particles, and in a local equilibrium approximation, one can write the time evolution of the ensemble-averaged one-body density as a functional of the density [3]

$$\frac{\partial \rho(\boldsymbol{r};t)}{\partial t} = \nabla \cdot \left(\mathrm{D}\rho(\boldsymbol{r};t)\nabla \left.\frac{\delta F[\rho]}{\delta\rho}\right|_{\rho(\boldsymbol{r};t)} \right) \qquad (1)$$

where D is the diffusion constant, and the Helmholtz free energy functional, $F[\rho(\boldsymbol{r})] = \Omega[\rho(\boldsymbol{r})] + \mu\rho(\boldsymbol{r})$. The chemical potential μ is constant throughout the system and the free energy functional has the form

$$F[\rho(\boldsymbol{r})] = \int \rho(\boldsymbol{r}')\left(\left(k_{\mathrm{B}}T \ln \Lambda^3 \rho(\boldsymbol{r}') - 1\right) + V(\boldsymbol{r}')\right) \mathrm{d}^3\boldsymbol{r}' + F_{\mathrm{ex}}[\rho(\boldsymbol{r})] \qquad (2)$$

where Λ is the thermal wavelength, $k_{\mathrm{B}}T$ is the thermal energy, and $V(\boldsymbol{r})$ is an external potential. The excess part of the free energy $F_{\mathrm{ex}}[\rho(\boldsymbol{r})]$ depends on the interactions among the particles and, apart from the trivial case of noninteracting (ideal) particles for which $F_{\mathrm{ex}}[\rho(\boldsymbol{r})] = 0$, it is only known exactly for a one-dimensional system of hard rods [3]. The key to the success of the equilibrium DFT as well as the nonequilibrium DDFT is to develop "good"functionals which can be tested against experiments and various simulations. Fundamental measurement theory has been very successfully used to construct functionals for hard sphere systems (a model for colloids in suspensions) [4]. Soft interactions, e. g., between polymer coils in a solution, can be treated in a nonlocal mean field (random phase) approximation as used by Penna et al. [5]. Their $F_{\mathrm{ex}}[\rho(\boldsymbol{r})]$ is written in a quadratic form in $\rho(\boldsymbol{r})$. For particles with a relatively hard core and an additional long-range interaction one can combine both concepts and write $F_{\mathrm{ex}}[\rho(\boldsymbol{r})]$ as the sum of a functional for hard spheres and a quadratic functional containing only the soft long-range part of the interaction [6].

Various extensions to DDFT have been proposed (see below). The generalization to mixtures of different particle types is straightforward. A background flow and a position-dependent diffusion constant can also be included.

To date, there has only been one attempt to develop a dynamic density functional theory for systems in which inertia plays a role [7]. However, it has been shown that the formal proof for the existence of a quantum mechanical dynamical density functional theory by Runge and Gross can be applied to classical systems [8]by starting from the Liouville equation for Hamiltonian systems (instead of the time-dependent Schrödinger equation), which therefore includes inertia terms. However, the proof is not of practical use (see below).

Dynamical density functional theories for the spatially coarse-grained density (to be distinguished from the ensemble-averaged density $\rho(\boldsymbol{r};t)$ discussed here) based on Zwanzig–Mori projection techniques have been suggested by many authors, but they are only valid on length scales that are large compared to the particle size. Their functional form is similar to Eq. (1) but with a conservative multiplicative noise term added. But in general, one is interested in ensemble-averaged quantities, i. e., quantities averaged over many realizations of the noise or the numerical experiment, such that a theory for ensemble-averaged quantities is of more practical use. For a discussion of the role of noise in DDFT see [9].

Basic Methodology

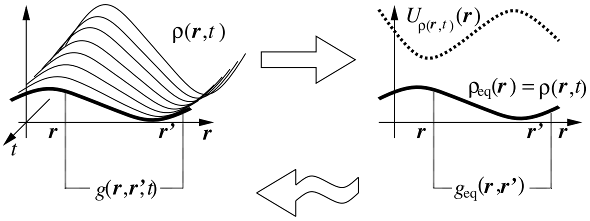
We now derive the DDFT (Eq. (1)) for the simplest case, i. e., a system of N pairwise interacting indistinguishable Brownian particles, following the derivation given in [9], before giving the DDFT equations (corresponding to Eq. (1)) for mixtures and for particles in a flowing solvent.

DDFT for Interacting Brownian Particles

A starting point for developing a DDFT for N interacting Brownian particles is the Fokker–Planck (or Smoluchowsky) equation for the probability density $W(\{\boldsymbol{r}_i\}_{i=1\ldots N})$ for finding particle 1 at position $\boldsymbol{r}_1$, particle 2 at position $\boldsymbol{r}_2, \ldots$, particle i at position $\boldsymbol{r}_i$, and finally particle N at position $\boldsymbol{r}_N$. For pairwise interactions among the particles we have

$$\frac{\partial W(\{\boldsymbol{r}_i\};t)}{\partial t} = \sum_{i=1}^{N} \nabla_i \cdot \left(\sum_{j=1}^{N} \mathbf{F}(\boldsymbol{r}_i - \boldsymbol{r}_j) + \mathbf{G}(\boldsymbol{r}_i) - k_{\mathrm{B}}T\nabla_i \right) W(\{\boldsymbol{r}_i\};t) \qquad (3)$$

where the interaction force $\mathbf{F}(\boldsymbol{r}) = -\nabla\Phi(\boldsymbol{r})$, the interaction potential is $\Phi(\boldsymbol{r})$, and the force due to the external potential $\mathbf{G}(\boldsymbol{r}) = -\nabla V(\boldsymbol{r})$. The generalization to many-particle interactions and to time-dependent external potentials is straightforward. The time evolution of the



Dynamic Density Functional Theory (DDFT), Figure 1 Illustration of the local equilibrium approximation involved in the development of the DDFT. The left-hand side illustrates the nonequilibrium evolution of the density $\rho(\boldsymbol{r};t)$ (thin lines) up to time t (thick line). For the time evolution the equal-time correlation function $g(\boldsymbol{r},\boldsymbol{r};t)$ is needed. It is approximated by the equilibrium correlations $g_{\text{eq}}(\boldsymbol{r},\boldsymbol{r}')$ in an equilibrium system (right-hand side) with the same density $\rho_{\text{eq}}(\boldsymbol{r})$ (thick line) as in the nonequilibrium system. For given particle interactions and density such an equilibrium system can be obtained by applying an external potential $U_{\rho(\boldsymbol{r};t)}(\boldsymbol{r})$

ensemble-averaged density, i. e., the density averaged over many realizations of the thermal noise and initial conditions samples from the initial $W(\{\boldsymbol{r}_i\};t=0)$, can be calculated by integrating out $N-1$ degrees of freedom in Eq. (3) to obtain

$$\frac{\partial\rho(\boldsymbol{r};t)}{\partial t} = -\nabla\cdot\Big((\mathbf{G}(\boldsymbol{r})-k_{\text{B}}T\nabla)\,\rho(\boldsymbol{r};t) + \int g(\boldsymbol{r},\boldsymbol{r}';t)\mathbf{F}(\boldsymbol{r}-\boldsymbol{r}')\,\mathrm{d}^3\boldsymbol{r}'\Big) \tag{4}$$

with the nonequilibrium two-point correlation function $g(\boldsymbol{r},\boldsymbol{r}';t)$. Equation (4) is only the starting point of a hierarchy of N time evolution equations for correlation functions of increasing order.

The key to DDFT is to truncate this hierarchy and to express $g(\boldsymbol{r},\boldsymbol{r}';t)$ in terms of the density. In order to arrive at Eq. (1) one assumes that $g(\boldsymbol{r},\boldsymbol{r}';t)$ can be approximated by the two-point correlation function of an equilibrium system with the equilibrium density distribution $\rho_{\text{eq}}(\boldsymbol{r}) = \rho(\boldsymbol{r};t)$, as illustrated in Fig. 1. This is possible because for every given interaction potential $V(\boldsymbol{r})$ and density $\rho(\boldsymbol{r};t)$ one can find an external potential $U_{\rho(\boldsymbol{r};t)}(\boldsymbol{r})$ such that the equilibrium density distribution $\rho_{\text{eq}}(\boldsymbol{r})$ of the system with $U_{\rho(\boldsymbol{r};t)}(\boldsymbol{r})$ is equal to $\rho(\boldsymbol{r};t)$. Moreover, the excess parts of the free energy functionals of both systems, with and without $U_{\rho(\boldsymbol{r};t)}(\boldsymbol{r})$, are identical. One can therefore use a sum rule relating the integral in Eq. (4) (with $g(\boldsymbol{r},\boldsymbol{r}';t)$ replaced by $g_{\text{eq}}(\boldsymbol{r},\boldsymbol{r}')$) via the first direct correlation function $c^1(\boldsymbol{r})$ to the functional derivative of the excess part of the free energy.

$$\int g_{\text{eq}}(\boldsymbol{r},\boldsymbol{r}')\mathbf{F}(\boldsymbol{r}-\boldsymbol{r}')\,\mathrm{d}^3\boldsymbol{r}' = k_{\text{B}}T\rho(\boldsymbol{r};t)\nabla c^{(1)}(\boldsymbol{r}) = -\rho(\boldsymbol{r};t)\nabla\left.\frac{\delta F_{\text{ex}}[\rho]}{\delta\rho}\right|_{\rho(\boldsymbol{r};t)} \tag{5}$$

Writing the first term on the right-hand side of Eq. (4) as a variational derivative one arrives directly at Eq. (1).

For clarity we only derive Eq. (1) for the simplest case. However, Eq. (1) is also valid for arbitrary many-body interactions [6] as well as time-dependent external potentials $V(\boldsymbol{r};t)$. The latter simply leads to a time-dependent free energy functional $F[\rho;t]$ which is of the same form as the functional in Eq. (2).

DDFT for Particle Mixtures

The generalization to mixtures of M different particle types is straightforward and for the density $\rho_X(\boldsymbol{r};t)$ of component $1 \le X \le M$one obtains

$$\frac{\partial\rho_X(\boldsymbol{r};t)}{\partial t} = \nabla\cdot\left(D_X\rho_X(\boldsymbol{r};t)\nabla\left.\frac{\delta F\left[\{\rho_Y\}_{Y=1\ldots M}\right]}{\delta\rho_X}\right|_{\{\rho_Y(\boldsymbol{r};t)\}}\right) \tag{6}$$

where the diffusivity D_X of component X and the joint free energy functional depend on the density distribution of all M components.

DDFT in a Flowing Solvent

Flow in the medium in which the Brownian particles are embedded (e. g., the solvent for colloids) can also be included, as long as the back-reaction of the Brownian particles on the flow field $\mathbf{u}(\boldsymbol{r};t)$ is not taken into account. This results in a coupling of the density field to the Navier–Stokes equations. In the case most relevant for microfluidics, i. e., for vanishing Reynolds numbers and incompressible flows, one obtains

$$\frac{\partial\rho(\boldsymbol{r};t)}{\partial t} + \mathbf{u}(\boldsymbol{r};t)\cdot\nabla\rho(\boldsymbol{r};t) = \nabla\cdot D\rho(\boldsymbol{r};t)\nabla\left.\frac{\delta F[\rho]}{\delta\rho}\right|_{\rho(\boldsymbol{r};t)} \tag{7}$$

$$0 = -\nabla p + \eta\nabla^2\mathbf{u}(\boldsymbol{r};t) \tag{8}$$

$$\nabla\cdot\mathbf{u}(\boldsymbol{r};t) = 0 \tag{9}$$

where p is the pressure and η is the viscosity. Here we neglect the displacement of the solvent by the Brownian particles. A more complete theory would also include the osmotic pressure of the particles in terms of a density dependent pressure tensor in Eq. (8), similar to the coupled Cahn–Hilliard/Navier–Stokes systems used in phase field modeling of multiphase fluid systems.

DDFT in Inhomogeneous Media

A spatially varying diffusivity can model not only inhomogeneities in the medium but also hydrodynamic interactions between the Brownian particles and channel walls. The diffusivity is then replaced by a diffusion tensor $\mathbf{D}(\boldsymbol{r})$ and instead of Eq. (1) one obtains

$$\frac{\partial \rho(\boldsymbol{r};t)}{\partial t} = \nabla \cdot \mathbf{D}(\boldsymbol{r}) \rho(\boldsymbol{r};t) \cdot \nabla \left. \frac{\delta F[\rho]}{\delta \rho} \right|_{\rho(\boldsymbol{r};t)} \tag{10}$$

Eqs. (6)–(10) only give the simplest forms of the generalization of Eq. (1) discussed in the corresponding section. All the generalizations can be combined with each other.

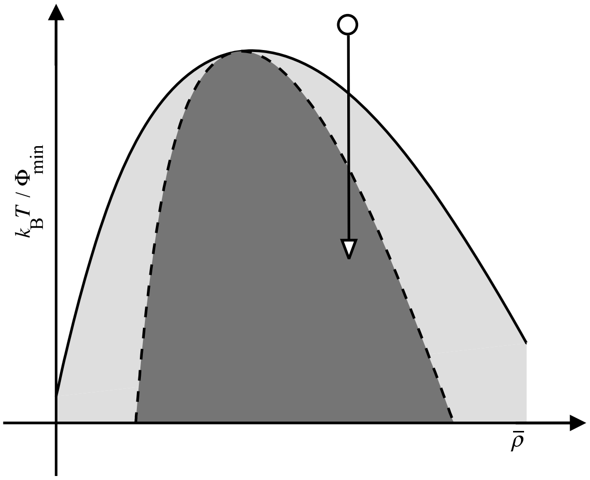
The local equilibrium approximation for the two-point correlation function involved in the development of the DDFT has two issues. First, it is not a priori clear when it is justifiable to approximate the nonequilibrium correlations by equilibrium correlations. It has been shown that there are cases in which this approximation breaks down, in particular in driven steady-state systems. Second, the equilibrium sum-rule in Eq. (5) gives the two-point correlations in a grand canonical ensemble. But the locally conserved dynamics underlying Eq. (1) requires a canonical ensemble. In a grand canonical ensemble each point in space is connected to a reservoir fixing the chemical potential by adding or removing particles, while in a canonical ensemble the number of particles is fixed.

Key Research Findings

As DDFT is a relatively young technique only a few results are available. The remaining part of this section is organized in terms of the particle system under consideration, i. e., in terms of the excess free energy functional $F_{\text{ex}}[\rho(\boldsymbol{r})]$ used.

One-Dimensional Systems

The difference between the correlation functions in a canonical and a grand canonical ensemble is largest for one-dimensional systems with hard core interactions. This occurs because in such a system the particles cannot pass each other. This also leads to a significantly different diffusion behavior (single file diffusion). In a grand canonical setting, however, particles can pass each other via the



Dynamic Density Functional Theory (DDFT), Figure 2 Schematic phase diagram of a system of Brownian particles with an attractive interaction. Φ_{min} is the depth of the attractive minimum of the interaction potential and $\bar{\rho}$ is the particle density (averaged of the system volume). Only states above the full line, the bimodal, are stable. States between the full and the dashed lines, the spinodal, are metastable, and states below the spinodal are linearly unstable. The system considered in [6] is quenched from a stable state (circle) into the unstable region as indicated by the vertical arrow

reservoir which keeps the chemical potential fixed. Therefore, an ensemble of hard rods was the first test system used for DDFT, also because the free energy functional for hard rods is the only nontrivial functional for interacting systems which is known exactly. Some discrepancies between DDFT and Brownian dynamics simulations of the same system were observed, mainly for extreme heterogeneities, i. e., very far from equilibrium [3]. However, the intermediate and long-term behavior was captured correctly by DDFT, at least for large enough systems. The same system has been considered as a model for the diffusion of colloids in a narrow channel with an obstacle inside the channel [10]. The goal of this study was to investigate the interplay between the external driving forces, the interparticle interactions, and the potential barriers in nanochannels.

Soft Particles

Polymer chains in solution form a loose coil such that two coils can interpenetrate. The resulting effective interaction potential $\Phi(|\boldsymbol{r}|)$ is repulsive and is well approximated by a Gaussian potential of strength Φ_0 and with a range r_0 which is proportional to the radius of gyration R_g. The excess free energy functional for such soft systems can be

approximated by a quadratic form

$$F_{\mathrm{ex}}\left[\rho(\boldsymbol{r})\right] = \frac{1}{2}\iint \rho(\boldsymbol{r})\Phi\left(|\boldsymbol{r}-\boldsymbol{r}'|\right)\rho(\boldsymbol{r}')\,\mathrm{d}^3\boldsymbol{r}\,\mathrm{d}^3\boldsymbol{r}' \quad (11)$$

where $\Phi(r) = \Phi_0 \exp(-r^2/r_0^2)$. This has been used in order to describe the dynamics of polymer solutions in the vicinity of colloidal particles driven through the solution [10]. The main finding is that the layering of polymer coils around the colloid can be broken up, leading to a strongly inhomogeneous polymer density in the vicinity of particles. The influence of this inhomogeneity on the depletion interaction between particles has been studied [11]. A tendency for the particles to align, a result most relevant for sedimentation processes and in line with the simulations, was found.

This type of model potential has been also used to study the phase separation dynamics of binary mixtures in cavities [12]. An excellent agreement between DDFT and Brownian dynamics simulations was found. In this particular example the fact that DDFT is a theory for the ensemble-averaged density becomes most evident, i. e., the density shows the same symmetry as the underlying system, even though the actual realizations may have a broken symmetry. In this example this means that since the probability of having one phase on the left-hand side of the cavity and the other phase on the right-hand side is equal to the probability of the mirrored situation the ensemble-averaged densities are symmetric even if every realization of the system is asymmetric.

Hard Particles

Hard particles with an additional soft attractive interaction have been used in a study of spinodal decomposition [6]. Such a system can be realized in a colloidal suspension and exhibits a fluid–fluid phase separation between a colloid-rich and a colloid-poor phase (see the phase diagram in Fig. 2). Quenched below the spinodal, the system undergoes spinodal decomposition which leads finally to the formation of dense and less dense clusters. The main progress, as compared to nonlinear Cahn–Hilliard theories, is the more accurate description of the short wavelength correlations, a property which will become most relevant in confined systems.

Future Directions for Research

Applications of DDFT

DDFT is a relatively new technique and therefore much effort will be needed toapply DDFT to microfluidic and biological systems. In particular, the transport of colloidal suspensions and polymer solutions in channels that are a few times larger than the typical particle diameter is a problem for which the DDFT method is well suited. Mixing of suspended interacting particles and polymers in such channels is also well modeled by DDFT.

The internal dynamics of complex fluids, e. g., the diffusion of colloids in polymer solutions, is another problem for which DDFT could be useful. It has been shown recently that the structure of the polymer solution in the vicinity of a diffusing colloidal particle strongly influences its diffusivity [13]. DDFT could be used to determine this structure.

Further Development of DDFT

The greatest challenges for DDFT are hydrodynamic interactions and inertia. Either one, or both of these, are needed for most systems of interest. The following paragraphs briefly outline the status of the development and the obstacles to further progress.

Hydrodynamic Interactions

Currently, hydrodynamic interactions between suspended particles cannot be included in a DDFT. However, it is well known, that, e. g., the rheology of suspensions cannot be explained without taking these into account. Hydrodynamic interactions in a simple approximation based on Oseen-tensors have been included in the Fokker–Planck equation (Eq. (3)) and the equivalent of Eq. (4) has been derived and discussed [14, 15]. However, this equation contains three-point and two-point correlations in a form such that the sum rule in Eq. (5) cannot be used.

Simple Fluids

The DDFTs discussed in this article describe the time evolution of the density of Brownian particles. Although there are formal arguments for the existence of a DDFT for a system of particles which follow a Newtonian dynamics [8], in other words a system of particles for which inertia is important, to date, only one effort has been made to extend the concept of DDFT in this direction [7]. However, hydrodynamic modes were still excluded in that work.

The greatest obstacle for developing a hydrodynamic DDFT is that, the viscosity of a liquid is determined by the deviation of the two-point correlation function $g(\boldsymbol{r},\boldsymbol{r}';t)$ from the equilibrium value $g_{\mathrm{eq}}(\boldsymbol{r};\boldsymbol{r}')$. Approximating the first with the latter, as in the derivation of the DDFT for Brownian particles discussed above, would therefore result in a theory almost without viscosity.

Effective Coupling Coefficient

Definition

A coupling coefficient describes the efficiency of energy transfer from one form to another in a material or physical mechanism. The effective coupling coefficient is determined based on measurement of a mechanism's characteristics rather than relying on a derivation of the coefficient from underlying principles. The effective coupling coefficient often combines several disparate phenomena in these cases.

Definition

Electrical current monitoring methods are the methods to measure the average velocity of electro-osmotic flow by monitoring the electrical current change for a replacement process, where one electrolyte solution is replacing another slightly less concentrated one (or slightly concentrated one) via electro-osmotic flow. For the purpose of measuring the specific surface conductivity, the replacement is not necessary.

Overview

When an external electrical field is applied to the liquid in a microchannel tangentially, the bulk liquid motion can be generated, which is commonly referred to as electroosmotic flow (EOF), due to the presence of a thin layer with net charges near the solid–liquid interface. This thin layer is called the electrical double layer (EDL) and the net charges in the EDL are the result of charge separation in the bulk liquid induced by the surface charge, which originates from several mechanisms [1], such as the ionization of surface groups and the electrolyte ion adsorption

to solid surfaces. The EDL generally consists of two layers: one is the inner compact layer where ions are strongly attracted to the charged surface and the other is the diffuse layer where ions are free to move. The electrical potential in the liquid generally decays dramatically from the surface and almost reaches zero at some distance slightly beyond the EDL region. The potential at the shear plane, which separates the compact layer and the diffuse layer, is referred to as the zeta potential, ζ, and can be experimentally measured [2].

When an EOF is generated by applying an external electrical field, an electrical current is also introduced, which commonly consists of three components:

- a conduction current, $I_{\text{cond,bulk}}$, resulting form the bulk conductivity of the electrolyte solution;
- a secondary conduction current, $I_{\text{cond,surf}}$, resulting from the surface conductivity; and,
- a convection current, I_{conv}, resulting from the electro-osmotic flow.

Generally, the convection current is evaluated by

$$I_{\text{conv}} = \int_{A_c} u\rho_e dA_c \ ,$$

which is several orders of magnitude smaller than the other two components of the current. Neglecting the contribution of I_{conv} results in the following equation for the total current, I_{total}:

$$I_{\text{total}} = I_{\text{cond,bulk}} + I_{\text{cond,surf}} = \lambda_b A_c \boldsymbol{E} + P\lambda_s \boldsymbol{E} \ , \qquad (1)$$

where $\boldsymbol{E}$ is the applied electrical field strength, λ_b is the bulk liquid conductivity measured in ohm^{-1}m^{-1}, λ_s is the surface conductivity measured along the length of the square sheet material of unit area and constant thickness (although negligible) and is measured in ohm^{-1}, P is the perimeter of the channel cross section, and A_c is the cross-sectional area of the channel. In many studies, the surface conductivity, λ_s, is neglected. This is a reasonable treatment for most high concentration solutions with a low net charge density in the EDL region; however, it may bring a significant error for low concentration solutions.

The zeta potential and surface conductance are functions of both interface and liquid properties and have significant influences on liquid flow. Lab-on-a-Chip devices have a wide range of applications in biomedical, chemical, environmental and biology areas, where a variety of liquid solutions and chip materials are involved. Each pair of solid–liquid interface has its unique zeta potential, specific surface conductivity, and electro-osmotic mobility, which makes the design and operational control of such devices very difficult and case specific. This requires the development of experimental methods for relatively easy and accurate measurements of the zeta potential, electro-osmotic mobility and surface conductivity.

There are three commonly used methods to measure the zeta potential, which involves pressure driven flow, electrophoresis, and electro-osmotic driven flow, respectively. For the measurement of the specific surface conductivity, there are primarily two methods involving pressure driven flow and electro-osmotic driven flow. In this entry, we will focus on the electrical current monitoring methods which can be used to measure the zeta potential, specific surface conductivity, volumetric flow rate, and electro-osmotic mobility, by employing electro-osmotic flow with a solution displacement process.

The traditional electrical current monitoring method was originally proposed by Huang et al. [3] to measure the average flow velocity in capillary zone electrophoresis. Since then, this method has been further developed for the measurements of the zeta potential, flow rate, and specific surface conductivity [4–6] for a given solid–liquid interface, which has been found more accurate, simpler and easier to operate as compared to the traditional streaming potential method involving pressure driven flow [7] and the electrophoresis method [8] involving the use of microscope techniques. The principles of the electrical current monitoring methods for measuring the zeta potential, electro-osmotic flow rate, and specific surface conductivity will be given in detail later. Briefly, when one solution is introduced into a channel to replace a slightly less concentrated one (vice versa) via electro-osmotic flow, the total resistance changes while the replacement is going due to their different conductivity values. Under a constant electrical potential difference applied to the ends of the microchannel, the electrical current will increase from a constant value at the beginning of the replacement when the channel is filled with the less concentrated solution and reach a plateau when the replacement ends and the channel is filled with the concentrated one. The electrical current can be monitored with respect to time for the replacement process and the current-time relationship in combination with numerical and analytical analysis allow the electro-osmotic flow rate, electro-osmotic mobility, zeta potential, and specific surface conductivity of a certain solid–liquid interface, to be determined.

Basic Methodology

Evaluation of the Electro-osmotic Flow Rate

Due to small dimensions and flow velocities in most microfluidic devices, microchannel flows are in the laminar flow regime with a typical Reynolds number below 0.1 and have a very small volumetric flow rate. For

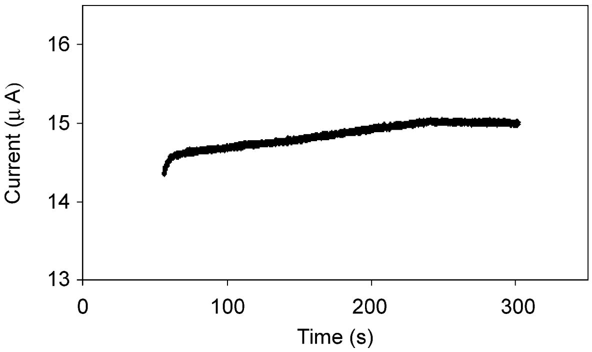
instance, for a $1\times$TAE buffer solution in a 10 cm length of 100 μm i. d. capillary, under an applied electrical field of 7.5 kV/m, the velocity is around 0.4 mm/s, which yields a volumetric flow rate of approximate 0.2 μl/min. It is extremely difficult to measure such a small volumetric flow rate accurately using the traditional methods such as observing the movement of a meniscus in an adjoining capillary [1]. The current-monitoring method, however, is able to measure small volumetric flow rates in a much easier and more accurate manner by monitoring the current-time relationship while one solution is replacing another less concentrated one via electro-osmotic flow.

In the electrical current monitoring methods, a microchannel filled with one electrolyte solution is brought into contact with two reservoirs, one of which has the same concentration as that in the microchannel and the other has a higher concentrated one. The electrical field is set up simultaneously so that the higher concentrated one will gradually replace the less concentrated one in the channel via electro-osmotic flow. At the beginning of the replacement process, the microchannel is filled with one uniform solution and thus the current is constant. When the higher concentrated solution is pumped into the channel and the less concentrated one gradually flows out of the channel, the total resistance changes because of their different conductivity values, which are approximately proportional to their concentrations. Under a constant potential difference applied at the two ends of the microchannel, the current will increase and reach a plateau when the channel is completely filled with the high concentrated one. The current change can be monitored with respect to time for the replacement process. A typical current-time relationship measured for a $1\times$TAE buffer solution in a 10 cm length of 100 μm i. d. capillary under an applied electrical field of 7.5 kV/m, is shown in Fig. 1. The time between the two plateaus, Δt, is the time required for the solution to travel through the microchannel length, L. Therefore, from the current-time relationship, the average electro-osmotic velocity can be evaluated by

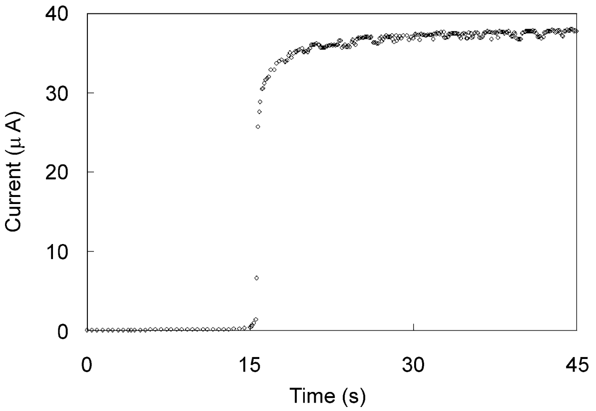
$$u_{\text{ave}} = \frac{L}{\Delta t} \,. \tag{2}$$

The electro-osmotic flow rate can then be calculated by $Q = u_{\text{ave}} A_{\text{c}}$. Although it is possible to directly measure the electro-osmotic mobility using the ultramicroscope technique [1], however, it is common to measure it by means of measuring the average electro-osmotic velocity. Once the average velocity is obtained, the electro-osmotic mobility can be easily determined by $\mu_{\text{eo}} = u_{\text{ave}}/E$.

In the current monitoring methods, the chemical species of the two solutions are the same, but the concentration is slightly different, i. e. 5% difference. For the purpose of measuring the average electro-osmotic velocity for one certain solution, it is important to maintain a small difference in concentration for the following two reasons. First, if there is a big difference in the concentration of the two solutions, the once sharp front surface between the two solutions becomes progressively blurred. The determined average velocity just indicates how fast for one solution to replace another solution under certain conditions. It can not, however, represent the average electro-osmotic velocity for any of the two solutions. Therefore, the measured average velocity can not be used to determine the electro-osmotic mobility, zeta potential or specific surface conductivity for a certain solution. Second, a big variation in concentration of the two solutions will cause a dramatic change in the electrical current at a certain point and very slow change at the beginning and the end of the replacement process. A typical current-time relationship for a 10 mM KCl solution replacing deionized ultrafiltered (DIUF) water (considered as a 1 μM KCl solution) in a 10 cm length of 100 μm i. d. capillary is shown in Fig. 2. This is because the total resistance is primarily determined by one of the two solutions for the majority time of the replacement process. For this particular case, the conductivity ratio between the two solutions can be assumed to be proportional to that of the concentration, which is around 10,000 times here. This means that as long as a very small portion of the channel (i. e. 1/10,000 of the channel length) is filled with 1 μM KCl solution, the total resistance and thus the current are dominated by this low concentration solution. When the channel is almost completely filled with the 10 mM KCl solution, the current will suddenly jump to a high value corresponding to this higher concentration solution and gradually reaches a maximum value. As shown in Fig. 2, it is very difficult to



Electrical Current Monitoring Methods, Figure 1 A typical current–time relationship measured for a $1\times$TAE buffer solution replacing a 95% $1\times$TAE buffer solution in a 10 cm length of 100 μm i. d. capillary, under an applied electrical field of 7.5 kV/m



Electrical Current Monitoring Methods, Figure 2 A typical current-time relationship measured for a 1×10 mM KCl solution replacing DIUF Water in a 10 cm length of 100 μm i. d. capillary, under an electrical field of 3.5 kV/m

identify the beginning or the end point for such a replacement process, which will bring errors when determining the time required for one solution to replace another solution and thus the average velocity. Therefore, it is necessary to maintain a small difference in concentration when using the current monitoring methods.

Once the average velocity and the electro-osmotic mobility are obtained from the current-time relationship, the zeta potential, and specific conductivity can be evaluated in combination with numerical and analytical analysis as summarized below.

Evaluation of the Zeta Potential

There have been many methods developed for the zeta potential measurements as mentioned above. Here we will focus on the methods using the current monitoring technique. The zeta potential can not be directly measured using this method; however, it can be determined numerically and analytically through the measured average electro-osmotic velocity, which will be summarized below.

Consider an electro-osmotic flow of an aqueous solution in a microchannel, the flow field generally can be described by the continuity equation and the momentum equation:

$$\nabla \cdot \boldsymbol{V} = 0 \tag{3}$$

$$\rho \left[\frac{\partial \boldsymbol{V}}{\partial t} + (\boldsymbol{V} \cdot \nabla)\, \boldsymbol{V} \right] = -\nabla p + \eta \nabla^2 \boldsymbol{V} + \rho_e \boldsymbol{E} \,, \tag{4}$$

where $\boldsymbol{V}$ is the mass average velocity vector, ρ is the density of the liquid, η is the viscosity of the liquid, p is the pressure, and ρ_e is the local net charge density. For most microfluidic applications, the viscous force is dominant and the time for the flow to reach steady state is very small, which is on the order of ms ($t \approx \rho D_h^2/\eta = 10^{-2}$ s where $\rho = 1.0 \times 10^3\ \text{kg m}^{-3}$, $\eta = 1.0 \times 10^{-3}\ \text{kg m}^{-1}$, and D_h is the characteristic length chosen as $D_h = 100\ \mu\text{m}$). Therefore the transient term in the momentum equation can be neglected. Because of small channel dimensions and flow velocities (the typical velocity in microfluidic devices is on the order of mm/s), the Reynolds number, $\text{Re} = \rho u D_h/\eta$, which represents the ratio between the inertial force and the viscous force, ranges approximately from 0.001 to 0.1. Therefore, the flow in microfluidic devices is laminar flow and the convection term on the left hand side of the momentum equation can be ignored. For most microfluidic applications, no pressure difference is applied and the pressure gradient term is dropped off. It should be pointed out that induced pressure gradients do exist in most applications, where a complex channel layout is designed, primarily due to the Laplace pressure originating from the presence of different meniscus curvatures in the reservoirs. It is difficult to quantify the induced pressure effects because meniscus curvatures vary from experiments to experiments. The possible solutions to minimize the Laplace pressure are to increase the reservoir sizes and/or increase the flow resistance which can be realized by reducing the channel cross section and increasing the length of the flow path without increasing the channel length in one direction. This is because increasing the channel length in one direction will increase the chip size, which mitigates the key advantages that microfluidic chips can provide. Considering the above simplifications, Eq. (4) can be reduced to a very simple format:

$$\eta \nabla^2 \boldsymbol{V} = -\rho_e \boldsymbol{E} \,. \tag{5}$$

In order to solve the above equation, the net charge density must be known. According to the theory of electrostatics, the relationship between the net charge density and the electrostatic potential, ψ, is described by the Poisson equation:

$$\varepsilon_r \varepsilon_0 \nabla^2 \psi = -\rho_e \,, \tag{6}$$

where ε_r is the dielectric constant of the liquid, and ε_0 is the permittivity of vacuum ($\varepsilon_0 = 8.854 \times 10^{-12}\ \text{C/Vm}$). Consider a symmetric electrolyte solution, such as KCl solution, the local net charge density, ρ_e, is described by the Boltzmann equation:

$$\rho_e(r) = ze\big(n_+ - n_-\big) = -2zen_0 \sinh\left(\frac{ze\psi}{k_b T}\right) \,, \tag{7}$$

where z is the valence of the ion which is the same for the ions in a symmetric electrolyte solution, e is the electrical charge of an electron, n_0 is the initial concentration of the bulk solution, k_b is the Boltzmann constant and T is the absolute temperature. The well-known Poisson–Boltzmann equation is obtained by replacing the net charge density in Eq. (6) using Eq. (7):

$$\nabla^2\psi = \frac{2zen_0}{\varepsilon_r\varepsilon_0}\sinh\left(\frac{ze\psi}{k_bT}\right) . \tag{8}$$

The relationship between the velocity and the electrical potential can be derived by substituting Eq. (6) into Eq. (5)

$$\nabla^2\boldsymbol{V} = \frac{\varepsilon_r\varepsilon_0}{\eta}\boldsymbol{E}\nabla^2\psi . \tag{9}$$

Considering a fully developed flow in a parallel plate microchannel with a channel height of $2H$, the velocity and the electrical potential only vary in the height direction (y-direction). If the electrolyte solution or the channel surface is not uniform, the electrical field strength varies along the channel length; however, we only consider a constant electrical field here for the purpose of analysis. Equation (9) can then be simplified as

$$\frac{d^2u}{dy^2} = \frac{\varepsilon_r\varepsilon_0}{\eta}E_x\frac{d^2\psi}{dy^2} . \tag{10}$$

Eq. (10) is subject to the following boundary conditions:

$y = 0$ (the center of the channel) :

$$\frac{d\psi}{dy} = 0, \frac{du}{dy} = 0 \tag{11a}$$

$y = H$ (the wall of the channel) :

$$\psi = \zeta, u = 0 \tag{11b}$$

Integrating Eq. (10) with the boundary conditions specified in Eq. (11), we get

$$u = -\frac{\varepsilon_r\varepsilon_0}{\eta}E_x(\zeta\text{-}\psi) . \tag{12}$$

The average velocity can be calculated by integrating Eq. (12), such as

$$u_{ave} = -\frac{\varepsilon_r\varepsilon_0}{\eta H}E_x\int_0^H(\zeta\text{-}\psi)\,dy . \tag{13}$$

Once the zeta potential is known, the electrical potential can be obtained by solving the Poisson–Boltzmann equation. In other words, the electrical potential is a function of the zeta potential. Equation (13) shows that the average electro-osmotic velocity is also a function of the zeta potential. If the zeta potential is known, the electrical potential distribution can be determined and thus the average electro-osmotic velocity can be determined. The average velocity determined by this approach should be the same as that experimentally measured. However, in most situations, the zeta potential is unknown, which can be determined using the approach explained below. A guess value of the zeta potential can be made to solve the Poisson–Boltzmann equation for the electrical potential and then the average velocity is calculated using Eq. (13). The discrepancy between the numerically (or analytically) and experimentally determined average velocity suggests a new guess value for the zeta potential, which is used to repeat the above procedure until the two average velocity values converge. Therefore, the key here is to solve the Poisson–Boltzmann equation to get the electrical potential distribution.

E

Simplified Solution

As discussed above, the electrical potential drop dramatically from the zeta potential at the shear plane to zero at some distance slightly beyond the EDL. The detailed derivation of the electrical potential distribution can be found elsewhere [4]. Equation (12) indicates that the electro-osmotic velocity increases rapidly from zero at the shear plane to a maximum value at the edge of the EDL and keeps constant for the rest of the channel cross section. For most buffer solutions used in microfluidic chip applications, the concentration is on the order of mM, which gives a very thin EDL of around 10 nm. The EDL is around 0.01% of the channel height for a 100 μm high microchannel. Therefore, it is reasonable to neglect the variation of the electrical potential over the EDL region and assume zero potential cross the channel height. Considering this assumption, the zeta potential can be derived as a function of the average velocity from Eq. (13):

$$\zeta = -\frac{\eta}{\varepsilon_r\varepsilon_0}\frac{u_{ave}}{E_x} . \tag{14}$$

The above equation is a different form of the Helmholtz–Smoluchowski equation. Equation (14) shows that if the average electro-osmotic velocity is determined from the experimentally measured current-time relationship, the zeta potential can be calculated. Introducing the electro-osmotic mobility concept, $\mu_{eo} = u_{ave}/E_x$, Eq. (14) can be further simplified in the following format:

$$\zeta = -\frac{\eta}{\varepsilon_r\varepsilon_0}\mu_{eo} . \tag{15}$$

Equation (15) can be used to determine the zeta potential if the electro-osmotic mobility is known, vice versa.

Full Solution

It is true for many microfluidic applications, the EDL is very small compared to the channel dimensions and it is reasonable to assume zero electrical potential and a plug-like velocity profile cross the channel height. However, for dilute solutions such as water, the EDL is relatively big. For example, for a 1×10^{-6} M KCl solution in a 10 μm high parallel plate microchannel, the double layer thickness is around 300 nm, which is characterized by the inverse of the Debye–Huckle parameter, $1/\kappa = (2z^2e^2n_0/\varepsilon_r\varepsilon_0 k_b T)^{-1/2}$. The electrical potential variation occurs over a distance about $3/\kappa$, which is around 1 μm and is 10% of the channel height for this particular case. The assumption of zero electrical potential cross the channel height and thus a plug-like electro-osmotic velocity profile are not appropriate. The electrical potential distribution and the velocity profile must be obtained through numerical or analytical methods.

Numerical method Consider a symmetric electrolyte solution such as KCl solution in a parallel plate microchannel with a height of $2H$, the electrical potential distribution is described by the one-dimensional Poisson–Boltzmann equation:

$$\frac{d^2\psi}{dy^2} = \frac{2zn_0e}{\varepsilon_r\varepsilon_0}\sinh\left(\frac{ze\psi}{k_b T}\right) \tag{16}$$

with the following boundary conditions:

$$y = 0 \text{ (the center of the channel)}: \quad \frac{d\psi}{dy} = 0 \tag{17a}$$

$$y = H \text{ (the wall of the channel)}: \quad \psi = \zeta\,. \tag{17b}$$

Equation (16) can be easily solved using numerical techniques with the boundary conditions specified in Eq. (17). A typical potential distribution in a parallel plate microchannel obtained through numerical methods is shown in Fig. 3. Once the EDL potential, $\psi(y)$, is known, the average velocity can be calculated through Eq. (13). From the above procedure, it should be realized that the average velocity, u_{ave}, is an implicit function of the zeta potential, ζ (in the boundary condition, Eq. (17b)). If the average velocity can be measured directly using the current monitoring methods, the zeta potential can be determined by solving Eq. (13) and Eqs. (16,17) using an iterative procedure. First, Eqs. (16,17) are solved with an initial guess value of the zeta potential; second, Eq. (13) is used to determine the average velocity, and third, this numerically predicted average velocity will be compared to the experimentally measured one. If they are not the same, a new value of the zeta potential is assumed to repeat the above procedure until the two average velocity values converge. The zeta potential used for the last step calculation is the real zeta potential. In this process, an initial guessing value of the zeta potential, ζ_{guess}, may be obtained by invoking the Debye–Huckel approximation, as described below.

Analytical method Equation (16) can also be solved analytically with the boundary conditions specified in Eq. (17). In order to solve this equation easily using analytical methods, Eq. (16) should be nondimensionalized by the following parameters, $\Psi = ze\psi/k_bT$, and $Y = y/H$. The nondimensionalized Poisson–Boltzmann equation takes the form of

$$\frac{d^2\Psi}{dY^2} = \kappa^2H^2\sinh(\Psi)\,. \tag{18}$$

Introducing a relation

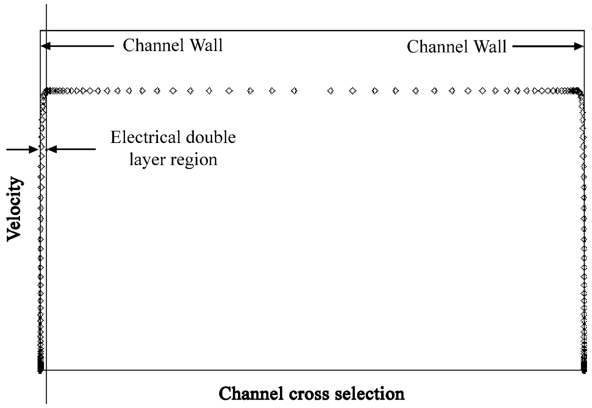
$$\frac{d}{dY}\left(\frac{d\Psi}{dY}\right)^2 = 2\frac{d\Psi}{dY}\frac{d^2\Psi}{dY^2} \tag{19}$$

and multiplying the both sides of Eq. (18) by $2(d\Psi/dY)$, yields

$$\frac{d}{dY}\left(\frac{d\Psi}{dY}\right)^2 = 2(\kappa H)^2\sinh(\Psi)\frac{d\Psi}{dY}\,. \tag{20}$$

Integrating the above equation gives:

$$\left(\frac{d\Psi}{dY}\right)^2 = 2(\kappa H)^2\cosh(\Psi) + C_1\,. \tag{21}$$



Electrical Current Monitoring Methods, Figure 3 Illustration of the velocity variation in a parallel plate microchannel

As explained above, for most microfluidic applications, the electrical potential is zero at some distance slightly beyond the EDL region. This is not true for the case where the EDL overlaps, which is not considered in this review. Interested readers are suggested consult with some of the recent publications [9] for more details. Therefore, the boundary conditions specified in Eq. (17a) can be extended to $Y = 0$, $\Psi = 0$, $\mathrm{d}\Psi/\mathrm{d}Y = 0$, which gives rise to $C_1 = -2(\kappa H)^2$ and Eq. (21) becomes:

$$\left(\frac{\mathrm{d}\Psi}{\mathrm{d}Y}\right)^2 = 2(\kappa H)^2(\cosh(\Psi) - 1) \tag{22a}$$

or

$$\frac{\mathrm{d}\Psi}{\mathrm{d}Y} = -\sqrt{2(\kappa H)^2(\cosh(\Psi) - 1)} = -2\kappa H \sinh\left(\frac{\Psi}{2}\right) . \tag{22b}$$

The negative sign in Eq. (22b) indicates that if the electrical potential is negative, the potential will increase from the zeta potential at the shear plane to zero in the bulk solution. Integrating Eq. (22b) yields $\tanh(\Psi/4) = -C_2\,\mathrm{e}^{-\kappa HY}$. Applying the boundary condition specified in Eq. (17b), C_2 is determined as $C_2 = -\tanh(\bar{\zeta}/4)$ where $\bar{\zeta}$ is the nondimensionalized zeta potential, $\bar{\zeta} = ze\zeta/k_\mathrm{b}T$. The final dimensional format of the solution to Eq. (16) is

$$\tanh\left(\frac{ze\psi}{4k_\mathrm{b}T}\right) = \tanh\left(\frac{ze\zeta}{4k_\mathrm{b}T}\right)\mathrm{e}^{-\kappa y} . \tag{23}$$

The electrical potential distribution can be determined using Eq. (23) with a guessed zeta potential value. The average velocity can then be calculated using Eq. (13). The comparison between the analytical solution and the experimentally determined average velocity will allow the zeta potential to be determined through iterative procedures as described above.

Debye–Huckle Approximation In some situations where the zeta potential is small (i.e. $< 25\,\mathrm{mV}$), the hyperbolic function in Eq. (16) can be approximated as $\sinh(ze\psi/k_\mathrm{b}T) \approx ze\psi/k_\mathrm{b}T$, which is called the Debye–Huckle approximation. Equation (16) then becomes

$$\frac{\mathrm{d}^2\psi}{\mathrm{d}y^2} = \kappa^2\psi . \tag{24}$$

With the boundary conditions specified in Eq. (17), the potential distribution can be obtained by solving Eq. (24), such as:

$$\psi = \zeta\,\mathrm{e}^{-\kappa(H-y)} \tag{25}$$

Using Eq. (13), the average velocity is determined by:

$$u_\mathrm{ave} = -\frac{\varepsilon_\mathrm{r}\varepsilon_0\zeta}{\eta}E_\mathrm{x}\left[\frac{\kappa H - 1 + \mathrm{e}^{-\kappa H}}{\kappa H}\right] \tag{26}$$

Thus, with the Debye–Huckel assumption, ζ_DH can be expressed as an explicit function of the channel height through the average velocity equation, such that if the average velocity is known, then the initial guess for the zeta potential can be determined as

$$\zeta_\mathrm{DH} = -\frac{\eta u_\mathrm{ave}}{\varepsilon_\mathrm{r}\varepsilon_0 E_\mathrm{x}}\left[\frac{\kappa H}{\kappa H - 1 + \mathrm{e}^{-\kappa H}}\right] \tag{27}$$

Using this ζ_DH value as the initial guess for ζ_guess in Eq. (16) to calculate u_ave, and comparing the result to the experimentally measured u_ave, a new ζ_guess is obtained. This procedure can be repeated until the calculated and the experimentally measured values of u_ave converge.

Evaluation of the Specific Surface Conductivity

As discussed above, the electrical current of an electro-osmotic flow can be described as:

$$I_\mathrm{total} = I_\mathrm{cond,bulk} + I_\mathrm{cond,surf} = \lambda_\mathrm{b}A_\mathrm{c}\boldsymbol{E} + P\lambda_\mathrm{s}\boldsymbol{E} . \tag{1}$$

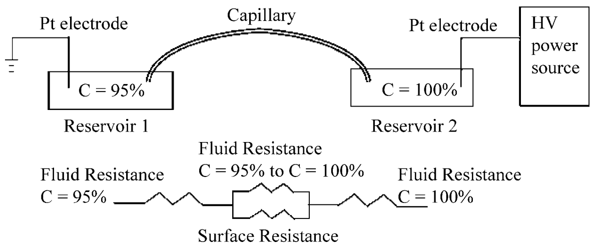
For the case of a parallel plate microchannel with a channel height of $2H$ and a channel width of $2W$, and an electrical field, E_x, applied in the length direction only, I_total is given by:

$$I_\mathrm{total} = 4HW\lambda_\mathrm{b}E_\mathrm{x} + 2(H+W)\lambda_\mathrm{s}E_\mathrm{x} . \tag{28}$$

For a parallel plate microchannel, the channel width, $2W$, is considered to be much larger than the channel height. In general, the surface conductivity, λ_s, is unknown. The channel dimensions can be measured using a microscope and the bulk liquid conductivity can be measured using an electroconductivity meter, which can be treated known. E_x is the applied electrical field strength and is known. The total electrical current, I_total, can be obtained using a data acquisition system. Therefore, the surface conductivity, λ_s, is the only unknown value in Eq. (28) and can be solved such that:

$$\lambda_\mathrm{s} = \frac{I_\mathrm{total} - 4HW\lambda_\mathrm{b}E_\mathrm{x}}{2(H+W)E_\mathrm{x}} . \tag{29}$$

As seen from Eq. (29), by measuring the total current during a steady electro-osmotic flow, the bulk conductivity, the applied electrical field and the channel dimensions, the surface conductivity can be determined. Generally, this is a relatively simple method with a reasonable accuracy. It should be noted that for the measurement of the specific



Electrical Current Monitoring Methods, Figure 4 Schematic diagram illustrating the experimental set-up for measuring the current variation and the complete displacement time of a two-concentration system

surface conductivity, the replacement between two similar solutions is not necessary.

Experimental

Traditional Electrical Current Monitoring Method

The experimental set-up commonly used for the current monitoring methods is shown in Fig. 4a [5]. In an experiment, reservoir 2 is filled with an electrolyte solution at a desired concentration. The microchannel and reservoir 1 are filled with the same electrolyte solution at a slightly lower concentration as compared with that in reservoir 2, for example, a 5% difference in concentration of the two solutions is often used. Immediately after the channel is brought contact with reservoir 2, a voltage difference between the two reservoirs is applied by setting reservoir 1 at ground potential and reservoir 2 to a high voltage power supply unit via Platinum electrodes.

The applied electrical field results in an electro-osmotic flow in the microchannel. During electro-osmosis, the higher-concentration electrolyte solution from reservoir 2 is gradually pumped into the microchannel and the same amount of the lower-concentration electrolyte solution is pumped out of the channel. As a result, the overall electrical resistance of the liquid and hence the current in the microchannel changes, as illustrated in Fig. 4b. A data acquisition chip and associated software are used to record the voltage (kV) and current (μA) as a function of time (seconds). Once the lower-concentration solution in the microchannel is completely replaced by the higher-concentration solution from reservoir 2, the current will reach a plateau. The measured time for the current to reach such a plateau value is the time required for the solution from reservoir 2 to travel through the entire channel length. The average velocity of the liquid flow can then be calculated by using Eq. (2),

$$u_{\text{ave,exp}} = \frac{L}{\Delta t} \tag{2}$$

where L is the length of the channel and Δt is the time required for the higher-concentration electrolyte solution to displace the lower-concentration electrolyte solution from the channel.

For the purpose of evaluating the specific surface conductivity, the solution replacement process is not necessary. In these cases, reservoir 1, reservoir 2 and the capillary tube will be filled with an electrolyte solution of the same concentration.

An Improved Method – Slope Method

The traditional current monitoring method as described above requires the determination of the time period for the current change during a replacement process via electro-osmotic flow. Experimentally it is very difficult to determine the exact required time for one solution completely replacing another solution because the gradual changing of the current with time and the small current fluctuations exist at both the beginning and the end of the replacement process. As shown in Fig. 1, it is very difficult to determine the exact beginning and ending time of the current change from the experimental results. In addition, for low concentration solutions, the average electro-osmotic velocity is very low, which requires a longer time to complete the replacement process. Two concerns arise from this situation. First, Joule heating is dependent on the running time of the replacement process, therefore, it may become an issue especially when the channel is made of polymer material such as poly (dimethylsiloxane) (PDMS) which has a low thermal conductivity. Second, the once sharp concentration front between the two solutions becomes progressively blurred. This mixing causes the sloped and plateau region of the current-time relationship to be smoothed together, which makes it difficult to determine the beginning and the end point for the replacement process. Consequently, significant errors could be introduced in the average velocity determined in this way.

It has been observed that, despite the curved beginning and ending sections, the measured current–time relationship is linear in most part of the process when the concentration difference is small. Therefore, a new method was developed [6] to determine the average electro-osmotic velocity by using the slope of the current–time relationship, which is often referred to as the slope method. To examine the reliability of this method, a numerical model is also developed in this study to calculate the average velocity in a microchannel with one solution displacing another similar solution.

When the concentration difference between the two solutions is small, a linear relationship between the current and time is observed. This may be understood in the follow-

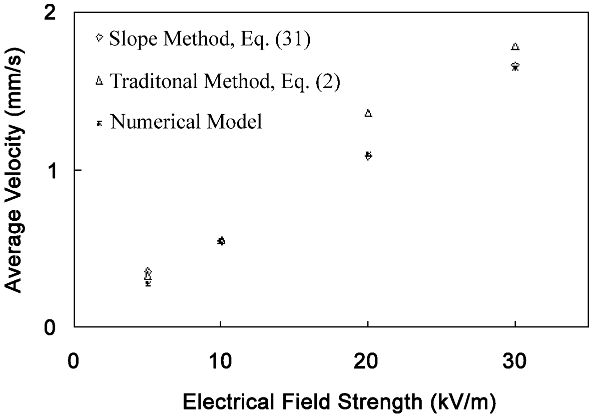
ing way. In such a process, the concentration difference between these two solutions is very small, e. g., one is 1×10^{-4} M and another one is 0.95×10^{-4} M, and therefore the zeta potential, which determines the net charge density and hence the liquid flow, can be considered constant along the microchannel. Consequently, the average velocity can be considered as a constant during the replacing process. As one solution flows into the microchannel, the same amount of the other flows out of the microchannel at essentially the same speed. The two solutions have different electrical conductivity values, therefore, the overall electrical resistance of the liquid changes linearly, and hence the slope of the current–time relationship is constant during this process. In other words, there is a linear relationship between the current and time during the process of one solution replacing another similar solution via electro-osmotic flow. The slope of the linear current–time relationship can be described as

$$\text{slope} = \frac{\Delta I}{\Delta t} = \frac{\Delta\left(EA_c\lambda_b\right)}{\Delta t} \cdot \frac{L_{\text{total}}}{L_{\text{total}}} = u_{\text{ave}} \frac{EA\left(\lambda_{b2} - \lambda_{b1}\right)}{L_{\text{total}}}\,, \tag{30}$$

where L_{total} is the total length of the microchannel and u_{ave} is the average electro-osmotic velocity, E is the applied electrical field strength, and $(\lambda_{b2} - \lambda_{b1})$ is the difference in the bulk conductivity between the two solutions. In Eq. (30), all the parameters are known and constant during the replacing process. If we group all the known parameters and denote $\Gamma = EA\left(\lambda_{b2} - \lambda_{b1}\right)/L_{\text{total}}$, Eq. (30) can be rewritten as

$$\text{slope} = \Gamma u_{\text{ave}} \tag{31}$$

Equation (31) shows that the average electro-osmotic flow velocity can be determined by measuring the slope of the current–time relationship.



Electrical Current Monitoring Methods, Figure 5 Comparison of the model-predicted average velocity with the experimentally determined average velocity by Eq. (2) and by Eq. (30) for a 1×10^{-3} M KCl solution in a 10 cm length of 100 μm i. d. capillary

Key Research Findings

Electro-osmotic flow has been used as a major pumping mechanism for microfluidic devices. The current monitoring methods, which uses electro-osmotic flow as a transport mechanism for solution replacement processes, has been used for the measurements of the zeta potential, electro-osmotic mobility, and surface conductivity. The development of the slope method allows the accuracy of the average velocity measurement to be improved. Figure 5 shows the comparison of the determined average velocity between the traditional current monitoring method which uses Eq. (29) to determine the average velocity, a numerical method, and the slope method which uses Eq. (31) to determine the average velocity. One can see that the slope method agrees better with the numerical predictions than the traditional current monitoring method. The current monitoring methods are relatively easy and accurate for measuring electro-osmotic mobility, which becomes more apparent for the average flow velocity measurement in nanofluidic devices. Pennathur and Santiago [10] experimentally measured the average velocity in a nanochannel using the traditional current monitoring method and found that the electro-osmotic mobility decreased nonlinearly when the channel dimensions approached the double layer thickness. The electro-osmotic mobility is normally independent on the channel size for most microfluidic applications. Their experimental data agreed with their numerical predictions where finite but non-overlapped double layer was assumed and thus Poisson–Boltzmann equation was used to describe the applied electrical potential field.

Future Directions for Research

Microfluidic and Nanofluidic chips have a wide range of applications in the chemical, biomedical, environmental and biology areas, where a variety of chemical solutions are used. With the development of microfabrication technology, many new materials such as PDMS and Poly(methyl methacrylate) (PMMA) are also employed for chip fabrication. Since each pair of solid–liquid interface has its unique zeta potential and electro-osmotic mobility, which have significant influences on flow control in such small scale devices, it is very important to experimentally determine these two parameters using the current

monitoring technique in order to develop microfluidic and nanofluidic devices for various applications.

Although the electrical current monitoring methods can make accurate and easy measurements for the zeta potential and electro-osmotic mobility, other methods such as microPIV and scalar-based image velocimetry have also been used to measure the velocity profile, from which the zeta potential and electro-osmotic mobility can be determined. However, with the ever-increasing interests in microfluidic and nanofluidic devices, the current monitoring methods will have very compelling features for measuring the zeta potential and electro-osmotic mobility. First, microPIV involves the use of micro sized particles, which may block or adhere to the channel surfaces when the channel size is scaled down to nanometer. Second, scalar based velocity measurement methods often require the injection of caged dye and the visualization of fluorescent dye, which becomes very challenging when the channel size is in the nano scale. The current monitoring methods, however, requires a very simple experimental system. It is true that when the channel size is small, the resistance is large. As a result, the electrical current is small, which may bring difficulty in measuring the current–time relationship accurately. Therefore, more improvements in acquiring accurate measurements for small currents for a replacement process via electro-osmotic flow must be made in the future study.

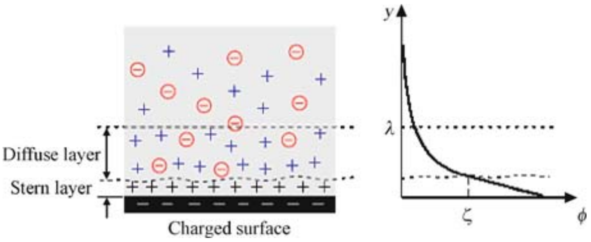
Definition

When a solid is in contact with an electrolyte, the chemical state of the surface is generally altered, either by ionization of covalently bound surface groups or by ion adsorption. As a result, the surface inherits a charge while counterions are released into the liquid. For example, common glass, SiOH, in the presence of H_2O, ionizes to produce charged surface groups SiO^- and release of a proton. At equilibrium, a balance between electrostatic interactions and thermal agitation generates a charge density profile. The liquid is electrically neutral, but for a charged layer adjacent to the boundary, which bears a charge locally equal in amplitude and opposite in sign to the bound charge on the surface. This charged layer is commonly known as the electric double layer (EDL).

Chemical and Physical Principles

It is well known that in contact with an aqueous solution, most solid surfaces tend to acquire a net positive or negative charge. The surface charging can occur by several mechanisms [1]. In one such mechanism, the surface groups can dissociate into ions, in contact with the liquid molecules. For example, protons can dissociate from the carboxylic groups of the surface ($-COOH \rightarrow -COO^- + H^+$), leaving behind a negatively



Electrical Double Layers, Figure 1 A schematic illustration of the ionic concentration and the potential field in an EDL in vicinity of a flat surface in contact with an aqueous solution. Zeta potential (ζ) is the potential at the shear plane. Debye length (λ) is the characteristic thickness of the EDL

charged solid substrate. On the other hand, if the surface contains basic groups such as OH, a dissociation of the basic groups (for example, release of OH^- ions to the aqueous solution, leaving behind positive charges on the surface) may generate a positively charged surface. Irrespective of the fact whether the surface is positively or negatively charged, the magnitude of the surface charge depends on the acidic or basic strengths of the surface groups and on the pH of the solution. A reduction in pH reduces the surface charge for a surface containing acidic groups, whereas an increase in pH reduces the surface charge for a surface containing basic groups. Another mechanism of surface charging can occur by means of preferential adsorption (binding) of ions from the solution. For example, Ca^{2+} ions can bind onto the zwitterionic headgroups of lipid bilayer surfaces to make the surface positively charged. The adsorption of ions from the solution can also occur onto oppositely charged surface sites. For instance, the adsorption of cationic Ca^{2+} to anionic COO^- sites (vacated by H^+ or Na^+ or K^+, as example) can occur by means of ion-exchange mechanisms. There may also occur a distribution of anions and cations between two immiscible phases such as water and oil. A similar situation may occur when a preferential dissolution of certain ionic species takes place. For example, when an AgI crystal is placed in water, dissolution takes place till the product of ionic concentrations of Ag^+ and I^- ions equals the solubility product ($= 10^{-16}$ mol/l^2). If equal amounts of Ag^+ and I^- ions were to dissolve, then the surface would be uncharged. However, in practice, the Ag^+ ions dissolve preferentially, leaving behind a negatively charged surface. In general, although the liquid solution is electrically neutral, an electrostatic force of attraction develops between the surface charges and the oppositely charged ions (counterions) in the liquid. Thus, a counterion concentration gradient establishes within the liquid, with a higher concentration near the solid surface and a lower concentration in the far-stream. On the other hand, the coion concentration near the surface is lower than that in the bulk liquid far away from the same, due to electrostatic repulsion. As a consequence, there is a net abundance of counterions close to the surface, which effectively balances the total charge of surface coions.

A schematic diagram depicting the charge and the potential distribution within an EDL is depicted in Fig. 1. Immediately next to the charged surface, a layer of immobilized counterions is present, which is known as the compact layer or the Stern layer or the Helmholtz layer. This layer is about a few Angstroms in thickness, and hence the potential distribution within the same can be taken as almost linear. The charge and the potential distributions within this layer are strong functions of the geometrical characteristics of the ions and the short-range interaction forces between the ions, wall and the adjacent dipoles. From the compact layer to the electrically neutral bulk liquid, the net charge density gradually reduces to zero. Since the Stern layer, featured with steep potential gradients (and hence steep velocity gradients), is extremely thin (of the order of the ion hydration radius, typically ~ 0.1 nm) as compared to the typical microchannel dimensions, the shear effects are virtually confined within this thin layer. This is extremely attractive in separation science, since it minimizes the hydrodynamic dispersion effects that are commonly associated with pressure-driven Poiseuille flows having parabolic velocity profiles. The layer of mobile ions beyond the Stern layer is called the Guoy-Chapman layer, or the diffused layer of the EDL. These two layers are separated by a shear plane. The potential at this shear plane is known as the zeta potential (ζ). The thickness of the EDL is known as the Debye length (λ), which is the length from the shear plane over which the EDL potential reduces to $(1/e)$ of ζ.

For a preliminary mathematical analysis, let us consider a single plate or surface in an infinite liquid phase. For the system to be in equilibrium, the electrochemical potential of the ions need to be constant everywhere, which implies that

$$\frac{d\bar{\mu}_i}{dy} = 0 \tag{1}$$

where the subscript i indicates type i ions and the electrochemical potential, μ_i, is defined as

$$\bar{\mu}_i = \mu_i + z_i e \psi \tag{2}$$

Here μ_i and z_i are the chemical potential and valence of type i ions and e is the charge of a proton. Further, from

thermodynamic considerations, one can write

$$\mu_i = \mu_i^0 + k_B T \ln n_i \tag{3}$$

where μ_i^0 is a constant for type i ions, k_B is the Boltzmann constant, T is the absolute temperature of the solution and n_i is the number concentration of the type i ions. Differentiating Eq. (3) with respect to y, one obtains

$$\frac{d\mu_i}{dy} = k_B T \frac{1}{n_i} \frac{dn_i}{dy} \tag{4}$$

Combining Eq. (4) with Eqs. (1) and (2), one gets

$$\frac{dn_i}{n_i} = -\frac{z_i e}{k_B T} d\psi \tag{5}$$

Equation (5) can be solved with the imposition of appropriate boundary conditions, based on the prevailing physical situation. Here we discuss two different boundary conditions (case 1 and case 2).

Case 1: At $y = h$, $\psi = \psi_h$, $n_i = n_i^h$. For this case, the solution of Eq. (5) is as follows:

$$n_i = n_i^h \exp\left(-\frac{z_i e}{k_B T}(\psi - \psi_h)\right) \tag{6}$$

Case 2: At $y \to \infty$, $\psi = 0$, $n_i = n_i^\infty$. The solution for this case is

$$n_i = n_i^\infty \exp\left(-\frac{z_i e \psi}{k_B T}\right) \tag{7}$$

Equation (7) gives the so-called Boltzmann distribution of ions near a charged surface [2]. The major assumptions implicit with the derivation of this distribution are as follows:

- The system is in equilibrium, with no macroscopic advection/diffusion of ions
- The solid surface is microscopically homogeneous
- The charged surface is in contact with an infinitely large liquid medium
- The strength (intensity) of the EDL field significantly overweighs the strength of any imposed electric field, close to the interface. As an example, for an EDL thickness of 10 nm and a surface potential of 100 mV, the EDL field strength is of the order of 10^7 V/m, which is significantly higher than the typical electric field strengths ($\sim$ kV/m) that are commonly employed to actuate fluid dynamic transport through microchannels.
- The far-stream boundary condition is applicable. This, however, loses its validity when the EDLs formed in vicinity of two narrowly-separated solid surfaces effectively protrude into the central plane that is located midway between the two surfaces and overlap with each other.

In practice, the validity of some of these assumptions may indeed be questionable, in a strict sense. For instance, one may cite the case of ionic charge distribution in presence of fluid flows, for which the system is not in thermodynamic equilibrium. However, for low flow velocities (Re < 10), the Boltzmann distribution can offer with a reasonably good approximation of ionic charge distribution. In order to prove this proposition, one may refer to the ionic species conservation equation, which describes the flux of the ith ionic species as

$$\nabla \cdot \boldsymbol{j}_i = 0 \tag{8}$$

In Eq. (8), $\boldsymbol{j}_i$ can be described by the Nernst–Planck equation as

$$\boldsymbol{j}_i = n_i \boldsymbol{u} - D_i \nabla n_i - \left(\frac{z_i e D_i n_i}{k_B T}\right) \nabla \psi \tag{8a}$$

Substituting Eq. (8a) in Eq. (8) and rearranging, one may write

$$\nabla \cdot (n_i \boldsymbol{u}) = \nabla \cdot (D_i \nabla n_i) + \nabla \cdot \left[\left(\frac{z_i e D_i n_i}{k_B T}\right) \nabla \psi\right] \tag{9}$$

In case the advection term in Eq. (9) can be neglected (which is true for low velocities), one can write, for a constant D_i

$$\nabla^2 n_i + \nabla \cdot \left[\left(\frac{z_i e n_i}{k_B T}\right) \nabla \psi\right] = 0 \tag{10}$$

For a one-dimensional situation (with gradients along y-direction only), Eq. (10) can be integrated to yield

$$\frac{dn_i}{dy} + \left(\frac{z_i e n_i}{k_B T}\right) \frac{d\psi}{dy} = 0 \tag{11}$$

which is same as Eq. (5), from which the Boltzmann equation can be derived by imposing the pertinent boundary conditions.

It is important to note here that the situations depicted by cases 1 and 2 are rather generic in nature, and can be judiciously extended to analyze the EDL formation

in between two parallel plates separated by a distance of $2h$, for example. When the characteristic EDL thickness (λ_D) is much less than h, the location of the midplane (centerline) can mathematically be treated as a far-field one, since the charge density gradients are only confined within the EDLs adjacent to the solid surfaces, beyond which the effects of near-wall potential distribution cannot effectively penetrate. In such situations, the mathematical description introduced by case 2 readily applies. On the other hand, case 1 is the representative of a more general situation, in which the EDLs formed in the vicinity of the two plates can penetrate into the mid-plane and in fact, may interfere with each other. We shall discuss about this situation more carefully, later in this article.

For analyzing the distinctive implications of the cases 1 and 2, let us first solve for the potential distribution consistent with case 1, with the consideration that the liquid phase is an aqueous solution with simple symmetric (1 : 1) electrolyte. In such situations, $z_1 = +1$, $z_2 = -1$, and accordingly, one may write

$$n_+ = n_+^h \exp\left(-\frac{e}{k_B T}(\psi - \psi_h)\right) \tag{12a}$$

$$n_- = n_-^h \exp\left(\frac{e}{k_B T}(\psi - \psi_h)\right) \tag{12b}$$

The net charge density per unit volume, ρ_e, can be described as

$$\rho_e = e\,(n_+ - n_-) \tag{13}$$

For further simplifications, one may note that for small values of the argument, it is possible to neglect higher order terms in an exponential series and approximate $\exp(x)$ as $1 + x$. This consideration, when applied to the potential distributions depicted by Eqs. (12a), (12b), forms the basis of the Debye–Hückel linearization principle [2], which effectively linearizes the pertinent exponential variation of ionic charge distribution for small values of $e\phi/k_B T$. Under such approximations, Eq. (13) can be simplified as

$$\rho_e = e\left[n_+^h\left(1 - \frac{e}{k_B T}\left(\psi - \psi_h\right)\right) - n_-^h\left(1 + \frac{e}{k_B T}\left(\psi - \psi_h\right)\right)\right] \tag{14}$$

The fundamental equation for electrostatic potential distribution within the system is nothing but the Poisson's equation, which states

$$\frac{d^2\psi}{dy^2} = -\frac{\rho_e}{\varepsilon} \tag{15}$$

where ε is the permittivity of the medium. Substituting Eq. (14) in Eq. (15), one gets

$$\frac{d^2\psi}{dy^2} - \frac{e^2}{\varepsilon k_B T}\left(n_+^h + n_-^h\right)\psi = \frac{e}{\varepsilon}\left[\left(n_-^h - n_+^h\right) - \frac{e}{k_B T}\left(n_-^h + n_+^h\right)\psi_h\right] \tag{16}$$

With the boundary conditions of $\psi = \psi_0$ at $y = 0$ (where ψ_0 is approximated as ζ, the zeta potential, in most electrokinetic models, although there is a minor difference between these two, in a strict sense) and $\psi = \psi_h$ at $y = h$, one gets

$$\psi = \psi_h + A_1 \exp\left(\sqrt{K_1}y\right) + A_2 \exp\left(-\sqrt{K_1}y\right) - K_2 \tag{17}$$

where

$$K_1 = \frac{e^2}{\varepsilon k_B T}\left(n_+^h + n_-^h\right)$$

$$K_2 = \frac{k_B T}{e}\frac{\left(n_-^h - n_+^h\right)}{\left(n_-^h + n_+^h\right)}$$

$$A_1 = \frac{\psi_0 - \psi_h}{1 - \exp\left(2\sqrt{K_1}h\right)} + \frac{K_2}{1 + \exp\left(\sqrt{K_1}h\right)}$$

$$A_2 = \frac{\psi_0 - \psi_h}{\exp\left(2\sqrt{K_1}h\right) - 1}\exp\left(2\sqrt{K_1}h\right) + \frac{K_2 \exp\left(2\sqrt{K_1}h\right)}{1 + \exp\left(\sqrt{K_1}h\right)}$$

The concentrations of cations and anions can be obtained by substituting Eq. (17) into Eqs. (12a) and (12b) to yield

$$n_+(y) = n_+^h\left[-\frac{K_3}{2}\exp\left(\sqrt{K_1}(y - h)\right) - \frac{K_3}{2}\exp\left(\sqrt{K_1}(h - y)\right) + K_3 + 1\right] \tag{18a}$$

$$n_{-}(y) = n_{-}^{h}\left[\frac{K_3}{2}\exp\left(\sqrt{K_1}(y-h)\right) + \frac{K_3}{2}\exp\left(\sqrt{K_1}(h-y)\right) - K_3 + 1\right] \tag{18b}$$

where $K_3 = \left(n_{-}^{h} - n_{+}^{h}\right)/\left(n_{-}^{h} + n_{+}^{h}\right)$.

It is important to mention here that the case of constant zeta potential boundary condition, as considered for the above analysis, may not be a very common feature for strongly interacting EDLs. Rather, the concerned boundary condition may be posed more appropriately by simultaneously invoking the pertinent equations for chemical equilibrium and surface charge density–surface potential relationship. For example, one may use [6]

$$\zeta(\sigma) = \frac{k_B T}{e}\ln\left(\frac{-\sigma}{e\Gamma + \sigma}\right) + \frac{\ln 10}{e/k_B T}(pK - pH) - \frac{\sigma}{C} \tag{18c}$$

where Γ is the surface density of chargeable sites, pH corresponds to that of the buffer solution, C is the Stern layer capacitance, pK is the equilibrium constant of the surface reaction. The surface charge density, σ, may be approximated using the Grahame equation for non-overlapped EDL conditions, as [6]

$$\sigma(\zeta) = \frac{2\varepsilon k_B T\kappa}{ze}\sinh\left(\frac{ze\zeta}{2k_B T}\right) \tag{18d}$$

In case of strong EDL overlap, Eq. (18d) ceases to hold valid. In that case, the variation of σ versus ζ is obtained by solving the potential distribution from the Poisson equation for different choices of the value of σ. The point of intersection of this characteristic with Eq. (18b) defines self consistent boundary values of σ and ζ.

Case 2 can be recovered as a special limiting form of case 1, with the following restrictions: as $h \to \infty$, $\psi_h \to 0$, $n_{-}^{h} = n_{+}^{h} = n^{\infty}$. This implies that for case 2 one can write $K_1 = 2e^2 n^{\infty}/\varepsilon k_B T$, $K_2 = 0$, $A_1 = 0$, $A_2 = \psi_0$. Thus, for case 2, the potential distribution takes the following form:

$$\psi(y) = \psi_0 \exp\left(-\sqrt{\frac{2e^2 n^{\infty}}{\varepsilon k_B T}}\,y\right) \tag{19}$$

The term $2e^2 n^{\infty}/\varepsilon k_B T$ appearing in Eq. (19) can be symbolized as κ^2, where $1/\kappa$ is commonly referred to as the characteristic thickness of the EDL, i.e., $1/\kappa \equiv \lambda$. This characteristic thickness solely depends on the properties of the liquid and not on any properties of the surface [1]. For example, for a 1:1 electrolyte of concentration C, $1/\kappa = 0.304/\sqrt{C}$ nm (where C is in molar units). This is estimated by taking $T = 298$ K, $\varepsilon = 78.5 \times 8.85 \times 10^{-12} C^2/\mathrm{N\,m}^2$, $e = 1.602 \times 10^{-19} C$, $k_B = 1.38 \times 10^{-23}$ J/K and $n^{\infty} = 1000N$, where N is the Avogadro number. Thus, for a 10^{-4} M NaCl solution, $1/\kappa \approx 30$ nm and for 1 M of the same solution $1/\kappa \approx 0.3$ nm. Physically, as the bulk ionic concentration increases, more counterions are attracted to the region close to the charged surface to neutralize the surface charge. As a result, the EDL thickness is reduced and the EDL appears to be somewhat *compressed*.

Out of the two cases described above, clearly the case 1 represents a more general situation in which the parameters n_{-}^{h}, n_{+}^{h} and ψ_0 are not independent constants, but are rather dependent on certain additional constraints. To appreciate the implications of these additional constraints, let us consider that the solid surface is composed of inorganic oxides (such as silica, zirconia, titania etc.). Either H_3O^+ or OH^- ions (formed as a consequence of dissociation of the aqueous medium carrying the electrolyte) can be adsorbed to the solid surface. The solid surface, accordingly, can become either positively or negatively charged, depending on the pH of the solution. The resultant surface charge density can then be described as [3]

$$\sigma_0 = \frac{eN_s\delta\sinh\left(\psi_N^* - \psi_0^*\right)}{1 + \delta\cosh\left(\psi_N^* - \psi_0^*\right)} \tag{20}$$

where $\psi_0^* = ze\psi_0/k_B T$, N_s is the site density on the oxide surface (a typical value may be of the order of 10^{14} to 10^{15} sites/cm^2, as an example), and ψ_N^* is the non-dimensional Nernst potential, given by

$$\psi_N^* = 2.303\left(\mathrm{pH_z} - \mathrm{pH}\right) \tag{21}$$

In Eq. (21), $\mathrm{pH_z}$ is the pH value when the solid surface reaches the point of zero charge (for most oxide surfaces, this value is between 5 and 6). For a pH value of the aqueous solution assumed as 7, the oxide surfaces would therefore be negatively charged due to an attachment of OH^- ions. This in turn implies that the concentration of OH^- ions in the bulk would decrease. As a consequence, to restore local equilibrium, certain number of H_2O molecules would further dissociate into H_3O^+ and OH^- ions. This consideration can be utilized to describe the mass conservation of H_3O^+ and OH^- ions in the charged EDL. The parameter δ in Eq. (20) can be described as

$$\delta = 2 \times 10^{-\Delta\mathrm{pK}/2} \tag{22}$$

where ΔpK is the dissociation constant difference (typically $\Delta\mathrm{pK} \sim 10$). For a given combination of the solid

surface and the solution, ψ_N^*, N_s and δ are uniquely prescribed, which implies that the parameter σ_0 varies with ψ_0^* only. Further, from the mass conservation of individual ionic types, one can write [3]

$$\int_0^h n_{H_3O^+}\,dy = n_{H_3O^+}^h + N_d \tag{23a}$$

$$\int_0^h n_{OH^-}\,dy = n_{OH^-}^h - \frac{\sigma_0}{e} + N_d \tag{23b}$$

where N_d is the number of H_2O molecules dissociated into H_3O^+ and OH^- ions. Defining the average concentration as $\bar{n}_i = \frac{1}{h}\int_0^h n_i\,dy$, Eqs. (23a) and (23b) can be re-written as

$$\bar{n}_{H_3O^+}h = n_{H_3O^+}^h + N_d \tag{24a}$$

$$\bar{n}_{OH^-}h = n_{OH^-}^h - \frac{\sigma_0}{e} + N_d \tag{24b}$$

Also, from the reaction equilibrium for dissociation of H_2O ($2H_2O \Leftrightarrow H_3O^+ + OH^-$), one can write

$$K_w = [H_3O^+] \times [OH^-] \tag{25}$$

where K_w is the dissociation constant depending on the prevailing temperature (for example, $K_w = 10^{-14}$ at 25 °C, provided that the ionic concentrations are taken in the units of M (mol/l)). The parameters $n_{H_3O^+}^h$ and $n_{OH^-}^h$, as appearing in Eqs. (24a) and (24b), can be obtained as

$$n_{H_3O^+}^h = N \times 10^3 \times [H_3O^+] \tag{25a}$$

$$n_{OH^-}^h = N \times 10^3 \times [OH^-] \tag{25b}$$

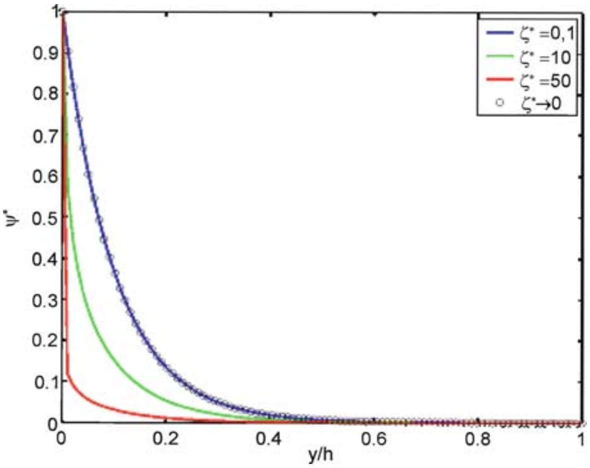
where N is the Avogadro number and the ionic concentrations are expressed in M (mol/l) units. Further, $[H_3O^+]$ and $[OH^-]$ can be described as

$$[H_3O^+] = 10^{-pH} \tag{25c}$$

$$[OH^-] = 10^{pH-14} \tag{25d}$$

With these considerations, the values of $n_{H_3O^+}^h$ and $n_{OH^-}^h$ can be estimated in consistency with the characteristics of the buffer solution under consideration. Furthermore, it can be assumed that the average concentrations of H_3O^+ and OH^- ions also obey equilibrium conditions, for which one can write, from Eqs. (25), (26a) and (26b)

$$\bar{n}_{H_3O^+} \times \bar{n}_{OH^-} = N^2 \times 10^6 \times K_w \tag{25e}$$



Electrical Double Layers, Figure 2 Variation of normalized electrical potential from the wall to the channel centerline

To obtain a correct description of the overall ionic charge distribution, one also needs to apply the charge conservation principle for all the positive and negative ions in the solution. Based on that, one may write (taking the example of a KCl solution as an electrolyte)

$$\int_0^h n_+\,dy = \int_0^h n_{K^+}\,dy + \int_0^h n_{H_3O^+}\,dy \tag{26a}$$

$$\int_0^h n_-\,dy = \int_0^h n_{Cl^-}\,dy + \int_0^h n_{OH^-}\,dy \tag{26b}$$

With the aid of Eqs. (18a) and (18b) and noting that $\int_0^h n_{K^+}\,dy = n^\infty \alpha h$, $\int_0^h n_{Cl^-}\,dy = n^\infty \beta h$ (where n^∞ is the original bulk ionic concentration of the electrolyte sample, $\alpha = \left(\int_0^h n_{K^+}\,dy\right)/\left(n^\infty h\right)$, $\beta = \left(\int_0^h n_{Cl^-}\,dy\right)/\left(n^\infty h\right)$),

$$\int_0^h n_{H_3O^+}\,dy = \bar{n}_{H_3O^+}h \quad \text{and} \quad \int_0^h n_{OH^-}\,dy = \bar{n}_{OH^-}h\,,$$

one can express Eqs. (26a) and (26b) in terms of the parameters n_+^h, n_-^h, $\bar{n}_{H_3O^+}$, and $\bar{n}_{OH^-}$. Finally, one may employ the asymptotic condition that as $\kappa h \to \infty$, and $n_+^h = n_-^h = n^\infty$. This hypothetical condition is practically satisfied when the value of κh is at least 10 or more, i. e., the location of the central plane of symmetry between the two plates is at a minimum distance of at least 10 times the EDL thickness from the solid surfaces. This consideration closes the system of Eqs. (20)–(26), and enables one to determine the parameters n_+^h, n_-^h and ψ_0, necessary for evaluation of the EDL potential for case 1 through Eq. (17).

Key Research Findings

From the analysis presented as above, it is apparent that the surface potential (or, equivalently, the ζ potential, in an approximate sense) plays a key role in determining the potential distribution within the EDL. The ζ potential, in turn, depends on the bulk ionic concentration and the pH [1]. The influence of ionic concentration can be quantitatively assessed by rewriting the Boltzmann distribution of ionic charges as

$$\frac{\mathrm{d}\,(\ln n_i)}{\mathrm{d}y} = \frac{-z_i e}{k_\mathrm{B} T}\,\frac{\mathrm{d}\psi}{\mathrm{d}y}\,,$$

or equivalently,

$$\frac{\mathrm{d}\psi}{\mathrm{d}\,(\ln n_i)} = \frac{-k_\mathrm{B} T}{z_i e}\,.$$

With $z_i = 1$, $T = 298\,\mathrm{K}$, the above implies $\mathrm{d}\psi/\mathrm{d}\ln n_i = -0.025689$. The above equation implies that a two-fold increase in n_i would result in only a small change in the value of ψ. On the other hand, the dependence of ψ on pH is much more dramatic. In fact, for a given electrolyte solution, the surface charge and ζ can be changed from positive to negative by varying the pH of the solution.

The mathematical descriptions outlined so far for analyzing cases 1 and 2 implicitly assume the validity of the celebrated Debye–Hückel linearization principle, as described earlier. However, for higher pH values (such as pH > 8), the surface potential may be such that the value of $e\psi/k_\mathrm{B}T$ cannot be taken to be small at all locations. A limiting condition that constraints the applicability of the Debye–Hückel approximation occurs for $e\psi/k_\mathrm{B}T \sim 1$, which for standard temperatures, corresponds to a value of approximately 25 mV for the surface potential. For values of ζ beyond this limit, the Debye–Hückel linearization might lose its validity and more general considerations need to be invoked. Such considerations are outlined in the following discussions.

In order to obtain a general solution of the Poisson equation (Eq. (15)) consistent with the Boltzmann distribution of ionic charges (Eq. (7)), one may first combine these two equations together to form the Poisson–Boltzmann equation, as

$$\frac{\mathrm{d}^2\psi^*}{\mathrm{d}y^2} = \kappa^2 \sinh\psi^* \tag{27}$$

It can be noted that in practice, the Poisson–Boltzmann equation can be used to a good effect even in the presence of *thick* EDLs, provided that the Peclet number based on the EDL thickness (i. e., $\mathrm{Pe}_{\kappa_D} = u_\mathrm{ref}\lambda/D$, where u_ref is the characteristic velocity scale along the axial direction and D is the diffusion coefficient of the solute) is small [4]. In such cases, a closed-form analytical expression for ψ can be obtained from Eq. (27) as

$$\psi(y) = \frac{8k_\mathrm{B}T}{ze}\sum_{i=0}^{\infty}\frac{q^{2i+1}}{\left(1-q^{4i+2}\right)}\,\frac{\cosh\left[(2i+1)\,\frac{y}{h}\chi\right]}{(2i+1)} \tag{28}$$

where

$$q = \exp\left(\frac{-\pi K}{K'}\right), \qquad K = F\left(\frac{\pi}{2}, k_0\right),$$

$$K' = F\left(\frac{\pi}{2}, \left(1-k_0^2\right)^{1/2}\right), \quad k_0 = \exp\frac{-ze\psi_h}{k_\mathrm{B}T},$$

$$\chi = \frac{\pi\kappa h}{2k_0^{1/2}K'},$$

ψ_h being the potential at the channel centerline. Here, the function F is an elliptic integral, defined as

$$F(\phi, k) = \int_0^{\phi}\frac{\mathrm{d}\theta}{\left(1-k^2\sin^2\theta\right)^{1/2}}\,.$$

An approximate solution of Eq. (28) can be obtained with a simplified consideration that $\psi_h^* \to 0$. In that situation, one may first multiply both sides of the Eq. (27) by $2\,\mathrm{d}\psi^*/\mathrm{d}y$ and integrate the same to obtain (noting that $\cosh\psi^* - 1 = 2\sinh^2\psi^*/2$)

$$\frac{\mathrm{d}\psi^*}{\mathrm{d}y} = -2\kappa\sinh\frac{\psi^*}{2} \tag{29}$$

Equation (29) can be integrated once more (noting that $\mathrm{d}/\mathrm{d}\psi^*\left(\ln\tanh\psi^*/4\right) = \frac{1}{2}\,\mathrm{cosech}\,\psi^*/2$), to obtain

$$\psi^*(y) = 4\left[\tanh^{-1}\left(\tanh\left\{\frac{\zeta^*}{4}\right\}\exp(-\kappa y)\right)\right] \tag{30}$$

Equation (30) is plotted in Fig. 2, for different values of ζ^*, by taking $\kappa h = 10$. It can easily be observed from the figure that for low values of ζ^*, the solution is virtually the same that is obtained with a Debye–Hückel approximation (as depicted by Eq. (19)).

It is also important to note here that the first integral of the Poisson–Boltzmann equation leads to an important relationship, known as the Grahame equation, and also as the Contact theorem [5]. This, fundamentally, is a relationship between the surface charge density, σ_0 (which is defined as $\sigma_0 = -\int\rho_\mathrm{e}\,\mathrm{d}y$, with a SI unit of $\mathrm{C/m^2}$) and the limiting value of the ionic density profile at the substrate-fluid interface. For a single flat surface with an infinite extent of

the adjacent liquid, an expression for σ_0 can be obtained from the Poisson–Boltzmann equation as

$$\sigma_0 = \frac{4n^{\infty}ze}{k}\sinh\left(\frac{ze\psi_0}{k_B T}\right) \quad (31)$$

Analogous to the case of flat surfaces, one can derive simple analytical expressions for the EDL field for cylindrical and spherical surfaces as well. A summary of the outcome of that analysis, under the Debye–Hückel approximation, is presented in Table 1.

A number of research investigations have recently been reported to elucidate several interesting aspects of EDL overlap. For example, Chakraborty and Padhy [6] reported the consequences of induced pressure gradients due to entrance and exit effects in electroosmotically driven flows through nanopores in presence of EDL overlap. Effects of EDL overlap in the context of AC electroosmosis have also been recently analyzed in a comprehensive manner [7, 8]. Other than using the traditional approaches of investigating the EDL effects, researchers have also employed order parameter based models (postulated on free energy formulation) for analyzing complicated physico-chemical effects within the EDL, including several issues of charge inversion [9]. Those aspects are not detailed here any further, within the scope of this introductory discussion.

Experimental Determination of Zeta Potential

From the discussions outlined so far, it is apparent that the zeta potential happens to one of the key parameters that dictates the overall potential distribution within the EDL. Several experimental techniques have been reported in the literature for an accurate measurement of this important parameter. In the subsequent discussions, the general principle behind these techniques is briefly outlined. The existing methodologies for the measurement of ζ primarily rely on the measurement of electroosmotic flow velocities through microfluidic conduits. When an electric field is applied tangentially to a solid-liquid interface, an electrical body force is exerted on the excess counterions in the diffuse EDL. These ions move under the action of the applied electric field, pulling the liquid with them. For thin EDLs (relative to the half channel width), the average electroosmotic flow velocity can be expressed as

$$\bar{u} = \frac{-\varepsilon\zeta E_x}{\eta} \quad (32)$$

where E_x is the applied axial electric field strength and η is the fluid viscosity. Under these conditions, the measured slope of the current (I)-time (t) relationship in electrosmotic flow can be utilized to measure zeta potential of flat surfaces [1], which can give more simple and accurate measurements in comparison to traditional streaming potential and electrophoresis based techniques [1]. If a capillary tube is connectedwith two different reservoirs containing different concentrations of an electrolyte at its two ends then during electroosmosis, the higher concentration electrolyte solution migrates from one reservoir into the capillary tube (which is initially filled with the electrolyte with a concentration same as that of the electrolyte in the lower-concentration reservoir) and displaces an equal volume of lower concentration electrolyte solution. As a result, the total resistance of liquid in the capillary tube changes and the current increases. The current reaches its maximum when the entire volume of lower concentration electrolyte is replaced with the higher concentration one. If a time of Δt is required to attain this state, then one can write

$$\bar{u} = \frac{L}{\Delta t} \quad (33)$$

where L is the length of the capillary. Based on this estimate of $\bar{u}$, one can obtain the values of ζ from Eq. (33). Although simple in principle, a major problem associated with this technique is the difficulty in the precise determination of Δt, due to small current fluctuations and gradual transitions in the current at the beginning and at the end of the replacement process. To avoid this problem, one might work with the linear portion of the $I-t$ characteristics experimentally observed (a major part of the $I-t$ characteristics is indeed linear, provided that the concentration differences are small) and calculate its slope (m) as

$$m = \frac{\Delta I}{\Delta t} \quad (34)$$

where ΔI and Δt are the changes in current and time, respectively, over the linear range. The total current, I, is the sum of the bulk conduction current, surface conduction current and the convection current. In practice, the first two contributions are significantly predominant over the third one, which means

$$\begin{aligned} I &\approx I_{\text{conduction,bulk}} + I_{\text{conduction,surface}} \\ &= \sigma_b A_c E_x + \sigma_s L E_x \end{aligned} \quad (35)$$

where σ_b is the bulk conductivity, σ_s is the surface conductivity and A_c is the area of cross section of the channel. Noting that $\Delta\sigma_s = 0$, one can write from Eqs. (33), (34) and (35)

$$m = \frac{\Delta\left(\sigma_b A_c E_x\right)}{\Delta t} = \frac{\Delta\left(\sigma_b A_c E_x\right)}{\Delta t} = \frac{\Delta\sigma_b A_c E_x \bar{u}}{L} \quad (36)$$

Electrical Double Layers, Table 1 A summary of EDL field adjacent to spherical and cylindrical surfaces (K_0 and K_1 are the 0th and 1st order modified Bessel function of 2nd kind, respectively)

	Governing equation	Boundary conditions	Surface charge balance equation	Charge on particle surface	EDL potential
Sphere	$\frac{1}{r^2}\frac{d}{dr}\left(r^2\frac{d\psi^*}{dr}\right) = \kappa^2 \sinh\psi^*$ where $\psi^* = \frac{ze\psi}{k_B T}$	$r = a$, $\psi^* = \frac{ze\psi_0}{k_B T}$, $r \to \infty$, $\psi^* \to 0$	$Q = -\int_a^\infty 4\pi r^2 \rho_e \, dr$	$Q = 4\pi\varepsilon a(1+\kappa a)\psi_0$	$\psi = \frac{1}{4\pi\varepsilon} \times \frac{Q}{1+\kappa a} \times \exp\left[-\frac{\kappa(r-a)}{r}\right]$
Cylinder	$\frac{1}{r}\frac{d}{dr}\left(r\frac{d\psi^*}{dr}\right) = \kappa^2 \sinh\psi^*$ where $\psi^* = \frac{ze\psi}{k_B T}$	$r = a$, $\psi^* = \frac{ze\psi_0}{k_B T}$, $r \to \infty$, $\psi^* \to 0$	$Q = -\int_a^\infty 2\pi r L \rho_e \, dr$	$Q = 4\pi\varepsilon a(2a+L)\psi_0 \times \frac{K_1(\kappa a)}{2K_0(\kappa a)}$	$\psi = \frac{\sigma_0 K_0(\kappa r)}{\varepsilon\kappa K_1(\kappa a)}$ where $\sigma_0 = \frac{Q}{2\pi aL + 4\pi a^2}$

Combining Eqs. (32) and (36), one gets

$$\zeta = \frac{\eta m L}{\varepsilon E_x^2 A_c \Delta\sigma_b} \tag{37}$$

Eq. (37) gives an expression for the determination of the value of ζ from the experimentally obtained I–t characteristics.

Restrictions on the Applicability of the Poisson–Boltzmann Equation

It is important to reiterate here that in most of the discussions presented in this article, the celebrated Poisson–Boltzmann equation has been utilized to describe the EDL potential distribution in simple analytical forms. However, as mentioned earlier, the Poisson–Boltzmann equation has its own limited applicability, especially when the surfaces under consideration constitute too narrow a fluid passage within which distinctive intermolecular and surface interactions take place. In brief, for such small separation distances, following effects are likely to occur, which are not considered while deriving the Poisson–Boltzmann equation [10]:

- Mobile counterions in the diffused EDL constitute a highly polarizable layer at each interface. These two opposing *conducting* layers experience an attractive van der Waals force (known as the ion correlation force), which becomes significant at small distances ($<$ 4 nm, typically).
- Effects of finite sizes of the ions (steric effects) tend to enhance the repulsion between two surfaces. This is analogous to the increased osmotic pressure of a van der Waals gas due to finite sizes of gas molecules. In a very similar manner, finite sizes of coions and counterions contribute to enhanced repulsion. In case of coions adsorbed on the surface, the repulsion is nothing but the steric repulsion between the overlapping Stern layers.
- Ionic charges interact with a surface because of the field reflected by the surface on being polarized. This reflected field is the same as if there were an image charge on the other side of the surface at the same distance. If ε be the permittivity of the aqueous medium and ε' be the permittivity of the surfaces, then an additional repulsive force due to this image charge interaction will occur if $\varepsilon' < \varepsilon$.
- Surface charges are discrete and are not *smeared out*, as has been implicitly assumed in the EDL theory. Discrete ions generally contribute to an additional attractive force, especially if the surface charges are mobile.
- Certain short range forces come into play when two surfaces approach closer than a few nanometers. Short-range oscillatory solvation forces of geometric origin arise whenever liquid molecules are induced to order into quasi-discrete layers between two surfaces or within highly restricted spaces. Additionally, surface-solvent interactions can induce orientational reordering in the adjacent liquid and can give rise to a monotonic solvation force that usually decays exponentially with the surface separation. Such forces are dependent on the physical and chemical properties of the surface and are not considered while describing the continuum-level EDL theories.

However, it is important to recognize here that interesting non-continuum effects (in many cases triggered by confinement induced hydrodynamic interactions) have recently been identified to alter the effective zeta potential [11] as a strong function of the slip coefficient. Such slip effects, in turn, may be prevalent in nanofluidic channels because of several reasons, including the formation of nanobubbles adhering to the wall on account of hydrophobic interactions. For more details, one may refer to [12–14].

Examples of Application

Some of the major applications of the EDL theory, in perspective of microfluidics research, are based on

the electrokinetics-based micro-flow actuation mechanisms. Based on these considerations, several Lab-on-a-Chip microdevices have been successfully constructed, which contain integrated microfluidic components such as pumps, mixers, reactors, dispensers, separators, along with the integrated circuitry, as embedded on thin glass or plastic plates (typically of a credit card size). Advantages of these devices include dramatic reduction in the amount of samples and reagents, very short reaction and analysis time, high throughput, automation and portability. Currently, technological improvements and requirements of economization of healthcare protocols are the major driving influences for electrokinetics-based microfluidic research. Some of the demanding applications are related to genomics and proteomics research, high-throughput screening, drug discovery and point-of-care clinical diagnostic devices. There are many specific applications of electrokinetics-based microfluidic actuation processes [1], including micro-total analysis systems (μTAS), capillary electrophoresis, electrochromatography, plymerised chain reaction (PCR) amplification, mixing, flow cytometry, DNA hybridization and analysis, protein analysis, cell manipulation, cell separation, cell patterning, immunoassay, enzymatic reactions, and molecular detection. An outline on these applications of microfluidics in biology and biomedical engineering are presented in the review papers of Beebe et al. [15] and Toner and Irimia [16].

Electrical double layer potential

Definition

The interaction forces and potentials between two charged surfaces in an electrolyte are fundamental to the analy-

sis of colloidal systems, and are associated with the formation of electric double layers (EDLs) in vicinity of the solid surfaces. The charged surfaces typically interact across a solution that contains a reservoir of ions, as a consequence of the dissociation of the electrolyte that is already present. In colloid and interfacial sciences, the EDL interaction potential, coupled with the van der Waals interaction potential, lead to the fundamental understanding of inter-surface interaction mechanisms, based on the Derjaguin–Landau–Verwey–Overbeek (DLVO) theory [1]. In practice, the considerable variations in the EDL interaction, brought about by the variations in electrolytic concentration of the dispersing medium, pH of the medium and the surface chemistry, lead to a diverse nature of the colloidal behavior. A fundamental understanding of the physics of EDL interactions, therefore, is of prime importance in understanding the colloidal interactions in various microfluidic applications.

Chemical and Physical Principles

To begin with the fundamental analysis of EDL interactions, let us first consider the distribution of potential between two charged infinite parallel plates at a distance of $2H$ apart and subjected to constant surface potentials (refer to Fig. 1). Assuming a Boltzmann distribution of the respective ionic concentrations, one can write, for a symmetric 1 : 1 electrolyte (see essay ►electrical double layers)

$$\nabla^2\psi = \frac{2n_0 e z}{\varepsilon}\sinh\frac{z e\psi}{k_B T} \tag{1}$$

where ε is the permittivity of the fluid medium, z is the valence of the ionic species in the solution, n_0 is the concentration of the same species in the bulk solution, e is the charge of an electron, k_B is the Boltzmann constant and T is the absolute temperature. For small surface potentials, the Debye–Hückel linearization principle can be employed, so that one can write

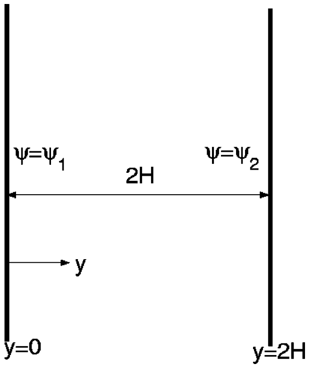
$$\nabla^2\psi = \kappa^2\psi \tag{2}$$

where $\kappa^2 = \frac{2n_0 e^2 z^2}{\varepsilon k_B T}$. A one-dimensional solution of Eq. (2) can be obtained as

$$\psi = A_1\cosh\kappa y + A_2\sinh\kappa y \tag{3}$$

where A_1 and A_2 are constants of integration. With the boundary conditions of $\psi = \psi_1$ at $y = 0$ and $\psi = \psi_2$ at $y = 2H$, one gets

$$A_1 = \psi_1 \quad \text{and} \quad A_2 = \frac{\psi_2 - \psi_1\cosh 2\kappa H}{\sinh 2\kappa H}\,. \tag{4}$$



Electrical Double Layers Interaction, Figure 1 Two parallel plates with constant surface potentials

Potential energy of interaction (V) per unit area between the two EDLs equals the change in free energy (G) of the system when the plates are brought from infinity to a distance of $2H$ apart. Thus,

$$V = \Delta G = G_{2H} - G_\infty \tag{5}$$

where

$$G_{2H} = -\frac{1}{2}(\sigma_1\psi_1 + \sigma_2\psi_2) \tag{5a}$$

with σ as the surface charge density (i. e., charge per unit area). Fundamentally, an expression for the surface charge density can be derived by assuming two parallel plates of the same charge density, σ, to be located at a distance $2H$ apart. Under these conditions, one may note that the total charge of counterions in the gap must be equal and opposite to the total charge on the surface. This implies (applying the above principle over the half space between the two plates)

$$\sigma = -\int_0^H \rho_e\,\mathrm{d}y \tag{6}$$

where ρ_e is the charge density in the fluid medium. Using the Poisson's equation $\left(\mathrm{d}^2\psi/\mathrm{d}y^2 = -\rho_e/\varepsilon\right)$ for electrical potential distribution, Eq. (6) can be rewritten as (assuming a homogeneous permittivity of the fluid)

$$\sigma = \varepsilon\int_0^H \frac{d^2\psi}{\mathrm{d}y^2}\,\mathrm{d}y \tag{6a}$$

which, on simplification (noting that $\mathrm{d}\psi/\mathrm{d}y = 0$ at $y = H$) yields

$$\sigma = -\varepsilon\left.\frac{\mathrm{d}\psi}{\mathrm{d}y}\right|_{y=0}\,. \tag{6b}$$

Equation (6b) can be generalized to read

$$\sigma = -\varepsilon \left.\frac{d\psi}{dn}\right|_{\text{surface}} . \tag{6c}$$

where n represents a direction normal to the surface that is oriented towards the intervening fluid. Thus, for the physical problem depicted in Fig. 1, one can write

$$\sigma_1 = -\varepsilon \left.\frac{d\psi}{dy}\right|_{y=0} , \quad \text{and} \quad \sigma_2 = \varepsilon \left.\frac{d\psi}{dy}\right|_{y=2H} . \tag{6d}$$

Using the above definition in Eq. (3), one gets

$$\sigma_1 = -\varepsilon\kappa \left(\psi_2 \operatorname{cosech} 2\kappa H - \psi_1 \coth 2\kappa H\right) . \tag{7a}$$

Similarly,

$$\sigma_2 = \varepsilon\kappa \left(\psi_2 \coth 2\kappa H - \psi_1 \operatorname{cosech} 2\kappa H\right) . \tag{7b}$$

Using Eqs. (7a) and (7b) in Eq. (5a), one gets

$$G_{2H} = \frac{\varepsilon\kappa}{2}\left(2\psi_1\psi_2 \operatorname{cosech} 2\kappa H - \left(\psi_1^2 + \psi_2^2\right)\coth 2\kappa H\right) \tag{8a}$$

When $H \to \infty$, it follows from Eq. (8a) that

$$G_\infty = -\frac{\varepsilon\kappa}{2}\left(\psi_1^2 + \psi_2^2\right) . \tag{8b}$$

Using Eqs. (8a) and (8b) in Eq. (5), one gets

$$V = \frac{\varepsilon\kappa}{2}\left(\left(\psi_1^2 + \psi_2^2\right)(1 - \coth 2\kappa H) + 2\psi_1\psi_2 \operatorname{cosech} 2\kappa H\right) . \tag{9}$$

The corresponding EDL interaction force per unit area, F_{2H}, can be calculated as

$$\begin{aligned} F_{2H} &= -\frac{dV}{d(2H)} \\ &= -\frac{\varepsilon\kappa}{2}\left(\left\{(\psi_1 - \psi_2)^2 \operatorname{cosech}^2 2\kappa H\right\}\right. \\ &\quad \left. + \left\{2\psi_1\psi_2 \operatorname{cosech}^2 2\kappa H\,(1 - \cosh 2\kappa H)\right\}\right) . \end{aligned} \tag{10}$$

It is clear from Eq. (10) that F_{2H} can either be positive or negative if ψ_1 and ψ_2 are of the same sign, since, in that case the terms within the two curly brackets in Eq. (10) are of opposite sign, the resultant of which can be either positive or negative. However, if ψ_1 and ψ_2 are of the opposite sign then both the terms are of the same sign and the resultant F_{2H} becomes negative. This, in turn, implies that with surface potentials of opposite signs, the EDL interaction force is always attractive.

Equation (9) can be conveniently utilized to derive the interaction potential between two spherical EDLs, following the Derjaguni's method [2]. This is done by utilizing the fact that the EDL interactions between two thin parallel slices of the spherical surfaces are essentially governed by Eq. (9). For the sake of analysis, let us consider two spherical surfaces at a minimum distance of separation of H_0, as depicted in Fig. 2. From Fig. 2, the total potential energy of interaction between two infinitesimally small parallel rings of width dx and radius x can be described as

$$U(H_0) = \int_{H=H_0}^{H\to\infty} V\,(2\pi x\,dx) \tag{11}$$

where V is given by Eq. (9) and x is a function of H. Further, from the geometry of Fig. 2, one may note that

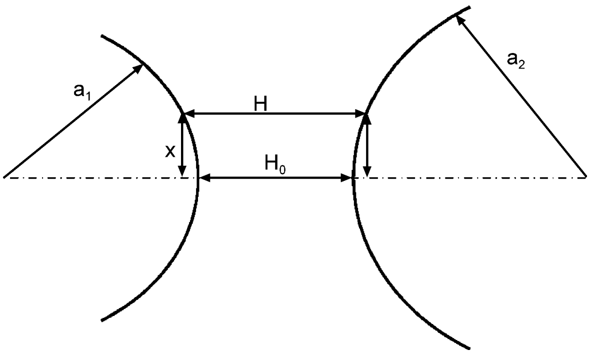
$$H - H_0 = a_1 + a_2 - \sqrt{a_1^2 - x^2} - \sqrt{a_2^2 - x^2} \tag{12}$$

which implies

$$dH = \left[\frac{1}{a_1\sqrt{1 - \frac{x^2}{a_1^2}}} + \frac{1}{a_2\sqrt{1 - \frac{x^2}{a_2^2}}}\right] x\,dx . \tag{13}$$

For $x \ll a_1$ and $x \ll a_2$, Eq. (13) gives

$$x\,dx \approx \frac{a_1 a_2}{a_1 + a_2}\,dH . \tag{14}$$



Electrical Double Layers Interaction, Figure 2 Geometrical features used for calculation of the EDL interaction potential between two spherical surfaces of radii a_1 and a_2

Using Eq. (9) and Eq. (14) in Eq. (11) and utilizing the facts that

$$\int_{H_0}^{\infty} (1 - \coth \kappa H)\, \mathrm{d}H = \frac{1}{\kappa} \ln\left[1 - \exp(-2\kappa H_0)\right] ,$$

$$\int_{H_0}^{\infty} \operatorname{cosech} \kappa H\, \mathrm{d}H = \frac{1}{\kappa} \ln\left[\frac{1+\exp(-\kappa H_0)}{1-\exp(-\kappa H_0)}\right] ,$$

one can obtain the following expression for the net EDL potential as

$$U(H_0) = \frac{\pi \varepsilon a_1 a_2}{a_1 + a_2}\Bigg(\left(\psi_1^2 + \psi_2^2\right) \ln\left[1 - \exp(-2\kappa H_0)\right] + 2\psi_1\psi_2 \ln\left[\frac{1+\exp(-\kappa H_0)}{1-\exp(-\kappa H_0)}\right]\Bigg) . \quad (15)$$

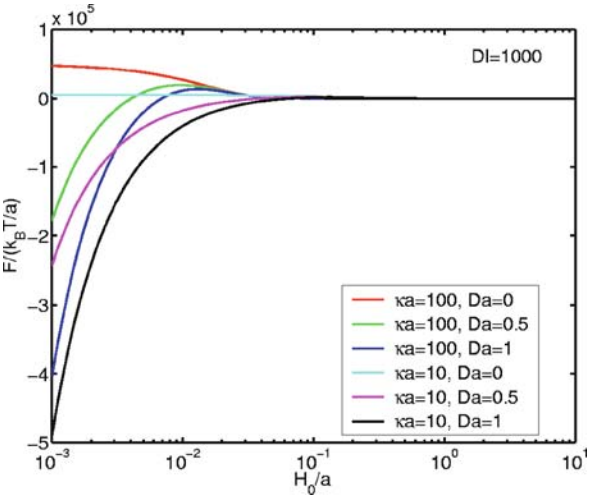
Equation (15) can be utilized to derive the EDL interaction potential between a sphere of radius a and a flat plate by setting $a_1 = a$, $a_2 \to \infty$, to obtain

$$U(H_0) = \pi \varepsilon a\Bigg(\left(\psi_1^2 + \psi_2^2\right) \ln\left[1 - \exp(-2\kappa H_0)\right] + 2\psi_1\psi_2 \ln\left[\frac{1+\exp(-\kappa H_0)}{1-\exp(-\kappa H_0)}\right]\Bigg) \quad (15a)$$

The corresponding EDL interaction force can be derived as

$$F(H_0) = -\frac{\partial U(H_0)}{\partial H_0} = 2\pi \varepsilon a \kappa \left(\psi_1^2 + \psi_2^2\right) \cdot \left(\frac{2\psi_1\psi_2}{\psi_1^2 + \psi_2^2} \frac{\exp(-\kappa H_0)}{1 - \exp(-2\kappa H_0)} - \frac{\exp(-2\kappa H_0)}{1 - \exp(-2\kappa H_0)}\right) . \quad (16)$$

Figure 3 depicts the EDL interaction force between a plane surface and a sphere. The non-dimensional parameters considered for plotting this figure are as follows: $DI = 4\pi \varepsilon a \psi_1 \psi_2 / k_B T$ and $Da = (\psi_1 - \psi_2)^2 / 2\psi_1\psi_2$, and ψ_1 and ψ_2 are taken to be of the same sign. Thus, a value of Da different from zero implies that ψ_1 and ψ_2 have different polarity and magnitude. In Fig. 3, however, only positive values of Da are represented. As evident from Fig. 3, the EDL interaction force becomes attractive at a small separation distance, despite the fact that the surface potentials have the same polarity. At larger separation distances, on the other hand, this force becomes repulsive in nature, analogous to the case with $Da = 0$. Further, larger the value of Da, stronger is the attractive potential at small distances of separation. It can also be observed that an asymmetry in the EDL interaction always reduces the repulsive force and moves the location of occurrence of the maximum repulsive force to a greater distance from the wall.



Electrical Double Layers Interaction, Figure 3 EDL interaction force (non-dimensional) as a function of the separation distance between the plane surface and the sphere

It is important to mention here that the EDL interaction potentials described by Eqs. (15) and (15a) are only applicable under the following restricted conditions:

1. $|e\psi/k_B T| < 1$ (consistent with the Debye–Hückel approximation), i. e., $|\psi_1|, |\psi_2| < 25$ mV. However, as shown by Hogg et al. [3], Eqs. (15) and (15a) are good approximations even for the values of ψ_1 and ψ_2 upto 50 to 60 mV.
2. $\kappa a_1 \gg 1$ and $\kappa a_2 \gg 1$, i. e., the EDL thicknesses are small relative to the particle sizes. However, Verwey and Overbeek [1] have showed that Eqs. (15) and (15a) are quite accurate if the values of κa_1 and κa_2 exceed 10.

The methodology described as above has recently been extended [4] to estimate the EDL interaction between a spherical particle (of radius a) and a cylinder (of radius R). The details of the derivations are presented elsewhere [4], and only the final results are summarized below.

$$U(H_0) = 4\varepsilon a^2 \psi_1 \psi_2 \kappa \int_0^{\frac{\pi}{2}} \left[\int_0^1 p\left(\bar{H}_0, \bar{x}, \theta\right) \bar{x}\, \mathrm{d}\bar{x}\right] \mathrm{d}\theta \quad (17)$$

where

$$p\left(\bar{H}_0, \bar{x}, \theta\right) = \operatorname{cosech} \kappa a \bar{H} + \left[\frac{(\psi_1 - \psi_2)^2}{2\psi_1\psi_2} + 1\right]\left(1 - \coth \kappa a \bar{H}\right) \quad (17a)$$

and

$$\bar{H} = \bar{H}_0 + 1 - \sqrt{1 - \bar{x}^2} + \frac{R}{a} - \sqrt{\frac{R^2}{a^2} - \bar{x}^2 \sin^2\theta} \,. \quad (17b)$$

Similarly,

$$F(H_0) = 4\varepsilon a \psi_1 \psi_2 \kappa \int_0^{\frac{\pi}{2}} \left[\int_0^1 f\left(\bar{H}_0, \bar{x}, \theta\right) \bar{x}\, \mathrm{d}\bar{x}\right] \mathrm{d}\theta \quad (18)$$

where

$$f\left(\bar{H}_0, \bar{x}, \theta\right) = -\frac{\partial p}{\partial \bar{H}_0} = \kappa a \left[\coth \kappa a \bar{H} \operatorname{cosech} \kappa a \bar{H} - \left[\frac{(\psi_1 - \psi_2)^2}{2\psi_1\psi_2} + 1\right] \operatorname{cosech}^2 \kappa a \bar{H}\right]. \quad (19)$$

The theoretical developments outlined so far pertain to a situation in which both the surfaces are kept at constant potentials. Another interesting situation may occur when both the surfaces posses constant charges. The analysis for this case is very much analogous to what has been presented here for the case of constant surface potentials. For illustration, one may consider the case of EDL interactions between two parallel plates with constant surface charge densities. For this case, employing the Debye–Hückel linearization principle, the potential distribution can be obtained in the same form as Eq. (3), although the constants of integration, A_1 and A_2, will differ from the earlier case of constant surface potential. To evaluate these constants for the constant surface charge case, one may utilize Eq. (6d) and obtain

$$A_1 = \frac{\sigma_2 + \sigma_1 \cosh 2\kappa H}{\varepsilon\kappa \sinh 2\kappa H}, \quad A_2 = -\frac{\sigma_1}{\varepsilon\kappa}. \quad (20)$$

For the case of constant surface charges, the free energy can be described as

$$G_{2H} = \frac{1}{2}(\sigma_1\psi_1 + \sigma_2\psi_2)\,. \quad (21)$$

Substituting the appropriate expressions in Eq. (21), a simplified expression of the free energy can be obtained as

$$G_{2H} = \frac{1}{2\varepsilon\kappa}\left[2\sigma_1\sigma_2 \operatorname{cosech} 2\kappa H + \left(\sigma_1^2 + \sigma_2^2\right)\coth 2\kappa H\right] \quad (22a)$$

Thus,

$$G_\infty = \frac{1}{2\varepsilon\kappa}\left(\sigma_1^2 + \sigma_2^2\right). \quad (22b)$$

Using Eqs. (22a) and (22b) in Eq. (5), one gets

$$V(2H) = \frac{1}{2\varepsilon\kappa}\left[2\sigma_1\sigma_2 \operatorname{cosech} 2\kappa H - \left(\sigma_1^2 + \sigma_2^2\right)(1 - \coth 2\kappa H)\right]. \quad (23)$$

The EDL interaction force per unit area can be evaluated from Eq. (23) as

$$F(2H) = -\frac{\partial V(2H)}{\partial (2H)} = \frac{1}{2\varepsilon}\left[\frac{\sigma_1^2 + \sigma_2^2 + 2\sigma_1\sigma_2 \cosh(2\kappa H)}{\sinh^2(2\kappa H)}\right]. \quad (24)$$

Eq. (24) can also be recast as

$$F(2H) = \frac{1}{2\varepsilon}\left[\left\{(\sigma_1 - \sigma_2)^2 \operatorname{cosech}^2 \kappa H\right\} + \left\{2\sigma_1\sigma_2 \operatorname{cosech}^2(\kappa H)(1 + \cosh \kappa H)\right\}\right]. \quad (24a)$$

Clearly, if σ_1 and σ_2 are of the same sign then Eq. (24a) predicts a positive (repulsive) interaction force. On the other hand, if they are of opposite polarity, the two expressions in the curly brackets of Eq. (24a) are essentially of opposite sign, which means that the resultant interaction can either be attractive or repulsive. It is important to note here that contrary to common intuitions, the origin of a net repulsive force between two identically charged surfaces in a polar solvent containing electrolyte ions is entropic (osmotic) and not electrostatic. It is true that the electrostatic contribution to the net force is attractive in nature, which is nothing but the Coulombic interaction between the coions and the counterions. Despite this attraction, the counterions remain away from the surface and maintain the diffuse EDL because of the repulsive osmotic pressure between themselves. This is also called an entropic interaction, since it tends to increase the

configurational entropy of the counterions. Bringing the two surfaces closer to each other forces the counterions to move towards the surface against their equilibrium state (i. e., against their osmotic repulsion), but favored by the electrostatic interactions. For identically charged surfaces, the former one dominates in reality, resulting the net force to be a repulsive one.

The two standard cases presented so far are by no means comprehensive and in reality, other types of boundary conditions could be operative as well. For example, out of the two parallel plates, plate 1 might be of constant surface potential and plate 2 might be of constant surface charge. The EDL free energy of formation, in that case, can be described as

$$G_{2H} = \frac{-\sigma_1\psi_1 + \sigma_2\psi_2}{2} . \tag{25}$$

The pertinent expressions for EDL potential energy and the interaction force are as follows:

$$V(2H) = \frac{\sigma_2^2 - \kappa^2\varepsilon^2\psi_1^2}{2\kappa\varepsilon}\left(\tanh 2\kappa H - 1\right) + \sigma_2\psi_1 \operatorname{sech} 2\kappa H \tag{26}$$

$$F(2H) = \operatorname{sech} h2\kappa H\left[-\frac{\sigma_2^2 - \kappa^2\varepsilon^2\psi_1^2}{2\varepsilon}\operatorname{sech} 2\kappa H + \kappa\sigma_2\psi_1 \tanh 2\kappa H\right] \tag{27}$$

Key Research Findings

The fundamental theories on EDL interactions have been substantially advanced by several researchers in the recent past, in order to incorporate the effects of other pertinent physico-chemical phenomena in the mathematical model and to generalize the underlying postulates. Kjellander and Mitchell [5] employed the dressed ion theory for EDL structure and interactions, which is nothing but an exact statistical mechanical formalism for electrolyte systems. In their theory, the *dressed ions* took equivalent roles as the bare ions in the Poisson–Boltzmann approximation. A practical method was also derived for evaluating the effective surface charge densities of the particles. Behrens and Borkovec [6] proposed a quantitative criterion to evaluate the degree of charge regulation for surfaces with arbitrary electrostatic potential. Their approach represented a generalization of the linearized regulation model that had been proposed earlier for the framework of the Debye–Hückel theory only. Their results suggested a new way of using the limiting conditions of constant charge and constant potential to approximate the interaction free energy of charge regulating surfaces. Based on the well-known Debye–Hückel approximation and the Derjaguin's integration method, Gu [4] obtained an integral solution for the EDL interaction between a spherical particle and a cylinder. The effects of the relative dimensions of the cylinder to the sphere on the EDL interaction were studied numerically. These numerical calculations indicated that, in general, the curvature effect on the EDL interaction cannot be neglected at small separation distances. The widely used sphere–flat plate approximation was found to considerably overestimate the actual EDL interaction between a spherical particle and a cylinder, under these circumstances. It was also revealed that the ratio of the radius of the particle to the EDL thickness also plays an important role in determining the EDL interaction at small dimensionless separation distances. Moreover, it was found that at small distances of separation, the EDL interaction can become attractive between two asymmetric EDLs, irrespective of their potentials having the same polarity. Briscoe and Attard [7] developed a counterion-only EDL theory, by adopting a constrained entropy maximization approach, based on an isothermal thermodynamic system. The free energy per unit area between two charged planar surfaces was obtained for the boundary conditions of constant surface charge density and charge regulation. Once applied to a non-polar medium, it was revealed that the electrical double-layer repulsion is weak and long-ranged. Asymptotically, the interaction was found to decay as a power law, in contrast with that in the presence of an ion reservoir which decays exponentially at large surface separations. Huang and Ruckenstein [8] developed a model for EDL interactions that accounts for the difference in dielectric constants because of the influences of hairy surfaces. The ion specificity was also taken into account by using Born's expression for the free energy of hydration of ions. The repulsive forces calculated via the Gouy–Chapman theory and via their new model were compared. It was revealed that the hairy regions can have a long range effect on the repulsive double-layer interactions, which cannot be captured if the short-range steric effects are only taken into account to model the hairy surfaces. Yu et al. [9] proposed a density-functional theory to describe the density profiles of small ions around an isolated colloidal particle. The excess Helmholtz energy functional was derived from a modified fundamental theory for the hard-sphere repulsion and a quadratic functional Taylor expansion for the electrostatic interactions. Their theoretical predictions were in good agreement with the results from Monte Carlo simulations and results from the previous investigations using integral-equation theory for the ionic density profiles and the zeta potentials of spherical particles. Their density-functional theory predicted the formation of a second

counterion layer near the surface of highly charged spherical particle. On the other hand, the nonlinear Poisson–Boltzmann theory and its variants were unable to capture the oscillatory behavior of small ion distributions and charge inversion. In fact, the density-functional theory predicted charge inversion even in a 1 : 1 electrolyte solution, so long as the salt concentration is sufficiently high. Das and Bhattacharjee [10] developed a finite element model of the EDL interaction between an approaching colloidal particle and a small region of a charged planar surface containing four previously deposited particles. The interaction forces obtained from their detailed three-dimensional finite element simulations suggest that with previously deposited spherical particles, the EDL repulsion experienced by the approaching particle is less than the corresponding sphere–plate interaction due to the presence of the previously deposited particles. The reduction in force is quite significant when the screening length of the electric double layer becomes comparable to the particle radius.

Examples of Application

In a very recent study, Zypman [11] outlined some exact expressions for colloidal plane–particle interaction forces and energies with applications to atomic force microscopy (AFM). A general formalism was employed in this study to assess the particle–plane interactions within the Derjaguin–Landau–Verwey–Overbeek (DLVO) framework. The main results of this work were employed to generate an analytical force-separation expression based on AFM experiments for a tip and surface immersed in an aqueous solution. The Derjaguin approximation was subsequently generalized by calculating the next order of approximation, thereby obtaining a useful formula for colloidal interaction estimations.

Electrical/Electrochemical Impedance

Definition

Impedance is a measure of the ability of a circuit to resist the flow of an alternating current. It is usually measured by applying an AC potential to an electrochemical cell and measuring the current through the cell. The current response to a sinusoidal potential will be a sinusoid at the same frequency but shifted in phase. The impedance of the system can be calculated as an expression analogous to Ohm's Law as:

$$Z = \frac{E(t)}{I(t)} = \frac{E_0 \cos(\omega t)}{I_0 \cos(\omega t - \phi)} = Z_0 \frac{\cos(\omega t)}{\cos(\omega t - \phi)} \qquad (1)$$

The impedance is therefore expressed in terms of a magnitude, Z_0, and a phase shift, f. It is also possibly represented

as a complex number,

$$Z = \frac{E}{I} = Z_0 \exp(\mathrm{j}\phi) = Z_0(\cos\phi + \mathrm{j}\sin\phi) \tag{2}$$

The total impedance of a system is the sum of the impedance of the electrical elements in the circuit such as resistors, capacitors, and inductors. For linear impedance elements in series, the equivalent impedance can be calculated from:

$$Z_{eq} = Z_1 + Z_2 + Z_3 \tag{3}$$

For linear impedance elements in parallel, the equivalent impedance can be calculated from:

$$\frac{1}{Z_{eq}} = \frac{1}{Z_1} + \frac{1}{Z_2} + \frac{1}{Z_3} \tag{4}$$

Electrocapillarity

Definition

Electrocapillary phenomenon refers to the modification of the interfacial tension by the presence of electrical charges. The first comprehensive investigations on electrocapillary phenomena were performed by Lippman, way back in 1875 [1]. In Lippman's experimental apparatus, the interfacial tension modulation due to electrical effects was observed through a capillary rise phenomenon, and hence, was later termed as electrocapillarity. A decisive advantage of electrocapillary actuation, in comparison to its thermal counterpart (i. e., the thermocapillary effect, in which surface tension differentials are created by imposed temperature gradients) is the speed with which electrical potentials can be applied and regulated, with possible characteristic timescales of even less than a few milliseconds. Further, electrocapillary based microacatuators consume much less power, as compared to the typical thermocapillary microdevices.

Chemical and Physical Principles

General Theory of Electrocapillarity

The electrocapillary principles are all based on the fact that the surface tension occurs to be a strong function of the electric potential acting across an interface. For illustration, let us consider a discrete liquid droplet in a microchannel, as depicted in Fig. 1. On application of a voltage across the two ends, a motion of the droplet can be actuated, because of the establishment of a pressure differential on account of an asymmetric change in the interfacial tension and a consequent asymmetric deformation of the two menisci. This principle of actuation of fluid motion, commonly known as continuous electrowetting (CEW), happens to be a fundamental principle of

operation of different types of optical switches, micromotors and micropumps. However, such metal/electrode systems might not always be well-suited for microchannel networks, because of the high electrical conductance of the fluid system that can cause high currents and cross-links between neighbouring channels and cells. Moreover, because of large density differences, metal-electrolyte systems are often very sensitive to gravitational forces.

Unlike the CEW, two other types of electrocapillary principles can be employed in practice, which can be utilized to manipulate liquid droplets without necessitating another liquid medium. One such technique is known as electrowetting (EW), which refers to the control of wetting properties of a liquid (commonly, an electrolyte) on a solid (typically, electrode surface), by the modification electric charges present at the solid–liquid interface. Because of a spontaneous ionic charge distribution, an electric double layer (EDL) of a few nm in thickness is formed between the electrode and the aqueous solution. On application of a voltage between the liquid and the electrode, the effective solid–liquid interfacial energy is lowered, on account of the fact that the EDL essentially acts like a parallel plate capacitor that stores electrostatic energy within the same. This leads to an alteration in the apparent contact angle (θ) with the applied voltage, resulting in a net change in the driving force that acts on the liquid meniscus, and a consequent advancing or retracting motion of the same (refer to Fig. 2). A large capacitance of the EDL ($c \sim \varepsilon/\lambda_D$, λ_D being the Debye screening length, typically of the order of a few nm and ε being the permittivity of the ionic medium) effectively allows large changes in the contact angle for relatively small applied voltages.

A third type of electrocapillary principle is known as electrowetting on dielectrics (EWOD), in which the liquid and the electrodes are separated by a thin dielectric layer (refer to Fig. 3). Major advantages of such an arrangement lie in the fact that higher potentials can be applied without causing undesired electrochemical reactions between the electrode and the aqueous medium. Moreover, highly non-wetting surfaces can be designed, which can respond more prominently to the electrowetting actuation mechanisms.

A fundamental postulate that is common to the three basic electrocapillary actuation principles, mentioned as above, is the change in surface energy with the application of electrical potentials, as governed by the Lippman equation:

$$\gamma = \gamma_0 - \frac{1}{2} c V^2 \tag{1}$$

where γ_0 is the surface tension when there is no voltage applied across the interface and c is the capacitance per unit area of the EDL (for CEW and EW) or the dielectric layer (for EWOD). However, these three actuation principles have their own characteristic distinctive features, which are summarized in Table 1.

In order to appreciate the fundamental physical postulates associated with the principles of electrowetting, one may first consider the total free energy of a liquid droplet, in the absence of an electric field, as

$$E = \sum_{i \neq j} A_{ij} \gamma_{ij} - \lambda \forall \tag{2}$$

where $\forall$ is the droplet volume and λ is a Lagrange multiplier to enforce a constant volume constraint (physically, λ is equal to the pressure drop across the liquid-vapour interface, thermodynamically consistent with the definition of free energy of a system). Here A_{ij} is the interfacial area that demarcates the phases i and j, with the corresponding surface energy being designated as γ_{ij}. In this article, the subscripts l, s and v will be employed to represent the liquid, solid and vapour phases, respectively. It can also be noted that if A_{ls} is increased by some amount, A_{sv} is decreased by the same amount.

The free energy evaluation can be best illustrated through the example of a spherical droplet with an equilibrium contact angle θ (refer to Fig. 4), for which case one can write: $A_{sl} = \pi R^2 \sin^2\theta$, $A_{lv} = 2\pi R^2 (1 - \cos\theta)$,

Electrocapillary, Figure 3 The arrangement for electrowetting on dielectrics of a liquid droplet. The right hand diagram is a simpler schematic illustration

Electrocapillary, Table 1 A comparison of different electrocapillary actuating mechanisms

	CEW	EW	EWOD
Capacitor	EDL	EDL	Dielectric layer
Modulated surface tension, γ	Liquid–liquid interfacial tension	Solid–liquid interfacial tension	Solid–liquid interfacial tension
Contact angle	Always 180°, as the droplet does not directly contact the solid surfaces	Variable	Variable

$\forall = \pi R^3(2/3 - 3/4\cos\theta + \cos 3\theta/12)$. Thus, for a spherical droplet

$$E = \underbrace{\pi R^2 \sin^2\theta\,(\gamma_{\mathrm{ls}} - \gamma_{\mathrm{sv}}) + \gamma_{\mathrm{lv}} 2\pi R^2\,(1 - \cos\theta)}_{f} - \lambda \left\{ \underbrace{\pi R^3 \left(\frac{2}{3} - \frac{3}{4}\cos\theta + \frac{\cos 3\theta}{12} \right)}_{g} \right\} \quad (3)$$

For minimization of E, one must have $\partial E/\partial\theta = 0$ and $\partial E/\partial R = 0$, which implies

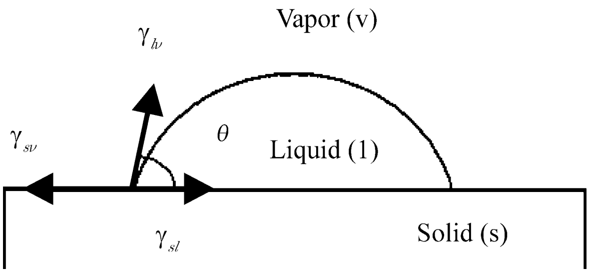
$$\frac{\partial f}{\partial\theta}\frac{\partial g}{\partial R} = \frac{\partial f}{\partial R}\frac{\partial g}{\partial\theta} \quad (4)$$

Performing the necessary algebra and simplifying, it follows from Eqs. (3) and (4) that

$$\cos\theta = \frac{\gamma_{\mathrm{sv}} - \gamma_{\mathrm{sl}}}{\gamma_{\mathrm{lv}}} \quad (5)$$

Eq. (5) can also be interpreted as a balance between the horizontal components of all the forces that act on the 3-phase contact line (refer to Fig. 4). The vertical component of of this resultant force, on the other hand, is balanced by the normal stress in the rigid solid substrate. Further, substituting the value of cosθ from Eq. (5), one may calculate a value of the parameter λ (= Δp), as

$$\Delta p = \frac{\partial f/\partial\theta}{\partial g/\partial\theta} = \frac{2\gamma_{\mathrm{lv}}}{R} \quad (6)$$



Electrocapillary, Figure 4 Equlibrium of a droplet

For a droplet of a more general shape, Eq. (6) can be generalized as

$$\Delta p = \gamma_{\mathrm{lv}} \left(\frac{1}{r_1} + \frac{1}{r_2} \right) \quad (7)$$

where r_1 and r_2 are the two principal radii of the curvature of the droplet surface. It is important to note here that the Eqs. (5) and (7) are two necessary conditions for equilibrium but not sufficient, since in addition, the second variation of E must also be positive for a minimization of the same. In fact, in presence of complex surfaces, certain morphologies may, indeed, result in unstable droplets, even though both of the necessary conditions are satisfied.

With the above perspective in view, let us take the example of a EWOD actuating mechanism, in which there is an additional electrostatic contribution (E_{el}) to the free energy, so that the net free energy (E_{net}) becomes an algebraic sum of E_{el} and E (as given by Eq. (5)). For that purpose, the following fundamental expression for E_{el} can be

utilized:

$$E_{\mathrm{el}} = -\frac{1}{2}\int \boldsymbol{E}(\boldsymbol{r}) \cdot \boldsymbol{D}(\boldsymbol{r})\, \mathrm{d}\forall \tag{8a}$$

where $\boldsymbol{E}(\boldsymbol{r})$ and $\boldsymbol{D}(\boldsymbol{r})$ are the electric field and the electrical displacement at a position vector $\boldsymbol{r}$ and $\mathrm{d}\forall$ is an elemental volume. In Eq. (8a), $\boldsymbol{D}(\boldsymbol{r})$ is given as

$$\boldsymbol{D}(\boldsymbol{r}) = \varepsilon(\boldsymbol{r})\boldsymbol{E}(\boldsymbol{r}) \tag{8b}$$

where $\varepsilon(\boldsymbol{r})$ is the permittivity of the medium at $\boldsymbol{r}$. In evaluating the integral in Eq. (8a), the liquid is considered to be a perfect conductor, which implies that the surface charges screen the electric fields completely from the interior of the liquid and consequently, the integral vanishes inside the droplet. Further, the electrostatic energy can be split into two parts. One part arises from a parallel plate capacitor formed by the droplet and the electrode, with $C = cA_{\mathrm{sl}}$, where $c = \varepsilon_d/d$, d being the thickness of the dielectric layer and ε_d being the corresponding permittivity. The second part arises from the stray capacitance along the edge of the droplet. However, since the fringe fields are mainly localised within a small range around the contact line, their contribution to the total energy can be neglected. The assumption that the insulator is a major contributor to the overall capacitance seems to be reasonable, since the insulator is much thicker than the EDL and a major part of the voltage drops across the insulator only. Thus, Eq. (8a) yields

$$E_{\mathrm{el}} = -\frac{1}{2}\frac{\varepsilon_d}{d}V^2 A_{\mathrm{sl}} \tag{9}$$

A physical interpretation to the E_{el} term can be provided as follows. Upon connecting the initially uncharged droplet to the power source (battery), a charge δQ flows from the battery to the droplet and to the electrode. The resultant work done on the droplet-electrode capacitor is given by $\delta W_{\mathrm{droplet}} = V_Q \delta Q$, where V_Q is the potential of the capacitor on being energized with an instantaneous charge of Q. Since V_Q = Q/C, the total work done is given by $\int \delta W_{\mathrm{droplet}} = 1/2CV_B^2$, where V_B is the potential of the power supply (battery). The incremental work done on the battery, on the other hand, is given by $\delta W_B = V_B \delta Q_B = V_B(-\delta Q)$. Since the battery voltage is a constant, we have, $\int \delta W_B = -V_B \int \delta Q_B = -CV_B^2$. Thus, the net work done on the battery-electrode system is given by $\int \delta W_{\mathrm{droplet}} + \int \delta W_B = -1/2CV_B^2$.
Substituting Eq. (9) in the expression for total free energy of the droplet (including the electrical energy), one obtains

$$E_{\mathrm{net}} = A_{\mathrm{sl}}\left(\gamma_{\mathrm{sl}} - \frac{1}{2}cV^2\right) + A_{\mathrm{sv}}\gamma_{\mathrm{sv}} + A_{\mathrm{lv}}\gamma_{\mathrm{lv}} - \forall \Delta p \tag{10}$$

Comparing Eq. (10) with Eq. (2), it can easily be observed that EWOD results in a lowering of the effective solid–liquid interfacial energy to a modified value, given by

$$\gamma'_{\mathrm{sl}} = \gamma_{\mathrm{sl}} - \frac{1}{2}cV^2 \tag{11}$$

Eq. (5) can now be utilized to describe the new equilibrium contact angle (θ') as

$$\cos\theta' = \frac{\gamma_{\mathrm{sv}} - \gamma'_{\mathrm{sl}}}{\gamma_{\mathrm{lv}}} \tag{12}$$

Combining Eqs. (5), (11) and (12), one gets

$$\cos\theta' = \cos\theta + \frac{1}{2}\frac{cV^2}{\gamma_{\mathrm{lv}}} \tag{13}$$

which is the well-known Young–Lippman equation [2] that relates a modification of the apparent contact angle with the applied voltage. In a physical sense, electrowetting decreases the effective contact angle, which is driven by the energy gain upon redistributing the charge from the battery to the droplet. This reduction of apparent contact angle is fundamentally related to the fact that a minimization of the free energy requires a maximization of the capacitance. Applying a potential between the droplet and the electrode, therefore, would tend to spread the droplet as much as possible, in an effort to increase the capacitance, which is proportional to A_{sl}. In even more simple terms, because of the applied electric field, opposite charge densities are induced at the fluid-solid interface and in the substrate electrode. The electrostatic attraction between the aqueous solution and the electrode enhances the coverage of the surface by the aqueous solution, thereby inducing an enhanced wetting effect. It can also be noted here that in general, there can be additional contributors to the capacitance per unit area, c, over and above the insulating material. Fundamentally, the solid–liquid interface consists of two layers: one electrically insulating coating in which the potential drops linearly with the thickness, the diffuse EDL being the other. However, when the EDL capacitance becomes much greater than that of the coating, the total capacitance is approximately same as the capacitance of the coating. Such conditions practically apply when the capacitance per unit area of the coating is typically less than $1\ \mu\mathrm{F/cm^2}$, which, for common dielectric materials, is equivalent to the capacitance of an insulator with a thickness greater than $0.1\ \mu\mathrm{m}$.

Electromechanical Viewpoint and Concept of Electrocapillary Pressure

The phenomenon of electrocapillarity, explained as above, can be looked from an electromechanical viewpoint as well, by noting that the net electrical body force per unit volume can be written as

$$f_i = \frac{\partial (\varepsilon E_j)}{\partial x_j} E_i - \frac{1}{2} E_k E_k \frac{\partial \varepsilon}{\partial x_i} + \frac{\partial}{\partial x_i} \left(\frac{1}{2} E_k E_k \frac{\partial \varepsilon}{\partial \rho} \rho \right) \quad (14)$$

Utilizing that $\nabla \times \boldsymbol{E} = 0$ (i. e., $\partial E_i/\partial x_j = \partial E_j/\partial x_i$), and noting that $f_i = \partial \tau_{ij}/\partial x_j$ (where τ_{ij} is the Maxwell stress tensor), one can write, for $\partial \varepsilon/\partial \rho = 0$,

$$\tau_{ij} = \varepsilon \left(E_i E_j - \frac{1}{2} \delta_{ij} E_k E_k \right) \quad (15)$$

To evaluate the resultant electromechanical force, one needs to utilize the fact that the tangential component of the electrical field at the surface of the liquid droplet vanishes, and accordingly, one may express the components of $\boldsymbol{E}$ on a plane with direction cosines n_i as $E_i = E n_i$. Utilizing the Cauchy's theorem relating the traction vector with the stress tensor components, one can write

$$F_i = \int \tau_{ij} n_j \mathrm{d}A \quad (16)$$

Assuming a uniform distribution of $\boldsymbol{E}$ over the droplet surface, Eq. (16) may be recast as (with the help of Eq. 15)

$$\frac{F_i}{A} = \frac{1}{2} \varepsilon E^2 n_i \quad (17)$$

The term $1/2\varepsilon E^2$, as appearing in Eq. (17), is a measure of the electrocapillary force per unit area, and therefore, can be termed as an equivalent electrocapillary pressure (p_{ec}). Since the local charge density (ρ_{e}) is given as $\rho_{\mathrm{e}} = \varepsilon E_i n_i = \varepsilon E$, Eq. (17) can be rewritten as

$$p_{\mathrm{ec}} = \frac{1}{2} \rho_{\mathrm{e}} E \quad (18)$$

Further, with the aid of Gauss' law, one can write $\rho_{\mathrm{e}} = \varepsilon_d V/d$. Moreover, $E = Vl/A_{\mathrm{c}}$, where l is the inner circumference of the conduit handling the liquid droplet and A_{c} is the cross sectional area (for a cylindrical capillary, $A_{\mathrm{c}}/l = R/2$. Thus, $p_{\mathrm{ec}} = 1/2\varepsilon_d V^2/dl/A_c$. Also, from Eq. (11), one can get an equivalent charge induced interfacial tension as $\Delta\gamma = 1/2\varepsilon_d V^2/d$. Hence, one can write

$$p_{\mathrm{ec}} = \frac{l \Delta\gamma}{A_{\mathrm{c}}} = \frac{l}{A_{\mathrm{c}}} \frac{1}{2} \varepsilon_d \frac{V^2}{d} \quad (19)$$

In a qualitative sense, the above represents the pressure generated in a microchannel by electrocapillary effects [3]. There is a subtle difference, however, between this concept and a general description of the electrowetting phenomenon, in a sense that this refers to a voltage dependent droplet meniscus pressure rather than the associated modifications in the apparent contact angles. Thus, material systems with a zero contact angle (complete wetting) or a contact angle of 180° (complete non-wetting) do not electrowet (i. e., do not exhibit a voltage dependence of the apparent contact angle), but do exhibit an electrocapillary pressure (i. e., a voltage dependent pressure in a capillary).

Fluid Dynamics in Presence of Electrocapillary Effects

The dynamics of droplets under electrocapillary actuation has probably been one of the key areas of research investigation over the past few decades, primarily dictated by the pertinent practical applications. In general, the motion of the centre of mass of a droplet (actuated by electrocapillary effects) is opposed by the dissipations originating out of the contact line friction, as well as the viscous resistances in the bulk. For the case in which the contact line friction is the dominating resistive mechanism, pressure within the droplet equilibrates quickly, retaining its spherical shape. However, the contact angle might still vary in a time-evolving manner. On the other hand, when the bulk viscous effects dominate, the contact angle assumes its local equilibrium value everywhere along the contact line. The resultant shape of the droplet becomes non-spherical, and a hydrodynamic pressure gradient prevailing within the same drives a local fluid flow.

To analyze the fundamentals of a droplet motion actuated by continuous electrowetting principles, for illustration, one may consider two infinite parallel plates separated by a distance H, with an intervening liquid. For a steady, fully developed incompressible flow along the x-direction, the Navier–Stokes equation assumes the following simplified form:

$$\mu \frac{\mathrm{d}^2 u}{\mathrm{d}y^2} = \frac{\mathrm{d}p}{\mathrm{d}x} \quad (20)$$

where y represents the transverse direction. The difference in inside and outside pressure across a meniscus of the liquid slug can be described by Eq. (7), with $r_1 = H/2$ and $r_2 \to \infty$. Thus, the difference in pressure between the advancing and receding ends of an hypothetical liquid slug of length Δx can be described as $\Delta p = 2\Delta\gamma/H$, where $\Delta\gamma$ is the surface energy differential across the two ends. Dividing the above expression by Δx and taking the limit as the same tends to zero, one obtains: $\mathrm{d}p/\mathrm{d}x = (2/H)\mathrm{d}\gamma/\mathrm{d}x$. In practice, however, the liquid slug is of

a finite length, and hence $d\gamma/dx$ can be replaced by its corresponding x-averaged value over the entire droplet length, i. e., $\langle d\gamma/dx\rangle$. With this understanding and the employment of the boundary conditions $u = 0$ at $y = 0$ (channel surface) and $du/dy = 0$ at $y = H/2$ (channel centreline), the following velocity profile can be obtained:

$$u = \frac{1}{\mu H}\left\langle\frac{d\gamma}{dx}\right\rangle(y^2 - Hy) \quad (21)$$

Averaging the above velocity profile over the channel cross section, one may obtain

$$\bar{u} = -\frac{H}{6\mu}\left\langle\frac{d\gamma}{dx}\right\rangle. \quad (22)$$

Physically, Eq. (22) implies that the liquid slug flows towards regions of lower surface energy, since it *attempts* to wet more the areas of lower surface tension. In electrowetting, the electrical voltage differentials are responsible for creating these gradients. For assessing the same, one may first differentiate Eq. (1) with respect to x and obtain $d\gamma/dx = -cVdV/dx$. The potential V, for this purpose, can be approximated as

$$V = \bar{\phi} - \langle\phi\rangle - \phi_Q \quad (23)$$

where $\bar{\phi}$ is the arithmetic mean of the potentials at the two ends of the slug of length L (i. e., $\bar{\phi} = (\phi_0 + \phi_L)/2$, the subscript 0 being an indicator of the receding meniscus and the subscript L being an indicator of the advancing meniscus of the slug), $\langle\phi\rangle = 1/L\int\phi dx$, and $\phi_Q = Q/c$, Q being the charge (per unit area) present at the interface in absence of the applied potential, ϕ (Q includes both externally applied charges and charges due to ion adsorption from the electrolyte). Further, $dV/dx \approx (\phi_L - \phi_0)/L$. Thus, Eq. (22) assumes the following form:

$$\bar{u} = \frac{cH}{6\mu L}\left(\bar{\phi} - \langle\phi\rangle - \phi_Q\right)(\phi_L - \phi_0) \quad (24)$$

It is important to observe from Eq. (24) that there is no dynamic effect if there is no interfacial charge and no axial gradient of electrical potential. Eq. (24) predicts $\bar{u}$ to be of the order of 1 cm/s, for $\bar{\phi} \approx \langle\phi\rangle$, $Q \approx 5\,\mu C/cm^2$ (typical to mercury in common aqueous electrolytes), $\mu = 0.001$ Pas, $\phi_L - \phi_0 \approx 1$ V and $H/L \approx 0.1$. Despite being a very crude estimate, the prediction is quite agreeable with the order of magnitude of the corresponding experimentally observed mean velocities (≈ 5 cm/s).

The droplet dynamics can also be analyzed in the perspective of the evolving contact angles at its advancing and receding ends, θ_A and θ_R, respectively. To analyze the situation, one may first note that for typical micro-capillaries, the Reynolds number is typically very small (~ 1 for a 10 µm diameter capillary handling water at a mean speed of 1 cm/s, as an example), which also implies that the hydrodynamic relaxation time of the fluid system is small enough to treat the interfacial regions to be in local electromechanical equilibrium. For the case of a cylindrical capillary, one can write the Newton's second law of motion of the advancing droplet (neglecting the inertial effects and assuming a fully developed velocity profile) as

$$\rho\pi R^2 L\ddot{x}_c = \underbrace{2\pi R\left[(\gamma_{lv}\cos\theta)_R - (\gamma_{lv}\cos\theta)_A\right]}_{\text{driving force due to surface tension}} - \underbrace{8\pi\mu L\dot{x}_c}_{\text{viscous resistance}} \quad (25)$$

where x_c is the position of the centre of mass of the droplet. Initial differences between the values of the apparent contact angles θ_A and θ_R can be created by electrocapillary actuation, resulting in a net driving force for initiation of the droplet motion. Subsequently, these initial contact angles can get further modulated during the droplet motion itself, because of complicated fluid dynamic phenomena such as contact line slip. On a microscopic scale, a possible mechanism in which such slip phenomena might occur on rough solid surfaces could be explained from the perspective that the contact line *jumps* across indentations while moving along the solid boundary (4). Moreover, in reality, the microscopic contact angle can itself be dependent on the capillary flow velocity. This can give rise to an additional velocity dependent frictional force in Eq. (25). The source of this frictional force is the excitation of damped capillary waves at the liquid–vapour interface due the contact line motions over the wall roughness elements. From experimentally obtained data, this can be modeled approximately in the following form:

$$F = 2\pi R\gamma_{lv}B\mathrm{Ca}^x \quad (26)$$

where Ca is the capillary number ($\mathrm{Ca} = \mu\bar{u}/\gamma_{lv}$), B and x are experimentally fitted constants [4]. A physical basis of the introduction of the Ca-dependent and slip-modulated frictional force, F, can be provided as follows. As mentioned earlier, the contact line jumps across the indentations on the solid boundaries, as the contact line moves forward. During the jump, the liquid–vapour interface is pulled forward by the interfacial tension and is retarded by the liquid viscosity. The jump speed is therefore of the order of γ_{lv}/μ, i. e., $\mathrm{Ca} \sim 1$. Because of the restoring effects, the liquid-vapour interface actually executes

a time-periodic motion on a local scale. Further, the contact line actually slips during the jump process, and the corresponding dissipative effects associated with this jump are responsible for the additional frictional force, which gives rise to a velocity dependent contact angle. One potential slip scenario is that the contact line actually leaves the solid surface on one side of the indentation and reattaches itself on the other side of the indentation, since, without that detachment, the large viscous stress near the contact line would retard the movement the same significantly, so that local jump speeds with Ca $\sim$ 1 would not be realizable.

During the droplet motion, it is also very much likely that the contact angle reaches its maximum value for the advancing meniscus and its minimum value for the receding meniscus. The difference between these two limiting values is known as contact angle hysteresis, which is related to certain non-idealities such as inhomogeneity and surface roughness. The physical mechanism associated with this phenomenon is far from being well understood at this stage.

Key Research Findings

EW Under AC Fields

The basic EW theory elucidated here has been directly extended to analyze electrocapillary effects under AC electric fields as well. For instance, if the AC frequency corresponds to a time scale that is less than the hydrodynamic response time of the droplet (typically ~ 0.01 s for mm-sized droplets), the droplet shape and contact angle evolution can be described by employing instantaneous quasiequilibrium considerations in accordance with Eq. (13). On the other hand, for higher frequencies, the droplet response depends only on the r.m.s value of the applied voltage, so long as the liquid can be treated as a perfect conductor. However, beyond a critical frequency (ω_c), the dissolved ions cannot follow the applied field and therefore, cannot screen the electric field from the interior of the liquid [2]). Far beyond ω_c, the droplet behaves like a dielectric, and is effectively actuated by dielectrophoresis mechanisms. For homogeneous bulk liquids, $\omega_c \sim \sigma_l/\varepsilon_l$, where σ_l and ε_l are the conductivity and permittivity of the liquid, respectively. For a typical aqueous solution (such as NaCl, with $\sigma_l \sim 0.1\ \mathrm{Sm}^{-1}$), $\omega_c \sim 10^8\ \mathrm{s}^{-1}$. However, for demineralised water ($\sigma_l \sim 10^{-6}\ \mathrm{Sm}^{-1}$), ω_c can be as low as $\sim 10^3\ \mathrm{s}^{-1}$.

Parametric Dependences of EWOD

EWOD has been found to be only weakly related to the liquid properties. On the contrary, the properties of the insulating layer are somewhat critical for controlling the EWOD phenomenon. The insulating material ideally needs to be such that the contact angle at zero voltage should be as large as possible, so as to achieve a large enough tuning range. This can be achieved by using either hydrophobic insulators (such as polymer materials) or by covering hydrophilic insulators with a thin hydrophobic coating (such as self-assembled monolayers or amorphous fluoropolymer layers). Further, thinner the dielectric material coating, higher is the effective capacitance and lower is the voltage necessary to achieve the same amount of contact angle modification. However, ultra-thin dielectric layers can lead to dielectric breakdown effects [5].

Optoelectrowetting

An optical actuation of the EW mechanism (termed as optoelectrowetting) has recently been experimentally demonstrated, by integrating a photoconductive material underneath a 2D array of electrowetting electrodes [6]. Contact angle changes as large as 30° have been achieved, when illuminated by a light source with an intensity in the tune of 50 to 100 $\mathrm{mW/cm^2}$. Electrode activation, in such situations, can be achieved by directing a laser beam onto the desired electrode, without necessitating electrical connections to all the electrodes.

Contact Angle Saturation in EW

The Young–Lippman equation has been experimentally found to hold only at relatively lower voltages. In fact, before a probable voltage induced transition to a complete wetting state ($\theta' = 0$) becomes possible, the contact angle tends to get saturated within a certain operating regime. The mechanisms that have been proposed by various researchers to explain this phenomenon are as follows:

- The immobilized charge carriers that get injected into the insulators partially screen the applied electrical field. With the assumptions that the immobilized charges are located at a fixed depth within the insulating layer and their densities are homogeneous within a distance of d (dielectric thickness) on both sides of the contact line, Eq. (13) gets modified as [7]

$$\cos\theta' = \cos\theta + \frac{1}{2}\frac{\varepsilon_d\,(V - V_\mathrm{T})^2}{d\gamma_\mathrm{lv}} \tag{27}$$

  where V_T is the potential of the trapped charge layer outside the droplet.
- For low conducting liquids (such as deionised water), the contact line itself is found to become unstable at

higher voltages, leading to the ejection of small satellite droplets from the edge of the main droplet. Such an instability is due to a mutual repulsion of like charges at the contact line. Beyond a critical voltage, surface tension cannot overcome the electrostatic repulsion, and emission of satellite droplets sets in [8].

- Contact angle saturation might also occur when either or both the assumptions of perfectly conductive liquid or perfectly insulating dielectric (as considered for deriving the Young–Lippman equation) are violated. Such situations can be encountered when the voltage partially drops within the bulk of the droplet, as an example. The potential drop within the droplet, in practice, increases with a decreasing contact angle, eventually causing a saturation.

It can easily be inferred from the diverse and case-specific explanations to contact angle saturation that the underlying physics is yet to be well understood, and still remains to be an open research issue.

Modulation of EW Through Surface Patterning

EW phenomena can be modulated to a significant extent by employing patterned substrates, which may alter the topology of the liquid by altering long range electrostatic attraction or repulsion at the contact line. Surface patterning of the electrodes has also been shown to have a profound effect on the droplet morphology. Topographical patterning of the surfaces, originated out of surface roughness elements, can also have profound influences on electrowetting. Due to small-scale surface undulations, the actual solid–liquid interfacial area ($A_{\mathrm{sl,act}}$) is always more than the apparent or projected solid–liquid interfacial area ($A_{\mathrm{sl,app}}$). This alters the apparent contact angle, as per Wenzel's law [2], as $\cos\theta_{\mathrm{mod}} = A_{\mathrm{sl,act}}/A_{\mathrm{sl,app}} \cos\theta$ (with $\theta_{\mathrm{c}} < \theta < 90°$, θ_{c} being a critical value of the contact angle, depending on the surface roughness). Beyond $\theta = 90°$, $A_{\mathrm{sl,act}}$ is dramatically reduced because of entrapped vapour layers underneath the droplet. With a reduced frictional contact, this can give rise to a higher mobility of the droplet.

EW on Hydrophobic Surfaces

If EW of an aqueous medium is done in another liquid environment (say, oil), then both the liquids can compete in wetting the solid surface [9]. With typical hydrophobic EW surfaces, complete wetting of the oil phase at zero voltage is quite common, resulting in the establishment of a thick layer of oil that separates the substrate and the aqueous phase. With higher voltages, however, the electrostatic pressures reduce the oil film thickness and tend to *push* the aqueous phase towards the substrate, leading to complicated micro-scale interactions, which are yet to be extensively investigated.

EW on Super-Hydrophobic Surfaces

EW on super-hydrophobic surfaces has received significant research attention for its engineering implications. Due to large contact angles, the liquid–vapour interfacial area of the droplet becomes quite large in these cases (however, since this area does not contribute to a differential in the surface energy, it does not result in a modification in the apparent contact angle). Not only that, the droplet-substrate interface is not equal to the solid–liquid interface, but is composed of a large number of tiny liquid–air and liquid–solid interfaces, which may be irregularly shaped. This can lead to a modification in the effective contact angle prediction of Eq. (13), through the incorporation of the fraction of solid of the solid–vapour heterogeneous super-hydrophobic surface as an additional parameter.

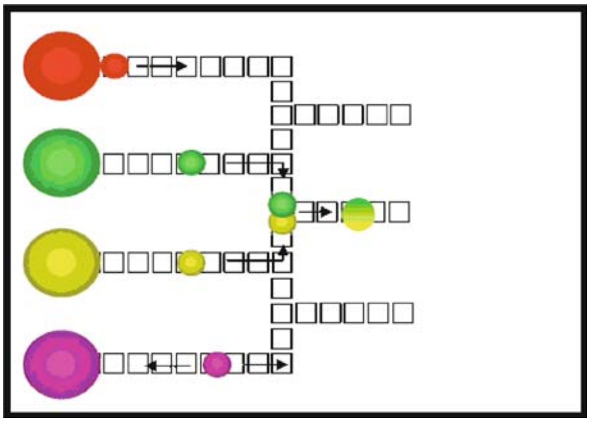
Examples of Application

Lab-on-a-Chip Applications

Lab-on-a-Chip applications [10] of EW have been primarily directed towards moving, merging, mixing and splitting of droplets. A sandwich design consisting of a droplet confined between two parallel substrates (typically, separated by a distance of $\sim$100 μm) has become a standard practice in this respect. For typical droplet volumes in the micro-litre range (dictated by the constraints that the droplet edges should preferably overlap two adjacent electrodes (with a characteristic electrode size of $\sim$1 nm), the droplet motion sets in with a typical threshold voltage in the tune of 10 V. Beyond this voltage, the droplet speed increases rapidly, reaching limiting values $\sim 10^{-2}$ m/s, within a relatively short interval of time.

One big challenge for all Lab-on-a-Chip devices is the tendency of biological macromolecules to be unspecifically adsorbed onto hydrophobic surfaces. This might alter the contact angles permanently. Such undesirable effects can be suppressed by using an oil phase as the ambient medium, instead of air. The oil phase may wet the hydrophobic surface and can act as a shield against a direct contact between the droplet and the polymer substrate.

EW has also been successfully employed for handling tiny amounts of liquid in biotechnological applications (see Fig. 5). For instance, using the EW-based dip-pin nanolithography technique, droplets in femtolitre to picolitre range have been successfully spotted onto surfaces, to form DNA and protein fluorescence-labelled arrays.



Electrocapillary, Figure 5 Electrowetting-based handling of tiny liquid droplets for Lab-on-a-Chip applications

Liquid Lenses

EW has been successfully used to tune the curvature of liquid lenses (by changing the contact angles of photopolymerizable conductive sessile droplets), so that they can be designed with variable focal lengths [11]. Once the desired refractive strength has been achieved through voltage modulation, the droplets can be cured by UV illumination. Subsequently, the solidified droplets can retain their shapes after removal of the applied voltage.

Fiber Optics Applications

More than two decades back, EW was identified as a possible mechanism for switching light in fibre-optic applications, in which Hg droplets can be moved inside channels to provide either a reflective surface or to allow for the transmission of light in an optical multiplexer. Subsequent applications of EW in fibre-optics have been based on surrounding the active (stripped off) part the optical fibres with liquids of suitably chosen refractive indices, in order to control the transmission of light waves through the fibre [12]. In this way, low power consuming ($\sim$1 mW) optical noise attenuators have been effectively designed, with a response time of as low as $\sim$100 ms.

Self-Excited Oscillations

Very recently, EW has been employed to trigger self-excited oscillations of millimetre-sized sessile droplets of water-glycerol mixtures [13]. During these oscillations, contact angles of the droplets have been found to vary periodically between 130° and 80°, with a frequency between 10 and 125 s^{-1}. The resultant mixing of fluids within the droplets has been found to be two orders of magnitudes faster than the conventional chaotic micromixing processes.

Reflective Fast Display on an Electronic Paper

EW has also been used to form the basis of a reflective fast display on an electronic paper (which combines the desirable viewing characteristics of a conventional printed paper with the ability to manipulate the displayed information electronically), so that the video contents can even be conveniently displayed [14]. This display principle utilizes the voltage-controlled movement of a coloured oil film adjacent to a white substrate. The reflectivity of the resultant colour displays has been found to be substantially stronger than the liquid crystal displays.

Radiation Absorption

EW-based optical absorbers have been designed to exploit EW-induced capillary rise for absorbing undesirable radiations (for example, X-rays), thereby minimizing unnecessary exposures of patients to radiations in medical diagnostics. Such absorbers can be formed by dissolving heavy salts in the liquid solution that can rise through a capillary or get depressed, on application of suitable actuation voltages [15].

Micromotors

EW based micromotors have been successfully designed, based on the motion of Hg droplets in electrolyte filled channels. By applying a small voltage along the channel, a charge density and interfacial energy gradient has been effectively established along the Hg droplet, leading to a continuous motion of the same [16].

Definition

Sensitive, selective detection techniques are of crucial importance for capillary electrophoresis (CE), microfluidic chips, and other microfluidic systems. Electrochemical detectors for microfluidic systems have attracted considerable interest, with features that include high sensitivity, inherent miniaturization of both detection and control instrumentation, low cost, low power demand, and high compatibility with microfabrication technology. The electrochemical detectors commonly used can be classified into three general modes: conductimetry, potentiometry, and amperometry.

Overview

CE in its modern form was first described by Jorgenson and Lukacs in 1981 [1] and has been used to separate and determine a variety of samples because of its minimal sample volume requirements, short analysis time, and high separation efficiency. Since the pioneering work of Harrison et al. [2], microfluidic devices, particularly CE microchip systems, have generated considerable interest because of their high degree of integration, portability, minimal solvent/reagent consumption, high performance, and speed. CE microchips have received special attention because of their high degree of integration, portability, minimal solvent/reagent consumption, high performance, and speed. These microchip analysis systems hold

considerable promise for biomedical and pharmaceutical analysis, clinical diagnostics, environmental monitoring, forensic investigations, etc. As with other analysis systems, sensitive detection techniques are also necessary for conventional CE, microchip CE, and other microfluidic systems.

Ultraviolet (UV) detectors have commonly been employed to provide detection in microfluidic systems. Because the absorbance path length of the microchannels is very short, the low sensitivity of the UV detector results in a low detection limit (typically 10 μM). Usually, the content of the target analyte in a real sample is very low. Therefore, highly sensitive detection methods are in great demand. To meet this need, laser-induced fluorescence (LIF) and mass spectrometry (MS) have been employed. Currently, LIF has dominated detection in microchip CE. However, both LIF and MS need rather sophisticated and expensive instrumentation. LIF is limited to fluorescent analytes and analyte derivatives. Recently, electrochemical detection (ECD) has been coupled with microfluidic systems to obtain highly sensitive detection. ECD offers great promise for such systems, with features that include remarkable sensitivity, inherent miniaturization of both detector and control instrumentation, independence of sample turbidity and optical path length, low cost, minimal power demand, and high compatibility with microfluidic systems. Various techniques for ECD in microfluidic systems have been reported in the past decade.

Basic Methodology

ECD can be classified into three general modes: conductimetry, potentiometry, and amperometry. Amperometry is the most widely reported ECD method for microfluidic analysis systems. It is accomplished by applying a constant potential to a working electrode and measuring the resulting current, which is proportional to the concentration of analyte oxidized or reduced at the electrode surface. In the conventional three-electrode system, a reference and an auxiliary electrode are also present. Sometimes, only a working electrode and a counterelectrode may be employed, in a two-electrode configuration. In CE, amperometric detection (AD) is usually performed in either an off-column or an end-column mode. In the case of off-column AD, a decoupling junction between the separation and detection capillaries is employed to minimize the effect of the separation voltage on the AD system. In the case of end-column AD, a microdisk detection electrode is placed directly opposite the outlet of the separation capillary, without a conductive joint. However, a gap is left between the capillary outlet and the detection capillary to reduce the interference of the high separation voltage. A major limitation that has prevented routine application of AD in CE is the precise alignment between the separation channel and the detection electrode. If the working electrode needs to be polished or changed, the whole system has to be refabricated. This is time-consuming and requires skilled personnel to operate the system. In the case of end-column detection in conventional and microchip CE, the development of a simple, convenient device to simplify the alignment procedures would be of great interest. A typical schematic diagram of a device for three-dimensional (3D) alignment between the detection electrode and the detection electrode is illustrated in Fig. 1. Before use, the disk detection electrode (Fig. 1d) is carefully positioned opposite the outlet of the capillary (Fig. 1f) with the aid of a 3D micromanipulator (Fig. 1j), and arranged in a wall–jet configuration. The interface between the capillary outlet and the surface of the detection electrode is illustrated in the inset of Fig. 1. The gap between the outlet and the detection electrode is usually adjusted to $25-50\,\mu$m using a micrometer caliper on the micromanipulator. A high voltage is applied between the anode in the anode reservoir and the grounded platinum electrode in the detection reservoir.
